The systematics and phylogeny of the Rhizophoraceae were discussed at a symposium held during the American Institute of Biological Sciences meetings in Amherst, Massachusetts, August 13, 1986. The following nine papers are a record and amplification of this event. The motivation for choosing such a topic was the uncertain ordinal status of the Rhizophoraceae, made evident at an earlier discussion of the Myrtales in Sydney, Australia (1981: see Ann. Missouri Bot. Gard. 71(3), 1984), together with increasing evidence for the exclusion of the tribe Anisophylleae from the family. In addition, the Rhizophoraceae are a very diverse group, both ecologically and morphologically, most obviously in the mangrove members of the family that form a discrete tribe, Rhizophoreae. Opportunity thus existed to examine a relatively small tropical family (about 140 species) from several points of view, and to assemble evidence for more reliable systematic and phyletic associations. Information was presented by a group of investigators having extensive acquaintance with the family in field and laboratory. The Rhizophoraceae are familiar to tropical biologists because of the widely distributed mangrove genera that often dominate intertidal forests. However, the symposium has made very clear the extent to which these genera are not entirely representative of the family, so that it is inappropriate to refer to the Rhizophoraceae as "the mangrove family." Nevertheless, the presence of mangrove species allows some assessment of the way in which systematic characters may or may not be useful in phylogenetic analysis depending on their obvious functional or adaptive significance. The symposium also generated a better understanding of the tribe Anisophylleae and indicated why it should be segregated as a separate family and, if excluded from the Myrtales, where its affinities might lie.

The objectives of the symposium were thus not only realized, but also serve as a model for the kind of systematic analysis that is needed for most groups of tropical plants, not necessarily because the information is all that complete for the Rhizophoraceae (the survey reveals just how limited is our knowledge of many of the plants under discussion), but rather it provides a model for the range of information from which phyletic conclusions might be drawn and demonstrates that this can only be assembled by extensive teamwork. It is noteworthy that the new evidence was generated by a range of techniques, from such simple approaches as phyllotactic analysis requiring minimal equipment, to the demonstration of distinctive ultrastructural features, as in sieve-tube plastid organization, requiring elaborate technology. The tropical investigator should take heart from this demonstration that simple approaches can produce worthwhile results that need not be overshadowed by the results obtained by otherwise unavailable technology. The overlying message is that syntheses of this kind are urgently needed for all tropical flowering plants if our appreciation of their phyletic relationships is to be developed to a greater degree of reliability.

The overview of the symposium was provided by Rolf Dahlgren as a critical re-evaluation of the ordinal position of Rhizophoraceae sensu stricto and Anisophylleaceae in a manuscript completed shortly before his untimely death. The tragedy of this accident is clearly perceived as we view the major intellectual achievement provided by his contribution. The paper is a monument to his own methodology; his line of reasoning is very clear and explicit. It demonstrates the unique ability he had to grasp intricate detail and from it to distill a balanced judgment. It is appropriate that the symposium be dedicated to his memory and that his summary paper be allowed to lead on to the panorama he was able to command so well.

We express our thanks to all the contributors whose collaborative efforts have made the venture entirely possible.

RHIZOPHORACEAE AND ANISOPHYLLEACEAE: SUMMARY STATEMENT, RELATIONSHIPS[1]

Rolf M. T. Dahlgren[2]

Abstract

Each of Rhizophoraceae and Anisophylleaceae, as now defined by Tobe & Raven, are here considered to represent monophyletic units. Conspicuous autapomorphies of the variable Rhizophoraceae are, for example, the constellation of protein bodies of the sieve-tube plastids and the presence of colleters. Autapomorphies of the less variable and smaller Anisophylleaceae are sets of embryological, anatomical, and morphological characteristics as well as aluminium accumulation. The contributors of this symposium show convincingly from various fields how the two families differ in numerous details. These differences in combination support very strongly that the families are distinct from each other and are probably even rather distantly related. The Rhizophoraceae do not belong to Myrtales, from which they were excluded by all participants of a recent Myrtales symposium. Comparisons with various other groups show that Rhizophoraceae agree in many characters with especially Elaeocarpaceae, previously placed in Malvales, Celastraceae of Celastrales, and families of Geraniales, e.g., Erythroxylaceae, Humiriaceae, Linaceae, Lepidobotryaceae, and Oxalidaceae. This is supported in particular by a syndrome of embryological attributes, but also from morphological, anatomical, pollen morphological, and chemical evidence. Anisophylleaceae, which possess a combination of quite trivial character conditions, technically fit most closely with Rosales in the wide sense, i.e., Rosales–Cunoniales–Saxifragales, without approaching any particular family. Anisophylleaceae may have evolved from taxa related also to the ancestors of Myrtales.

At a previous symposium held in Sydney (1982) the circumscription of the order Myrtales was critically considered. It was concluded (Raven, 1984) that two anatomical character states can be considered diagnostic features ("autapomorphies" in evolutionary terms) of this order: vestured pitting of the vessels and presence of intraxylary phloem. This implies that these character states were established in the ancestor of Myrtales.

At the Myrtales symposium (Raven, 1984) Thymelaeaceae and Rhizophoraceae were excluded with some misgivings from that order. Whereas the Thymelaeaceae possess the two above-mentioned anatomical characteristics (but show important differences from the Myrtales), the Rhizophoraceae lack them. The relationships of Thymelaeaceae as well as Rhizophoraceae have remained uncertain. The purpose of this symposium is to analyze and settle the relationships of the Rhizophoraceae.

Each of the families Thymelaeaceae and Rhizophoraceae, in their wide circumscriptions, contains a group of somewhat erratic genera—the Gynystyloideae in Thymelaeaceae and the Anisophylleoideae in Rhizophoraceae. When included, these elements amplify the variation in the two families and make difficult a proper evaluation of their affinities and evolutionary backgrounds.

The history of the systematic treatment of four genera, which are here assigned to Anisophylleaceae, has been outlined by Tobe & Raven (1987b; see also Juncosa & Tomlinson, this volume). Ridley (1922) was the first to acknowledge Anisophylleaceae as a family. Although genera of Anisophylleaceae have occasionally been referred to other families such as Euphorbiaceae, Olacaceae, and Saxifragaceae, they are usually considered closely related to the Rhizophoraceae, which is nearly always so for the Anisophylleaceae as a family.

The Rhizophoraceae have generally been placed in Myrtales, which is partly explained by the great similarity between the most well-known rhizophoraceous genera, *Rhizophora* and *Bruguiera*, with,

for example, *Sonneratia*, which is a clear member of Myrtales. Previously, this genus and *Duabanga* made up the family Sonneratiaceae, but recent evidence shows that both are best placed separately in Lythraceae.

Looking aside from parallel mangrove adaptations, there remain a number of vegetative, floral, chemical, and pollen morphological similarities between Rhizophoraceae and Myrtales, which together have justified a position in or next to this order until the structures were more fully analyzed and the relationships carefully reconsidered in connection with the recent Myrtales symposium (see above). These similarities extend to habit, phyllotaxis, occurrence of leaf sclereids, floral construction (e.g., diplostemony), and some embryological details. In fact, the occurrence of intercolpate grooves ("pseudocolpi") on the pollen grains in genera (at least *Anopyxis*) of Rhizophoraceae (see Vezey et al., this volume) are surprisingly reminiscent of those in several families of Myrtales, although they must be explained as convergence or parallelism. A misleading psychological reason for considering Rhizophoraceae and Myrtales closely related may be that the colleters in Rhizophoraceae resemble the axillary, rudimentary stipule homologues in many Myrtales; however, well-developed stipules occur beside the colleters in Rhizophoraceae.

The Rhizophoraceae have also occasionally been placed in Loranthales (Dumortier, 1829) but more often in Cornales (as by Cronquist, 1968; Thorne, 1968). A position of Rhizophoraceae—or Anisophylleaceae—in Cornales is unjustified in view of the embryological and chemical pattern in that order, largely defined by unitegmic, tenuinucellate ovules and cellular endosperm formation combined with common occurrence of iridoid compounds (Dahlgren, 1975). The placement of Anisophylleaceae in Cornales by Dahlgren (1980a) was explained by the record at that time of unitegmic ovules in *Anisophyllea* (Karsten, 1891), but embryological conditions were otherwise largely unknown.

Airy Shaw (1966) claimed relationships between Rhizophoraceae and Combretaceae, Elaeocarpaceae, and Tiliaceae, and (in 1973) with Combretaceae, Rubiaceae, and Elaeocarpaceae. Combretaceae are clear members of the Myrtales; the possible relationships between Rhizophoraceae and these have been commented on above. Rubiaceae agree with Rhizophoraceae in having opposite leaves, interpetiolar stipules, and colleters, but in floral, chemical, and especially embryological characters, they are extremely different, ruling out a close relationship. More interesting is the mention of Elaeocarpaceae. The similarity with this, for example in the laciniate petals, may first seem superficial, but other shared features (perhaps not considered by Airy Shaw), including some in embryology and chemistry, are worthy of careful consideration and will be evaluated below. Less obvious are the similarities between the Rhizophoraceae and the typically malvalean Tiliaceae.

In recent years, the Rhizophoraceae (without Anisophylleaceae) have sometimes been placed in an independent order, Rhizophorales, in either Rosidae (Cronquist, 1981) or in Myrtiflorae (Dahlgren, 1980a). The order Rhizophorales as established by van Tieghem & Constantin (1918) included Lecythidaceae in addition to Rhizophoraceae.

The position of the family Rhizophoraceae in any other order than its own has been regarded more or less unsatisfactory. Cronquist (1981) considered it, when placed in Myrtales, "as a giraffe in a herd of bison," and it is clearly out of place in both Cornales and Olacales.

Placing Rhizophoraceae in its own order solves no problem if our ambitions are to ally Rhizophoraceae with other groups of dicotyledons. It also remains to relate Anisophylleaceae with a family group and place it satisfactorily in an order.

When attempting to relate each of the Rhizophoraceae and Anisophylleaceae to other groups, the procedure has been to consider the variation pattern in each family in order to assess which character conditions can logically be regarded as relatively ancestral (plesiomorphic), that is, least advanced in the family, and which can be regarded as derived (apomorphic).

For the Anisophylleaceae, this poses no great problems, as the family is rather homogeneous. Tobe & Raven (1987b) have sketched the apomorphic conditions for the embryological features: unitegmic rather than bitegmic ovules; tapetal nuclei fused rather than not fused; a thin rather than thick seed coat; a base chromosome number $x = 8$ rather than $x = 7$; an *Allium*-type rather than *Polygonum*-type of embryo sac development; and unvascularized rather than vascularized integuments. These conclusions are based on common consensus and experience in evolutionary trends in dicotyledons and not on proper outgroup comparison, as is normally required in cladistic analyses. Actually, what we are still hunting is an acceptable outgroup of that family. In this case there is little controversy connected with the conclusions, but one can easily see risks in choosing which states are plesiomorphic first and concluding afterwards about an outgroup on the basis of biased opinions.

It is important that the choices of which features are considered plesiomorphic in a family are soundly based, since the plesiomorphic and not the apomorphic states decide the conclusions as regards relationships to other families, whereas the apomorphic states and not the plesiomorphic must govern the conclusions on evolution within the family.

Risks for biased opinions become more obvious when dealing with the much more variable Rhizophoraceae. Here, the logical step has been to regard the mangrove genera, the tribe Rhizophoraceae, as secondarily adapted in a number of characters ranging over vegetative and reproductive structures, a view for which Juncosa & Tomlinson (this volume) give ample evidence.

We are thus left mainly with the other tribes in Rhizophoraceae for conclusions on outward relationships, although presumably various chemical, anatomical, and embryological character states of tribe Rhizophoreae may have retained features of ancestral Rhizophoraceae, such as perhaps peculiar sieve-tube plastid inclusions, features of flavonoid and alkaloid chemistry, and presence of colleters, endosperm, and endothelium. Thus, emphasis is first laid on character states shared among all the tribes of the family, then on states common to tribes Macarisieae, Hypogyneae, and Gynotrocheae, or at least to some members in each of these tribes.

In my contribution I have disregarded completely the alignments between each of Rhizophoraceae and Anisophylleaceae and other groups in current systems of classification. I have compared character conditions of the kind just mentioned with those in various conceivably related families. It turned out that the current classifications help little in indicating groups with profound and all-around similarity to each of the two families.

Contrary to what was first expected, it has been much easier to suggest relationships for the larger and more variable Rhizophoraceae than for the small, more homogeneous Anisophylleaceae. This depends on the fact that Rhizophoraceae possess a number of rather unusual, presumably advanced attributes, such as a peculiar combination of embryological character states matched only in a few other families, peculiar alkaloid chemistry, and a characteristic seed coat. Luckily enough, the collective evidence all points in the same direction: toward a few families rarely or never considered previously as close relatives of Rhizophoraceae. Even though some of the similarities used in the forthcoming arguments are likely to be caused by convergent evolution, all are not likely to be so. According to the conclusions, the Rhizophoraceae are considered to be most closely related to families previously referred to three different orders, Malvales, Celastrales, and Geraniales, leading to a completely new view of their positions in the dicotyledons.

For Anisophylleaceae, the conditions are less favorable, since nearly all character states in which they differ from the Rhizophoraceae represent frequent states, some of them presumably less derived than the corresponding ones in Rhizophoraceae, giving fewer clues to the closest relationships.

Within some orders and superorders certain families possess many plesiomorphic character conditions, making them rather similar and difficult to place. Thus, a combination of various trivial character conditions, such as in Anisophylleaceae, with small to medium-sized, tetramerous, heterochlamydous, choripetalous, diplostemonous, and isomerous flowers, gives little guidance to any particular relationships.

CHARACTERIZATION OF RHIZOPHORACEAE

The Rhizophoraceae comprise a variable group of genera divisible into three tribes after the following model:

Tribus **MACARISIEAE**: *Anopyxis* (Pierre) Engl. (3 species); *Blepharistemma* Wall. ex Benth. (1 species); *Cassipourea* Aubl. (55 species); *Dactylopetalum* Benth. (15 species, if distinct from *Cassipourea*); *Comiphyton* J. J. Floret (1 species); *Macarisia* Thouars. (7 species); and *Sterigmapetalum* Kuhlm. (7 species).

Tribus **GYNOTROCHEAE**: *Carallia* Roxb. (9 species); *Crossostylis* J. R. & G. Forst. (10 species); *Gynotroches* Bl. (1–4 species); and *Pellacalyx* Korth. (8 species).

Tribus **RHIZOPHOREAE**: *Bruguiera* Lam. (6 species); *Ceriops* Arn. (2 species); *Kandelia* W. & A. (1 species); and *Rhizophora* L. (8 species).

The difficulty in defining the family by gross morphology is reflected in the fact that it comes out in 17 different places in the revised Thonner key (Geesink et al., 1981), although in this key Anisophylleaceae are included in Rhizophoraceae and account for four of these places.

Differences from the Anisophylleaceae are the opposite leaves and the interpetiolar stipules.

The most characteristic feature of Rhizophoraceae is perhaps the unusual type of sieve-tube plastids: with ca. 20 or more square to polygonal protein bodies of variable size (0.1–0.5 μm) (Behnke, this volume). These were found in *Bruguiera, Carallia, Crossostylis, Rhizophora* (Behnke, 1982), *Cassipourea, Ceriops, Kandelia,* and *Sterigmapetalum* (Behnke, 1984). Sieve-tube plastids of this type are known only in two more families: Erythroxylaceae and Cyrillaceae, both with somewhat fewer protein bodies, and the last family also with protein filaments in the plastids (Behnke, 1982). This character state represents a significant autapomorphy of the Rhizophoraceae. In Anisophylleaceae the sieve-tube plastids possess starch grains only (Behnke, 1982, 1984).

Another unusual feature, an autapomorphy found in both mangrove and nonmangrove genera of Rhizophoraceae, is the presence of colleters at the leaf bases (Hou, 1958, 1960). Lersten & Curtis (1974) described their construction in *Rhizophora mangle.*

These characters, especially when supplemented with some embryological features mentioned below—for instance, the combination of bitegmic crassinucellate ovules with integumentary tapetum (endothelium)—may suffice as arguments for considering Rhizophoraceae as a monophyletic unit, which could otherwise be doubted from the rich variation in vegetative, floral, wood anatomical, and other characters.

According to Keating & Randrianasolo (this volume), the leaves have brochidodromous or eucamptodromous venation. Lateral teeth are associated with mainly the latter kind of venation and are found in less coriaceous leaves of certain nonmangrove taxa, mainly in the tribe Macarisieae; they are called "macarisioid teeth." Whether occurrence of teeth represents a plesiomorphic or apomorphic state is uncertain, and perhaps no phylogenetic conclusions can be based on them. Stomata are confined to the lower surface of the leaves; the brachyparacytic type is most widespread in the family; and this was possibly the plesiomorphic state. Cyclocytic stomata are found in the Rhizophoreae and appear to represent a derived type in the family. It is interesting that prismatic crystals and crystal druses occur in Rhizophoraceae but are largely vicarious: prismatic crystals being found in the Macarisieae, where crystal druses are very rare (confined to *Blepharistemma*), while all other genera only have crystal druses. Thus crystals help with tribal division within the family. Laticifers, often articulated, are common in some species (Keating, 1984).

According to van Vliet (1976), the wood anatomy of the Rhizophoraceae is highly variable. The perforation plates of the vessels are usually scalariform, with 5–87 perforations. In this the Rhizophoraceae differ from the Anisophylleaceae, which have simple perforation plates. The vessel diameter in Rhizophoraceae is also typically smaller than in Anisophylleaceae. Furthermore, intervessel pits are alternate in Anisophylleaceae but opposite in most Rhizophoraceae. Within Rhizophoraceae, it is the tribe Gynotrocheae that approaches most the Anisophylleaceae, and within that tribe particularly the genus *Carallia,* in which vessel perforation may even be simple.

The inflorescences of Rhizophoraceae are generally few- to several-flowered cymes, or the flowers may also be simple. The inflorescences are situated in leaf axils.

Rhizophoraceous flowers vary from hypogynous to epigynous. They are, for example, hypogynous in Macarisieae, for some genera of which a particular tribe, Hypogyneae, has been proposed. Other genera have more or less perigynous, half-epigynous, or epigynous flowers. The hypogynous (or possibly somewhat perigynous) condition is likely to be plesiomorphic.

According to Juncosa & Tomlinson (this volume) Rhizophoraceae exhibit subepidermal floral laticifers of two tribally distinctive types. The numbers of sepals and petals each vary between 4 (as in *Rhizophora*) and 16 (in *Bruguiera*). The sepals are valvate. The sepal traces are of the split-lateral type (Juncosa, unpubl.). Apically laciniate petals are common in the nonmangrove genera. Among these, especially in *Cassipourea,* the petals recall the laciniate petals in certain genera of Elaeocarpaceae (Arena & Orsini, 1973). Fringed petals also occur in Anisophylleaceae and may represent the main reason why the genera of this group have so readily been included previously in Rhizophoraceae.

Interestingly, in the tribe Rhizophoreae the petals do not form a whorl, but each individual petal encloses one or more stamens opposite it. Juncosa & Tomlinson (1987) regarded this as an autapomorphy of this tribe. Stamens with a narrow filament and a well-defined truncate, tetralocular anther, as found in most nonmangrove genera, probably represent the plesiomorphic state, whereas the more specialized types of mangrove genera are derived. Tomlinson et al. (1979) showed that pollen is often released explosively, and pollen dispersal is highly variable: by wind, flies, other small insects, butterflies, night-flying moths, or even birds.

It is assumed that the plesiomorphic androecial condition for Rhizophoraceae is the diplostemonous, but many more stamens occur in some genera, e.g., about six times the petal number in *Kandelia* (Juncosa & Tomlinson, 1987). In *Ceriops tagal,* at least, all stamens belong to one whorl and arise on a ring primordium, whereas in *Bruguiera* two whorls of stamen initials are formed. This was used as evidence by Juncosa & Tomlinson (1987) that the remarkable explosive pollen discharge mechanism is derived independently in the two groups. The multistaminal condition is here regarded as derived by increase in number of initials. This is a common phenomenon in Myrtales, where increased stamen number has evolved in several families independently, and, for example, in Lythraceae obviously a few times.

Pollen grains of Rhizophoraceae according to Vezey et al. (this volume) are 3(–4)-colporate, and their exine has a rugulate-punctate (to psilate) surface. (The exine is proportionally thicker than that in Anisophylleaceae, where the surface sculpture is reticulate-punctate.) Vezey et al. (this volume) report "subsidiary colpi" or "pseudocolpi" on the pollen grains in some members of the tribe Macarisieae, this being a conspicuous similarity to the conditions in many Myrtales. The pollen grains in Rhizophoraceae are dispersed in the two-cellular stage.

The pistil is usually surrounded by a fleshy, often conspicuously lobate disc (said by Hou, 1958, to be lacking in *Pellacalyx*). The base of the stamens may be variably attached to this disc (Hou, 1968).

The pistil generally has a 2–12-locular ovary, each locule with from two to rather numerous (in *Pellacalyx* to ca. 25) ovules on an axile placenta. *Kandelia* is, however, an exception from this; its ovary is unilocular and contains about six apically inserted ovules.

The style is simple or slightly branched apically, as in *Gynotroches*; the latter state may be the most ancestral in the family. The stigma is terminal and capitate or more or less lobate; in *Gynotroches* the apical stylar branches are stigmatic. (The simple style contrasts to the separate stylodia in Anisophylleaceae.)

The embryological conditions in Rhizophoraceae (see, for example, Karsten, 1891; Cook, 1907; Mauritzon, 1938; and Juncosa, 1982, 1984a, b) are as follows. The ovules are anatropous or hemitropous, bitegmic, and crassinucellate, although sometimes rather weakly crassinucellate. The inner integument is three- to multilayered, and the outer two- to multilayered, depending on genus and stage of the ovule. The micropyle is at least usually zigzag. A parietal cell is always cut off from the primary archesporial cell and divides a number of times to form a modest parietal tissue. Embryo sac development, as far as known, is of the *Polygonum*-type. Endosperm formation is nuclear. During embryo sac development and the early stages of endosperm formation, the nucellar tissue lateral to the embryo sac disintegrates, so that this comes to border upon the inner integument. The inner layer of this develops an endothelium in at least several genera. The seeds are endospermous. The cells of the outermost layer of the inner integument (the exotegmen) become elongate and fibrous in most genera (comprising "Legnotidaceae" in Corner, 1976), although this is not the case with the genera of the tribe Rhizophoreae nor in *Carallia* of Gynotrocheae; see Juncosa, 1984a).

An aril is present in at least four genera of the tribe Macarisieae, e.g., *Cassipourea* (Schimper, 1892) and *Comiphyton* (Floret, 1974; Tobe, pers. comm.). This aril represents an expansion from the micropylar part of the outer integument, i.e., it is *exostomal.*

The fruits are normally capsular, dry or fleshy, although nonclassifiable in the viviparous genera. They are sometimes stated to be indehiscent. Frequently they do not have more than one seed per locule, sometimes only one seed altogether. The seeds (see above) have a chlorophyllous embryo (Schimper, 1892). The embryo has two well-developed cotyledons in the nonmangrove genera; in *Bruguiera* there are 2–4 cotyledons according to Schimper (1892); in *Rhizophora, Kandelia,* and *Ceriops* the cotyledons are fused into a handweight-shaped structure. In the mangrove genera the embryo grows continuously and the seed has no resting period, a condition called "vivipary." Vivipary and specializations connected with this are secondary adaptations.

The basic chromosome number according to Raven (1975) is $x = 18$ and $x = 32$.

Chemically, the Rhizophoraceae can be classified as tannin plants. Bark of some genera has up to 40% or more of condensed-type tannins (for references, see Hegnauer, 1973). Ellagic acid has rarely been detected, and then in low quantities (in *Cassipourea*). Both caffeic acid and proanthocyanin are present. Of flavonoid compounds, also kaempferol, quercetin, myricetin, leucodelphinidin, and leucocyanin are recorded within the family (Hegnauer, 1973).

Alkaloid chemistry in Rhizophoraceae is possibly important and will be further discussed below. Derivatives of tropane, pyrrolizidin, and hygrolin bases have been detected in different genera and, according to Hegnauer (1973), are probably all

TABLE 1. *Features judged to be primitive (plesiomorphic) in Rhizophoraceae sensu stricto.*

Sieve-tube plastids with several to numerous, square to polygonal protein bodies
Vessels with scalariform perforation plates
Intervessel pitting opposite
Laticifers probably present
Leaves opposite
Leaf venation at least partly brochidodromous
Stomata brachy-paracytic on lower surface of leaves
Prismatic oxalate crystals present (possibly also crystal druses)
Colleters at leaf bases
Inflorescences multiflorous cymes or cymules
Flowers hypogynous, probably pentamerous, diplostemonous
Disc present, prominent
Petals probably apically laciniate
Stamens with narrow filaments
Anthers well defined, ± ovate, tetralocular, with longitudinal dehiscence; insect pollination
Pollen grains tricolporate, with rugulate-punctate surface; without pseudocolpi(?)
Perhaps style simple, apically five-brachiate
Ovary with five locules
Ovules probably two per locule, axile
Ovules anatropous, bitegmic, crassinucellate, with three- to several-layered inner integument
Endothelium present
Seed coat exotegminal, with "fibrous" cells
Aril probably present, formed from the apex of the outer integument (exostomal)
Fruit capsular
Embryo chlorophyllous, with well-developed cotyledons
Alkaloids formed from the amino acid ornithine present

derived from ornithine. Some of the alkaloids are sulphated (Ettlinger & Kjaer, 1968). Rhizophoraceae (contrary to Anisophylleaceae) do not show aluminium accumulation. The endosperm of the seeds is nonstarchy and contains fatty oils.

The above evidence, in combination with the pantropical distribution pattern with Old World concentration, will form the basis for the following comparative remarks.

"RHIZOPHORACEOUS" CHARACTER CONDITIONS IN OTHER FAMILIES

METHODOLOGY

In the search for one or more families that are closely related to Rhizophoraceae it is essential to consider the character conditions judged to be plesiomorphic in Rhizophoraceae. These states have been indicated for a number of characters above.

The characters that should be most successful in the search for closely related families will simultaneously fulfill the following qualifications:

1. Character states that occur in most or all Rhizophoraceae or at least in a fair variety of the nonmangrove genera; these states are likely to be *plesiomorphic in Rhizophoraceae.*
2. Character states that are likely to be *apomorphic in a larger assemblage,* such as in a superorder; i.e., *character conditions that are not archaic in dicotyledons.*
3. Character states that are rather *unusual in dicotyledons at large, or have a defined distribution among them.*

Briefly expressed, we must first search for more or less advanced character states that are likely to have been established in an ancestor of a group of families that includes Rhizophoraceae.

Beyond individual peculiar character states present in Rhizophoraceae, *combinations* of character states should be considered, because unusual combinations are not likely to have evolved in different evolutionary lines. Exceptions are such combinations of character states that have evolved in response to a defined, extreme environmental pressure favoring special syndromes. Therefore, the mangrove genera, which are specialized in numerous respects and show multiple similarity to other mangrove genera, are unsuitable for comparison. It is true that also rainforest habitats favor certain morphs, but these are presumably less specialized than the mangrove ones.

Character conditions evaluated here include the following:

1. Presence of endothelium.
2. Presence of aril.
3. Exotegmic seed coat.
4. Chlorophyllous embryo.
5. Sieve-tube plastids with the protein bodies typical of Rhizophoraceae.
6. Presence of certain types of alkaloids.
7. Combined occurrences of the above (and other features).

Families found to share with Rhizophoraceae the unusual character conditions mentioned above will be compared further with Rhizophoraceae with regard to more general characters. If these turn out to be greatly divergent, the selected character conditions mentioned above are likely to reflect convergence rather than close relationship. If, however, a family shows similarity with Rhizophoraceae both in these selected characters and overall prop-

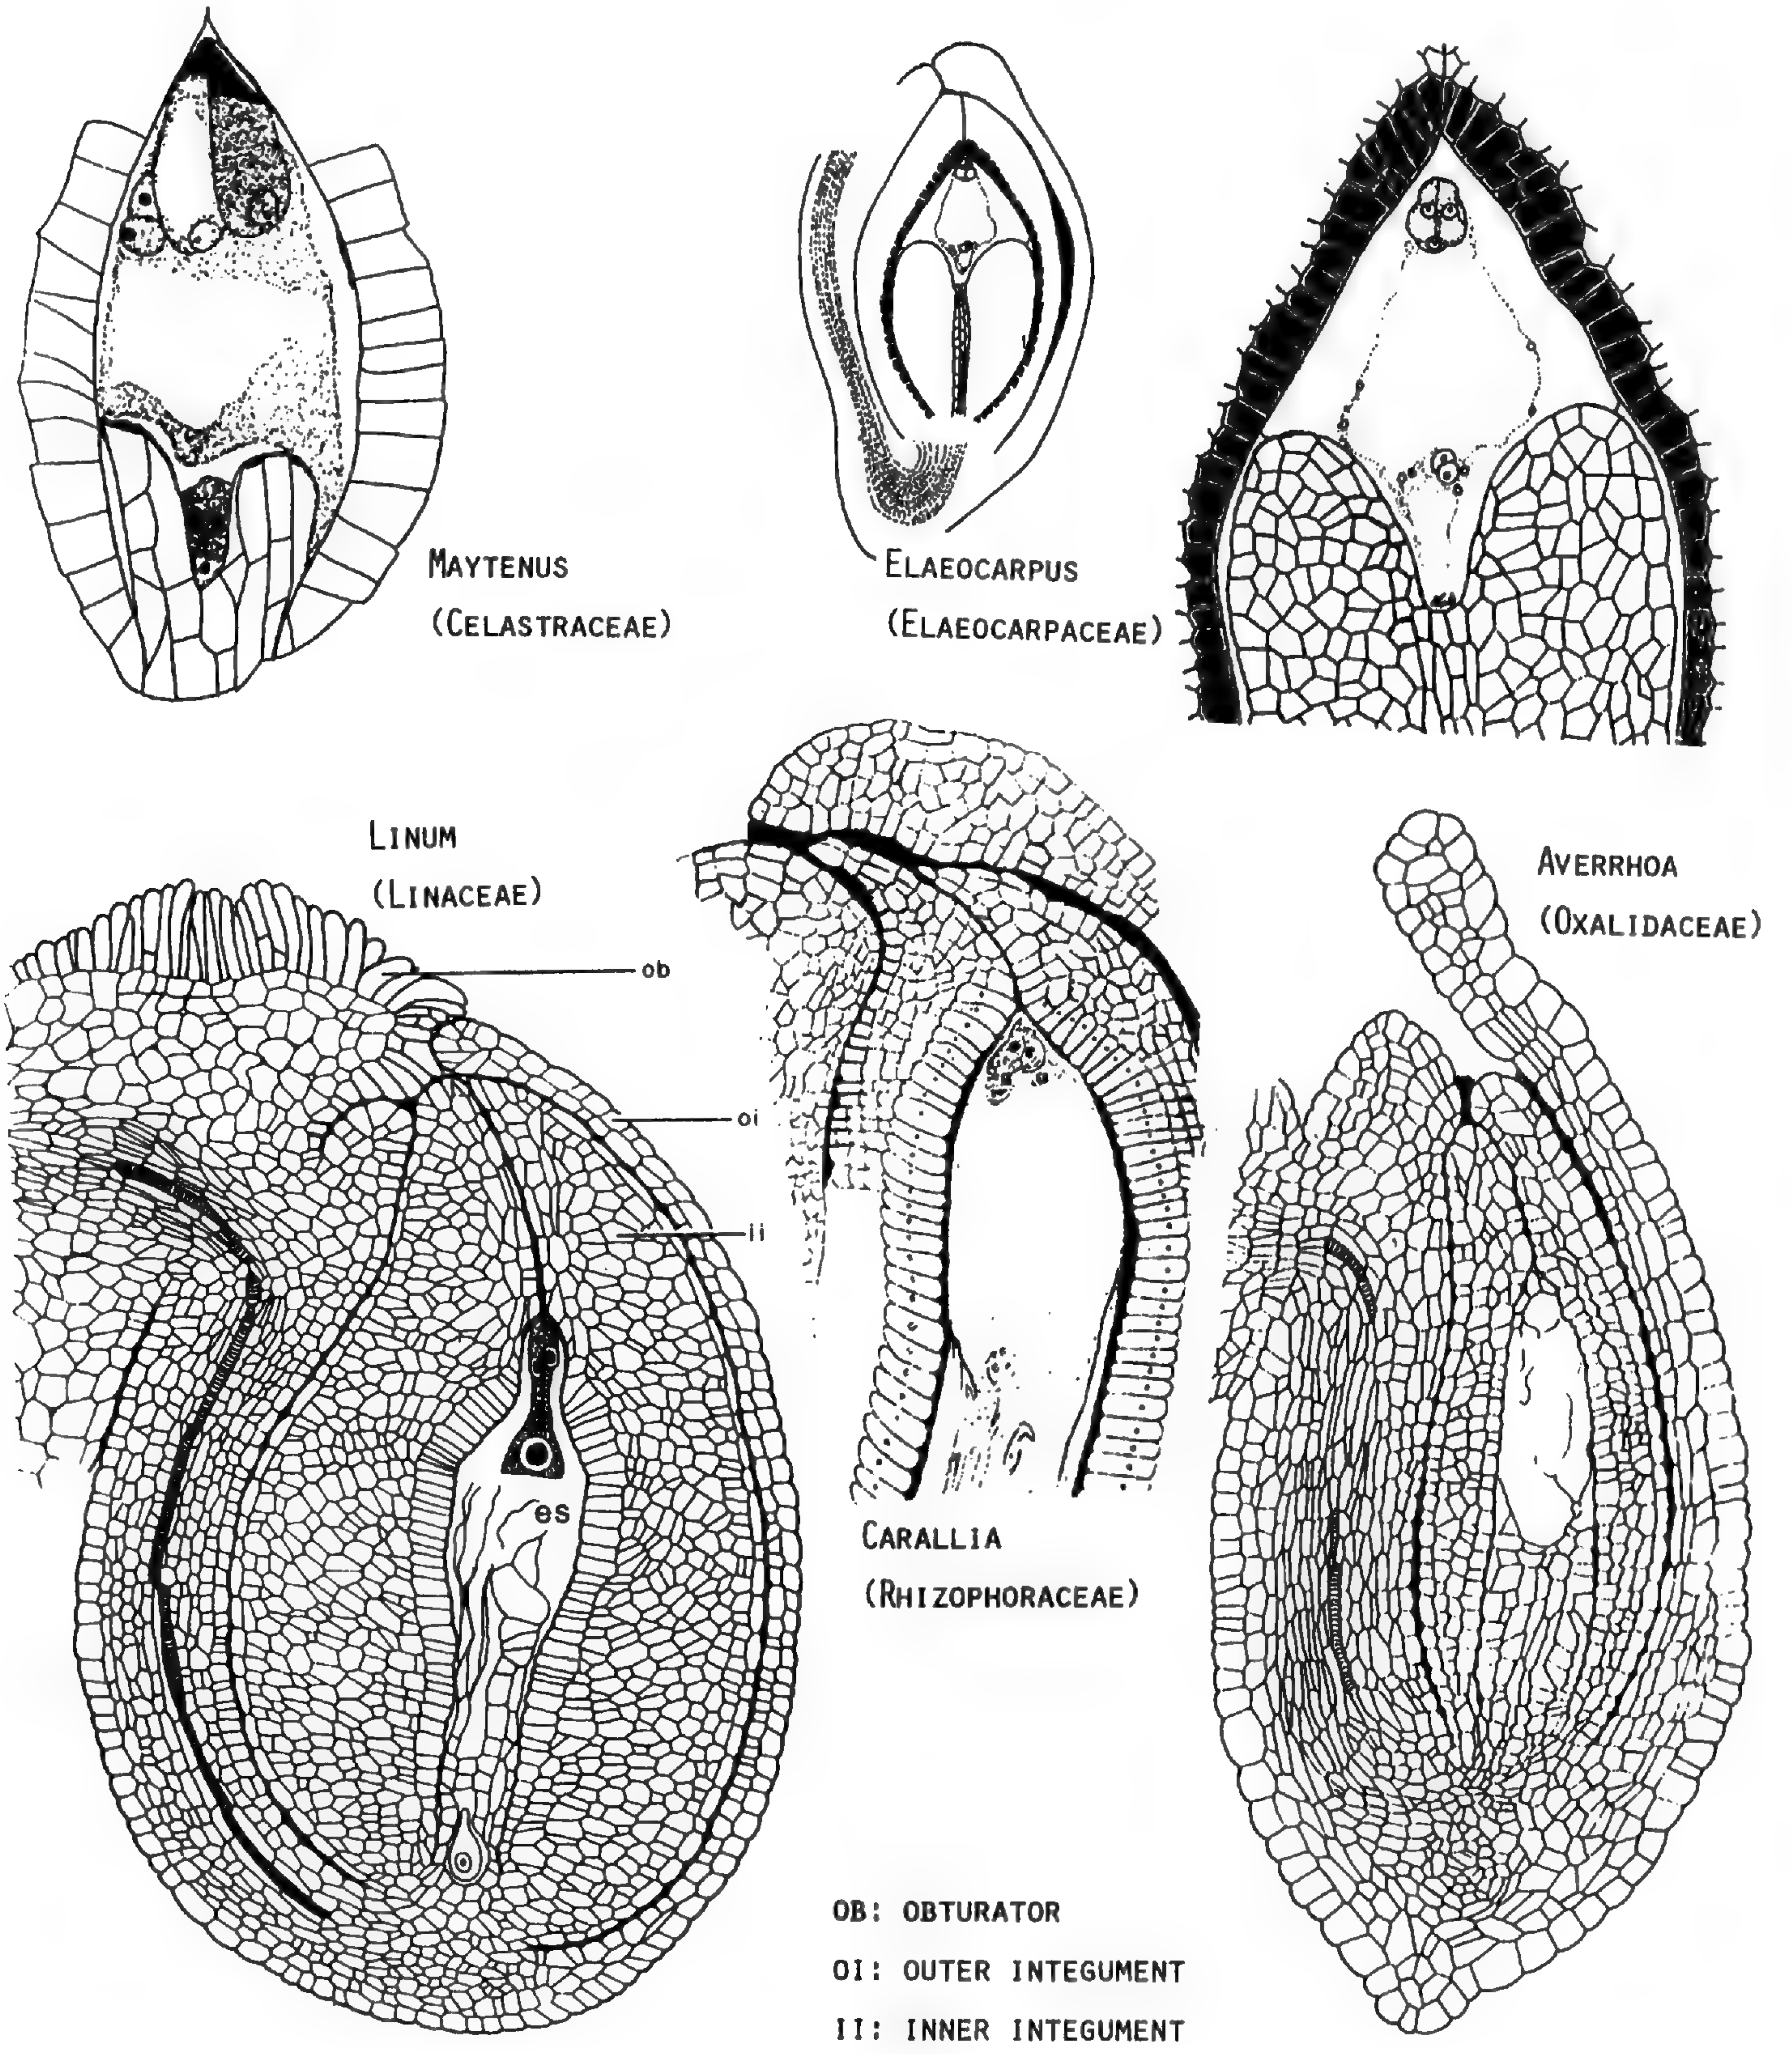

FIGURE 1. *Comparison of anatropous bitegmic ovules in several families having an endothelium lining the embryo sac. All have nuclear endosperm formation.* Maytenus *from Andersson (1931)*, Elaeocarpus *from Venkata Rao (1953)*, Linum *from Boesewinkel (1980)*, Carallia *from Karsten (1891), and* Averrhoa *from Boesewinkel (1985).*

erties, that family is likely to be closely related to Rhizophoraceae.

"RHIZOPHORACEOUS" CHARACTER CONDITIONS

For the following properties, most emphasis has been laid on families that are realistic as potentially related to the Rhizophoraceae. For example, monocotyledons, most sympetalous dicotyledons, taxa of Magnoliiflorae, Ranunculiflorae, Caryophylliflorae, and others have largely been ignored.

1. Presence of endothelium. Occurrence of endothelium (integumentary tapetum) was surveyed by Kapil & Tiwara (1978). In most groups having endothelium the ovules are unitegmic and tenuinucellate. These will not be considered here. Groups having a combination of endothelium and bitegmic ovules are shown as follows. They have nuclear (or rarely helobial) endosperm formation and include taxa with crassinucellate as well as tenuinucellate ovules.

Endothelium

I. In combination with crassinucellate ovules
  Rhizophorales: Rhizophoraceae (Narayana, 1970)
  Malvales: Elaeocarpaceae (Mauritzon, 1934; Venkata Rao, 1953)
  Geraniales: Erythroxylaceae (Boesewinkel & Geenen, 1980), Linaceae (Boesewinkel, 1985), Oxalidaceae (Boesewinkel, 1985), Zygophyllaceae, Balanitaceae (Narayana, 1957)
  Celastrales: Celastraceae (Andersson, 1931)
II. In combination with tenuinucellate ovules
  Theales: Lecythidaceae, Scytopetalaceae
  Ebenales: Ebenaceae
  Primulales: Myrsinaceae, Primulaceae

Most Rhizophoraceae probably have endothelium (although vestigial in the Rhizophoreae according to Juncosa, pers. comm.).

Rhizophoraceae were not mentioned by Kapil & Tiwara (1978), and the list thus is likely to be somewhat incomplete.

The endothelium will be further discussed below under the combination of character conditions.

2. *Presence of aril formed from the exostome.* Occurrence of arils is scattered and has restricted significance. Corner (1949, 1976) tended to regard the presence of arils as an archaic feature, while most other botanists seem to consider them polyphyletic and of rather recent origin. Arils comprise histologically diverse structures and are thus undoubtedly polyphyletic. However, it is likely that arils have developed early in some groups and then have been reduced or lost in some of their derivates, e.g., in combination with fruit evolution from capsules to berries or drupes. Occasional presence of arils, as in Rhizophoraceae, thus could be considered potentially useful and a possibly plesiomorphic character state.

What is of primary interest here is the occurrence of *exostomal arils*, as this is the kind present in Rhizophoraceae. Such arils occur at least in the following taxa:

Rhizophorales: Rhizophoraceae *pro parte* (at least 4 genera of tribe Macarisieae)
Malvales: Elaeocarpaceae: *Peripentadenia* (Hyland & Coode, 1982)
Celastrales: Celastraceae (common; see Andersson, 1931)
Theales: Clusiaceae *pro parte* (at least in *Clusia*)
Rutales: Meliaceae *pro parte* (at least in *Apanomixis*)
[Geraniales: Erythroxylaceae: *Aneulophus* (dubiously)]

Arils present in various other groups such as genera of Elaeocarpaceae (Malvales), Lepidobotryaceae (Geraniales), Gonystylidaceae (Thymelaeales), Connaraceae and Sapindaceae (Sapindales), Clusiaceae (Theales), and Rutaceae and Meliaceae (Rutales) according to Corner (1976) are mostly or wholly formed from the chalaza or raphe, or both. More studies are needed to clear up homology conditions for using aril structures.

3. *Seed coat with fibrous exotegmen.* According to Corner (1976), a fibrous exotegmen occurs in the following taxa:

Rhizophorales: Rhizophoraceae *pro parte*; probably all genera except the Rhizophoreae and *Carallia* of Gynotrocheae (Juncosa, pers. comm.).
Malvales: Elaeocarpaceae
Geraniales: Erythroxylaceae, Ixonanthaceae, Linaceae, Humiriaceae, and Oxalidaceae
Celastrales: Celastraceae
Euphorbiales: Euphorbiaceae: Phyllanthoideae
Sapindales: Connaraceae, Sapindaceae *pro parte*, and Staphyleaceae *pro parte*
Myrtales: Combretaceae, Lythraceae (including Punicaceae and Sonneratiaceae), and Onagraceae
Others: Aristolochiaceae, Capparidaceae, Caricaceae, Flacourtiaceae, Malpighiaceae, Violaceae, and additional families

Corner (1976) commented on *Gynotroches* and *Pellacalyx* (of his Legnotidaceae) that the exotegminal cells are long and sclerotic. This condition could represent the ancestral type in Rhizophoraceae and must be considered potentially useful in phylogenetic considerations (see Juncosa, 1984a).

Further notes on the seed coat will be given below.

4. *Chlorophyllous embryo.* The embryo in Rhizophoraceae is always or at least generally chlorophyllous (Schimper, 1892; Cronquist, 1981). A chlorophyllous embryo is often found in exendospermous seeds, a tendency that is marked in

monocotyledons but not as clear in dicotyledons; for instance, the seeds are endospermous in Rhizophoraceae.

Yakovlev & Zhukova (1980) and Dahlgren (1980b) have respectively listed and commented on the distribution of chlorophyllous embryos in seeds. In choripetalous dicotyledons their distribution is as follows (mainly according to Yakovlev & Zhukova, 1980):

Rhizophorales: Rhizophoraceae (all or most species; not included by Yakovlev & Zhukova)
Malvales: virtually all families: Bombacaceae, Cistaceae, Dipterocarpaceae, Elaeocarpaceae, Malvaceae (most taxa), Sterculiaceae, and Tiliaceae
Celastrales: Celastraceae
Geraniales: virtually all families, including Erythroxylaceae, Geraniaceae, Linaceae, Oxalidaceae, and Zygophyllaceae
Sapindales: various families, e.g., Aceraceae, Anacardiaceae, Hippocastanaceae, Sapindaceae, and Staphyleaceae
Rutales: most families, among them, Burseraceae, Meliaceae, Rutaceae, and Simaroubaceae
Polygalales: Polygalaceae
Rhamnales: Rhamnaceae
Fabales: all
Theales: Clusiaceae
Other groups: including scattered families of Myrtales; many Capparales, especially Brassicaceae; many Nymphaeales; many Caryophyllales; all Salicales; many Euphorbiales; many Santalales; Plumbaginales; and some taxa in Violales (Violaceae) and Cornales (Icacinaceae, Alangiaceae, Cornaceae)

This character previously has been quite overlooked in phylogenetic considerations.

5. Sieve-tube plastids with numerous, variably large, square or polygonal protein bodies. This type of protein has been found by Behnke (1982, 1984) in all genera of Rhizophoraceae studied (see above), *Erythroxylon* (Erythroxylaceae, Geraniales), and *Cyrilla* (Cyrillaceae, Ericales). In the last-mentioned family the sieve-tube plastids also contain thin protein filaments.

Cyrillaceae are so different from Rhizophoraceae in overall characters that they can probably be dismissed from consideration as closely related.

Of other families with different shapes and numbers of protein bodies in the sieve tubes may be mentioned Oxalidaceae (including *Averrhoa*), Connaraceae, Eucryphiaceae, and Vitaceae (Behnke, 1981).

The presence of the same type of protein configurations in Rhizophoraceae and Erythroxylaceae is of interest in light of a number of other similarities between the two families. If this type represents a synapomorphy of these two families, this would indicate a *very* close relationship (a sister group relationship). As will be commented on below under Erythroxylaceae, there is not sufficient evidence for that.

6. Presence of certain types of alkaloids. Rhizophoraceae contain three types of alkaloids (see Hegnauer, 1973): pyrrolidine, tropine, and pyrrolizidine alkaloids.

Hygroline, an alcohol of hygrine, is a *pyrrolidine alkaloid.* It is known in species of *Carallia* (Fitzgerald, 1965) and *Gynotroches* (Johns et al., 1967) of Rhizophoraceae, in at least two species of *Erythroxylon* of Erythroxylaceae, and in *Cochlearia* of Brassicaceae. Hygrine is also known in Convolvulaceae, Solanaceae, and Orchidaceae (Gibbs, 1974).

Of other pyrrolidine alkaloids, gerrardamine, gerrardine, and gerrardoline are known in *Cassipourea gerrardii* of Rhizophoraceae but not in other taxa (Gibbs, 1974). Pyrrolidine alkaloids are otherwise rather scattered in angiosperm families.

Tropane alkaloids, surveyed by Romeike (1978) are known in the following groups:

Rhizophorales: Rhizophoraceae (*Bruguiera*) (Loder & Russel, 1966)
Malvales: Elaeocarpaceae (*Peripentadenia*) (Johns et al., 1971)
Geraniales: Erythroxylaceae (*Erythroxylon*)
Euphorbiales: Euphorbiaceae (*Phyllanthus*)
Other groups: Solanaceae (numerous genera), Convolvulaceae, Brassicaceae, Proteaceae, Dioscoreaceae, and Orchidaceae

Bruguiera contains a few tropane alkaloids. Some, like brugine, are unique to *Bruguiera*; others are shared between *Bruguiera* and either of *Dyboisia* (Solanaceae) or *Erythroxylon* (Erythroxylaceae). *Peripentadenia* (Elaeocarpaceae) contains tropacocaine, as does *Erythroxylon*.

Pyrrolizidine alkaloids, surveyed by Culvenor (1978), are represented by cassipourine, a 1-aminopyrrolizidine derivative, in *Cassipourea* of Rhizophoraceae. Pyrrolizidine alkaloids are scattered in angiosperms and are known in the following groups (Culvenor, 1978; Seigler, 1977):

Rhizophorales: Rhizophoraceae (*Cassipourea*; Bull et al., 1968)
Malvales: Elaeocarpaceae (*Aristotelia*) (Bick et al., 1971)
Celastrales: Celastraceae (*Bhesa*)
Euphorbiales: Euphorbiaceae (*Phyllanthus*, *Securinega*)
Ebenales: Sapotaceae (*Mimusops*, *Planchonella*)
Santalales: Santalaceae (*Thesium*)
Other groups: Apocynaceae, Scrophulariaceae, Asteraceae (many genera), Ranunculaceae, Fabaceae, Boraginaceae (many genera), Poaceae, and Orchidaceae

It is difficult to judge the significance of these three alkaloids. According to Hegnauer (1973), they are all derived from the amino acid ornithine. A shared inherent ability to synthesize such alkaloids in taxa of Rhizophoraceae, Elaeocarpaceae, Celastraceae, and Erythroxylaceae (perhaps also some Euphorbiaceae: Phyllanthoideae) based on a common ancestry should be considered.

COMBINED OCCURRENCE OF EMBRYOLOGICAL AND SEED CHARACTERS

The following combination of character conditions is found in Rhizophoraceae. Its occurrence in other families will be considered particularly significant here in the evaluation of the closest relationships of the family.

1. Ovules anatropous (to hemianatropous).
2. Ovules bitegminal, with a micropyle tending to be zigzag.
3. Inner integument three- to several-layered.
4. Ovules modestly to weakly crassinucellate.
5. Parietal cell cut off from primary archesporial cell, dividing a few times.
6. Nucellus lateral to embryo sac disintegrating at an early stage.
7. Inner integument forming an integumentary tapetum of ± palisadelike cells (an endothelium).
8. Endosperm formation nuclear.
9. Endosperm retained and ± copious in the ripe seed.
10. Embryo of the ripe seed chlorophyllous.
11. Seed coat exotegminal, exotegmen fibrous.
12. Aril tending to be present, exostomal.

The first eleven states are found in the following groups:

Rhizophorales: Rhizophoraceae *pro parte*
Malvales: Elaeocarpaceae
Celastrales: Celastraceae
Geraniales: Erythroxylaceae, Humiriaceae, Linaceae, and Oxalidaceae

Exostomal arils, additionally, are found at least in Celastraceae. Apart from these families, certain other not yet sufficiently investigated minor families, e.g., Lepidobotryaceae of Geraniales, are likely to agree with these groups mentioned. Also, members of Theales (e.g., Clusiaceae), Euphorbiales (members of Phyllanthoideae, Dichapetalaceae), Thymelaeales (Gonystylaceae), and others agree in some of these characters and cannot be wholly excluded from consideration as potentially close relatives of Rhizophoraceae.

As regards alkaloids, it is also obvious that families like Elaeocarpaceae, Erythroxylaceae, and Celastraceae show similarity to Rhizophoraceae, supporting (rather than being neutral or contradictory to) the embryological evidence.

CONCLUSIONS

Having used a limited number of characters to select families that qualify as more or less closely related to Rhizophoraceae, each of the following families and orders will be briefly compared with this family with respect to all-around similarity.

1. Elaeocarpaceae, which are presumably incorrectly placed in Malvales.
2. Celastraceae (including Hippocrateaceae), which are generally placed in their own order Celastrales, often along with various minor and insufficiently known families.
3. Erythroxylaceae of Geraniales; their position in this order has never been questioned in recent years and they also agree well with other Geraniales (or Linales) such as Hugoniaceae, Linaceae, and Oxalidaceae.
4. Lepidobotryaceae and Ctenolophonaceae, two unigeneric families of Geraniales, which are unknown in practically all of the respects considered above but which in general morphology approach Rhizophoraceae tribe Macarisieae.
5. Other taxa of Geraniales.
6. Certain other groups of Theales, Ebenales, Sapindales, and Rutales.
7. The order Myrtales.

FAMILIES PUTATIVELY RELATED TO RHIZOPHORACEAE

1. Elaeocarpaceae. This family, with about 10 genera and 400 species, is usually placed at the "bottom" of the Malvales near Tiliaceae. In various systems, e.g., that of Hutchinson (1959), and some textbooks (Davis, 1966; Hegnauer, 1973), Elaeocarpaceae are even included in Tiliaceae. The absence of mucilage cells and cavities, stellate hairs, nectar hairs at the calyx base, and of fatty acids with a cyclopropenyl ring, in combination with the presence of imbricate sepals, a nectariferous disc at the base of the stamens, endothelium, and other features are all foreign to other Malvales and justify their exclusion from that order.

Elaeocarpaceae and Rhizophoraceae are woody, and in wood anatomy Elaeocarpaceae are more advanced than most Rhizophoraceae, having, as a rule, vessel members with simple perforations. Wood rays are heterogeneous, mixed uniseriate and pluriseriate, as in Rhizophoraceae. The parenchyma is usually paratracheal and very sparse (different from most primitive Rhizophoraceae); mucilage canals and cavities are present.

The nodes are trilacunar, as in Rhizophoraceae. The leaves are often alternate in Elaeocarpaceae. As in Rhizophoraceae, stipules are present; they may be persistent or caducous. The leaf venation is at least partly brochidodromous, as in some Rhizophoraceae, but sometimes eucamptodromous, although Hickey & Wolfe (1975) attributed Malvales in general with actinodromous venation. Furthermore, the leaf teeth in Elaeocarpaceae according to Hickey & Wolfe (1975) are mainly of the violoid type, this resembling the theoid type, which these authors reported for Celastraceae. The teeth in Elaeocarpaceae are obviously more or less different, however, from the peculiar macarisioid teeth in Rhizophoraceae (Keating & Randrianasolo, this volume). Stomata in Elaeocarpaceae are paracytic to cyclocytic and are restricted to the lower leaf surface, as in Rhizophoraceae. Crystals are present in the parenchyma and are generally solitary and prismatic, as are the crystals in Rhizophoraceae tribe Macarisieae. The hairs, when present, are simple and unicellular, as in Rhizophoraceae.

Likewise matching this family, the inflorescences are mostly axillary cymes or panicles, and the flowers are hypogynous and probably primitively pentamerous. The sepals are valvate to imbricate, and the petals are distinct (rarely basally connate) and frequently distally lobate or fimbriate, as in most nonmangrove Rhizophoraceae. A more or less conspicuous disc is present (Balgooy, 1982), as in nearly all Rhizophoraceae. The stamens are 1–3 times the petal number or usually more (van Heel, 1966), the diplostemonous condition being probably plesiomorphic. Haplostemony, as in Celastraceae, is found within *Sloanea*. Both in the basic state and in the increase of stamens, Elaeocarpaceae agree with Rhizophoraceae. The stamens have narrow filaments, as in Rhizophoraceae tribe Macarisieae, but the anthers are advanced, having at least in some genera a nonfibrous endothecium and, as a rule, apical dehiscence by short slits or pores.

The two families largely agree in pollen morphology, the pollen grains being mostly tricolporate, with rather thick exine and a rugulate-punctate surface. They are dispersed in the two-celled state in both families.

Carpel number is variable, as in Rhizophoraceae; the carpels are fused in the stylar region, the style being simple or apically lobate. The ovary is two- to several-loculed with axile placentation, in which the Elaeocarpaceae agree with Rhizophoraceae. As pointed out above under Rhizophoraceous Character Conditions, embryology in Elaeocarpaceae is essentially similar to that in Rhizophoraceae, although the arils when present in the former (according to Corner, 1976) are not exostomal but developed from the chalaza and raphe.

The fruit in Elaeocarpaceae is a capsule or drupe. The seeds have copious endosperm, with fat oils and protein and a chlorophyllous embryo, all the conditions in Rhizophoraceae. Arillate seeds occur in some species, and the aril in *Peripentadenia* is reportedly "a total covering of thick flesh outgrown from the distal cap" (Hyland & Coode, 1982).

Elaeocarpaceae agree with Rhizophoraceae in alkaloid chemistry (see above) and both are tannin plants. Ellagic acid is (rarely) present in both families. Both produce proanthocyanins as well as caffeic acid, and in both the flavonoids include myricetin, quercetin/kaempferol, and pelargonidin (Gornall et al., 1979). In fact, Elaeocarpaceae agree much better with regard to their secondary metabolites with Rhizophoraceae than with Tiliaceae, with which they are generally associated.

Briefly, the Elaeocarpaceae differ from the Rhizophoraceae mainly in some wood-anatomical details, in having usually alternate leaves and different anther morphology, and in basic chromosome number. Furthermore, the sieve-tube plastids accumulate starch, not protein. The floral receptacle is rarely as well developed as in Rhizophoraceae. Arils, when present, may be of different origin.

This supports the following conclusions: 1. Elaeocarpaceae make up a distinct family. 2. They are misplaced in Malvales. 3. They are closely related to Rhizophoraceae.

2. Celastraceae. Celastraceae comprise a fairly large family of roughly 50 genera and 800 species (Cronquist, 1981). The family is variable and somewhat difficult to define. All members are woody plants. Secretory canals ("laticifers") are often present in phloem of stem and leaves; this is also a feature met with in Rhizophoraceae (see, for example, Keating, 1984). Contrary to Rhizophoraceae, the Celastraceae are said to have unilacunar nodes. Vessel perforation is simple or rarely scalariform; variation is great in wood rays and wood parenchyma. Oxalate crystals of simple, prismatic type and as crystal druses (also crystal sand) occur in Celastraceae as well as in Rhizophoraceae. The leaves are opposite or alternate and simple and generally have small and/or caducous stipules or none at all (the stipules are generally larger in Rhizophoraceae). The venation is pinnate-brochidodromous with apically elongated arches; lateral teeth, where present, are of the theoid type (Hickey & Wolfe, 1975), agreeing probably more with Elaeocarpaceae than with Rhizophoraceae.

Hairs are infrequent and short and unicellular when present (Metcalfe & Chalk, 1950), as in Rhizophoraceae; in both families the stomata are generally confined to the lower surface of the leaves. In the Celastraceae they are anisocytic or anomocytic, only rarely paracytic, and thus mostly different from those in Rhizophoraceae.

The inflorescences in the Celastraceae and Rhizophoraceae are frequently axillary cymes or panicles (or solitary). The flowers are generally small and greenish, regular, 4–5-merous, and hypogynous, perigynous, or half-epigynous. In these respects the Celastraceae largely agree with Rhizophoraceae. However, the sepals are less developed and valvate to imbricate, the petals are often roundish, and the disc in most cases is more conspicuous and often square or 5-angular. The petals in Celastraceae to my knowledge are never fimbriate or laciniate apically, as is usual with Rhizophoraceae. Further, the androecium is restricted to a single alternipetalous whorl, although clearly derived from a diplostemonous condition (alternisepalous staminodes occur in *Lophopyxis*).

The pollen grains are mostly tricolporate, with sexine thicker than nexine, simplibaculate (Erdtman, 1952), and basically agree with the pollen in Rhizophoraceae. They are two- or three-celled when dispersed (Brewbaker, 1967).

The pistil consists of 2–5 carpels and has a single terminal style with capitate or lobate stigma. Each of the 2–5 locules contains as a rule two axile ovules. In these respects, as in nearly every detail of the embryology, the Celastraceae agree with the Rhizophoraceae tribe Macarisieae, including presence of endothelium, exostomal aril, and exotegminal, fibrous seed coat. The seeds have a chlorophyllous embryo.

The Celastraceae show a much wider chemical spectrum than Rhizophoraceae and Elaeocarpaceae but agree in being essentially tannin plants. They produce proanthocyanins and caffeic acid; ellagic acid has been reported in some individual species. Furthermore, the flavonoid spectrum agrees (Hegnauer, 1964) with the mentioned two families in presence of quercetin, kaempferol, myricetin, and other flavonoids. A pyrrolizidine alkaloid has been reported (see above), the significance of which is, however, uncertain. On the other hand, Celastraceae generally produce saponins (Bosser & Pernet, 1957) and often alkaloid amines, e.g., cathine (Cronquist, 1981), which are unknown in Rhizophoraceae and Elaeocarpaceae.

Besides other basic chromosome numbers, $x = 8$ is known in Celastraceae, as in some Rhizophoraceae.

Celastraceae obviously agree well with the Rhizophoraceae in essential characters but can be considered more derived in the haplostemonous flowers with little-developed calyx and generally massive disc. Further, they have the ability to produce saponins and certain amines and differ with regard to sieve-tube plastid inclusions. They form a more heterogeneous assemblage, with some genera having spread to temperate climates.

3. Erythroxylaceae. Erythroxylaceae consist of only the genera *Erythroxylon*, *Nectaropetalum*, *Pinacopodium*, and *Aneulophus*, the last often placed in Linaceae. *Erythroxylon* consists of ca. 200 species; the other genera are small. Erythroxylaceae are placed in Geraniales (or Linales) near Linaceae and Humiriaceae in all current classifications, and a number of shared features support this. Nevertheless, Erythroxylaceae (as well as some other families of Geraniales) agree with the Rhizophoraceae in several conspicuous features, warranting a close comparison between the two families.

Like the Rhizophoraceae, all Erythroxylaceae are woody but generally shrubby. The vessels have simple perforations in the end walls, a conspicuous difference from most Rhizophoraceae, but the wood rays are mostly heterocellular, mixed uni- and pluriseriate, as in that family. Essential oils are sometimes found in the wood.

A highly conspicuous similarity between Rhizophoraceae and Erythroxylaceae is the similar kind of protein bodies of the sieve-tube plastids (see above).

The leaves are alternate or rarely (*Aneulophus*) opposite and have brochidodromous venation of the secondary veins (Hickey & Wolfe, 1975), agreeing in this rather well with various Rhizophoraceae. Their teeth are mostly of the theoid type. Stipules are present, as in Rhizophoraceae; they are intrapetiolar and often tricuspidate. The stomata are paracytic and generally restricted to the lower surface of the leaves. Sclereids are sometimes present, while this in Rhizophoraceae is mainly the case with mangrove genera (tribe Rhizophoreae). Hairs are simple and unicellular when present. Solitary crystals of oxalate are found in some tissues.

The inflorescences are axillary panicles or cymes or consist of solitary flowers, as in Rhizophoraceae. A peculiarity of the Erythroxylaceae is that the axis of these inflorescences often bears a great number of bracteate leaves (raments, cataphylls). The flowers are small, actinomorphic, pentamerous in perianth and androecium, and hypogynous. The sepals are valvate or imbricate and basally connate. The petals are entire (not fimbriate or laciniate), free from each other, and usually adaxially appendaged. Unlike most Rhizophoraceae, Elaeocarpaceae, and Celastraceae, disc structures are lacking. The androecium is diplostemonous; the ten stamens are situated in a single whorl and the bases of their filaments are usually connate into a short tube. The anthers are tetrasporangiate, longitudinally dehiscent, and extrorse.

The pollen grains, as in most Rhizophoraceae, are tricolporate, with rather thick exine and often with a reticulate surface. They are, however, three-celled, whereas those in Rhizophoraceae are two-celled.

The pistil is 2–4-carpellary, with (2–)3(–4) locules and usually with 3 separate stylodia, each with a more or less expanded, often capitate stigma; sometimes, as in *Nectaropetalum*, there is a single, apically bilobate style (Verdcourt, 1981). Each locule contains one (or two) axillary and pendulous ovule(s); only one ovule usually develops in each fruit. The embryological characters are essentially as in Rhizophoraceae (see above). The fruit is generally a drupe, the single seed of which usually has copious endosperm (with starch) but may lack endosperm. Arils are lacking, except in *Aneulophus*, but the nature of the aril in this genus is uncertain, possibly exostomal (see Wilczek, 1958).

The chemical conditions are somewhat similar to those in Rhizophoraceae as regards alkaloids (tropane alkaloids—cocaine, for instance—are present and sometimes copious) and tannins; however, saponins, cyanogenic compounds, and ethereal oils are sometimes present, which is obviously not the case in Rhizophoraceae.

The basic chromosome number, $x = 12$, deviates from Rhizophoraceae.

Accordingly, Erythroxylaceae and Rhizophoraceae exhibit important differences and important similarities. The flowers in Erythroxylaceae lack a floral disc, in contrast with most Rhizophoraceae (but it is absent from *Pellacalyx* of this family). In Erythroxylaceae the floral receptacle is much less developed and never cupular, cataphyllous leaves are common (but probably evolved within Erythroxylaceae), and the pollen grains are three-celled.

Erythroxylaceae agree well with other Geraniales in most respects; in fact there are difficulties in delimiting them from, for example, Linaceae (*Aneulophus* and *Nectaropetalum* having been referred to both families). This is no argument against considering Rhizophoraceae (as well as Elaeocarpaceae and Celastraceae) as closely related to Erythroxylaceae and other families of Geraniales.

The following conclusions are drawn from the evidence presented here:

1. There are no arguments to exclude Erythroxylaceae from Geraniales (or from Linales, if this order is separated from Geraniales, as by Cronquist, 1981).
2. The Erythroxylaceae show numerous and essential similarities to Rhizophoraceae, which together support that they are relatively closely related.
3. This similarity is, however, not as far-reaching as that between Rhizophoraceae and Elaeocarpaceae, and there is not sufficient evidence that Rhizophoraceae and Erythroxylaceae can be "sister groups" in the phylogenetic sense.
4. Therefore, it is most likely that the very particular kind of sieve-tube plastids that the two families have in common has evolved by convergent evolution in the ancestors of each of the two families. (An alternative is that a certain disposition for them evolved in a common ancestor, although this is concealed or blocked in other related families.)

4. Lepidobotryaceae, Ctenolophonaceae. Lepidobotryaceae are often included in either Oxalidaceae or Linaceae. They may be circumscribed so as to include either only *Lepidobotrys* Engl. or also *Sarcotheca* Blume and *Dapania* Korth. *Lepidobotrys* occurs in Africa, *Sarcotheca* in Malaysia, and *Dapania* in Malaysia and Madagascar.

The present comments will be restricted to *Lepidobotrys* (see Leonard, 1950, 1958) without evaluating the circumscription of the family.

Lepidobotrys is a tree with alternate leaves, which have small stipules and one large leaf lamina; somewhat below this the petiole has a "joint" at which is situated a much smaller sheathing leaflet, often called a "stipel." The anatomical features remain insufficiently known, but according to Metcalfe & Chalk (1950), the vessels have scalariform perforation plates, and the intervascular pitting is minute and alternate.

Wood parenchyma is abundant and consists of scattered cells containing oxalate crystals. The rays are almost exclusively uniseriate and almost homogeneous (Metcalfe & Chalk, 1950). The inflorescences are small, axillary and racemelike; their axis bears densely set scales, in the axils of which the flowers are situated. Young inflorescences therefore are conelike. The flowers are fairly long-pedicelled, actinomorphic, mainly pentamerous, diplostemonous, functionally unisexual, and tricarpellary. The petals are imbricate, and the mutually free filaments of the 10 stamens are inserted on a lobate, well-developed disc. The pollen grains are tricolporate with reticulate exine (see Oltmann, 1971). The pistil is trilocular and has three free, apically bilobate stylodia. The functionally male and female flowers differ in having either well-developed stamens and rudimentary (but distinctive) pistil or smaller, nonfunctional stamens and a well-developed pistil. Each locule possesses two apical-axile ovules. The embryology is unknown. The fruit is a one-seeded capsule with a funicular aril.

This genus has a floral structure similar to that in certain species of Rhizophoraceae tribe Macarisieae, although in stylar conditions it more resembles Anisophylleaceae. It is an example of some rather isolated genera in Geraniales that have been variously treated as separate families or included in Oxalidaceae or Linaceae.

Another isolated genus, *Ctenolophon*, is sometimes treated as the separate family Ctenolophonaceae and is sometimes included in Linaceae. This genus has opposite, stipulate leaves, as in Rhizophoraceae, and a panicle of pentamerous, diplostemonous flowers with a prominent disc and a bilocular pistil with a single style, all known in Rhizophoraceae. The pollen grains are extraordinarily different, however (see, for example, Erdtman, 1952; Oltmann, 1971). The fruit is a nutlet with a single arillate seed. The nature of the aril is not quite clear. *Lepidobotrys* and *Ctenolophon* are mentioned here as a complement to Erythroxylaceae, as they are currently considered good members of Geraniales (or Linales) yet resemble the Rhizophoraceae in some respects in which the Erythroxylaceae differ from the Rhizophoraceae; *Lepidobotrys* in the more enlarged floral axis with a prominent, somewhat lobate disc and in the free filaments, a floral structure clearly similar to that in, for example, *Gynotroches*; *Ctenolophon* in the opposite leaves, distinct floral disc, separate filaments, and single (although apically bibrachiate) style.

5. *Other Geraniales.* Whereas it seems as if the Rhizophoraceae show closest similarity to Erythroxylaceae and certain variously placed genera such as *Lepidobotrys* and *Ctenolophon*, which deserve further embryological, anatomical, and chemical studies, there is also, as noted above, great embryological similarity with Linaceae, Oxalidaceae, and Balanitaceae. Woody members of the first of these families and of Balanitaceae, Humiriaceae, Hugoniaceae, and Zygophyllaceae need be considered as potentially closely related to Rhizophoraceae.

6. *Members of Theales, Ebenales, Sapindales, and Rutales.* It has been stated above that several character states of the above-mentioned combination of embryological attributes occur in other groups, mainly of these four orders.

The Theales are variously circumscribed, with Lecythidaceae included or not. Within this complex in the wide sense, endothelium is reported for Lecythidaceae and may well occur in other families; an exostomal aril is found in at least some species of *Clusia*, of Clusiaceae; within this family the embryo may also be chlorophyllous. Sapotaceae in the probably highly heterogeneous order Ebenales show quite a number of similarities to Rhizophoraceae (and various Theales). Presumably primitive Theales and, separately, primitive Malvales evolved from ancestors with rather simple tetra- or pentamerous, diplostemonous flowers; in each of the Theales and Malvales lines an increase in stamen number seems to have occurred. Such an increase of stamen number can also be observed *within* each of Rhizophoraceae and Elaeocarpaceae. It is probable that other evolutionary lines evolved from groups with such simple, diplostemonous flowers, e.g., Geraniales, Sapindales, and Rutales, each line retaining some of the plesiomorphies while developing its own specializations (autapomorphies).

7. *The Myrtales.* Myrtales also most likely evolved from an ancestor with penta- or tetramerous, actinomorphic, hypogynous, diplostemonous flowers with a disc (see Dahlgren & Thorne, 1984). The Myrtales are less specialized in embryological characters than the Rhizophoraceae, having a more persistently multicellular nucellus and no endothelium (Tobe & Raven, 1983) and having nonchlorophyllous embryo and exendospermous seeds. The

nodes in Rhizophoraceae are trilacunar, which is extremely rare in Myrtales (found only in *Alzatea*). Vessels in Rhizophoraceae are more primitive than those in Myrtales in having scalariform perforation plates. The alkaloid chemistry in Rhizophoraceae has no correspondence in Myrtales. Finally, Rhizophoraceae lack internal phloem and vestured pits. This evidence all supports the view held at the Myrtales symposium (see, for example, Dahlgren & Thorne, 1984) that Rhizophoraceae are not closely related with Myrtales.

For Anisophylleaceae, earlier included in Rhizophoraceae, most of these objections against a close relationship to Myrtales are lacking (although some others may be added, as lack of stipules).

MONOPHYLY AND CHARACTERIZATION OF ANISOPHYLLEACEAE

Anisophylleaceae consists of the genera *Anisophyllea* R. Br., *Combretocarpus* Hook. fil., *Poga* Pierre, and *Polygonanthus* Ducke.

Anisophylleaceae are trees and shrubs, sometimes of considerable size. Characteristic wood anatomical features according to van Vliet (1976) are the simple perforations in the vessels, fibers with distinctly bordered pits, very broad (up to 30 cells wide) multiseriate rays, and the half-bordered, alternate vessel–parenchyma pits. These character states do not distinguish the family absolutely and sharply from Rhizophoraceae; rather the variable Rhizophoraceae with the genera of the tribe Gynotrocheae, in particular *Carallia*, join up with the Anisophylleaceae. As regards vessel diameter, van Vliet (1976) showed that the Anisophylleaceae normally have higher values than Rhizophoraceae (Anisophylleaceae: tangential diameter mostly 160–340 μm, radial diameter to 370–420 μm; Rhizophoraceae: tangential diameter mostly 40–200 μm, tangential diameter mostly to 85–340 μm). As other character conditions argue against a close relationship between Rhizophoraceae and Anisophylleaceae, it is not adequate to discuss the wood anatomical "limits" between the families—*Carallia* and other Gynotrocheae are not really intermediate between other Rhizophoraceae and Anisophylleaceae; they are only extreme in the former family. Lysigenous secretory cavities are present in *Poga* (Metcalfe & Chalk, 1950).

The leaves in Anisophylleaceae are alternate, simple, entire, and exstipulate. According to Keating & Randrianasolo (this volume), the secondary venation in most Anisophylleaceae is transitional between brochidodromous and (basally on the lamina) eucamptodromous, but it is acrodromous in *Anisophyllea*. No teeth are present. There is marked anisophylly and often strong asymmetry in the leaves of *Anisophyllea*, which are generally two-ranked and strongly horizontally oriented on plagiotropic shoots.

The inflorescences are axillary and generally elongate and catkin- or spikelike.

The flowers are small, usually 4(–5)-merous, but 3-merous in *Combretocarpus* and rarely in *Anisophyllea*; they are actinomorphic, epigynous, diplostemonous, and often unisexual by partial reduction of stamens or pistil (Tobe & Raven, in press). The floral receptacle, which encloses and is fused with the ovary wall, continues as a variably long hypanthium, resembling the condition in many Myrtales.

The petals (see Tobe & Raven, in press) are usually deeply incised, generally with 3, 5, or 7 lobes, which may have an enlarged, glandular tip. These enlarged tips are present in taxa of *Anisophyllea* (*A. laurina*) and *Poga*, and they support these genera as closely related (although they belong to different main branches in the cladogram of Tobe & Raven, this volume). Only *Polygonanthus* has entire petals, although the margin is sometimes finely fimbriate.

Incised to fimbriate petals may represent an autapomorphy of Anisophylleaceae but also occur in most nonmangrove Rhizophoraceae, in most Elaeocarpaceae, in certain genera of each of Diapensiaceae, Primulaceae, Malpighiaceae, and others. The value of this character in connecting Rhizophoraceae and Anisophylleaceae is dubious in the light of the numerous differences. A striking condition, stressed especially by Tobe (pers. comm.), is that the above-mentioned swollen, glandular tips of the petal lobes in Anisophylleaceae are matched in at least *Ceriops* of Rhizophoraceae. However conspicuous this similarity may be, I consider this the result of convergent evolution; Juncosa & Tomlinson (1987) showed that in *Ceriops* these structures are hydathodes.

A lobate intra- and interstaminal, discontinuous disc surrounds the style base. Nectar is produced at the filamental bases. The (6–)8(–10) stamens are incurved in bud and have mutually free, narrow filaments and dorsifixed, ovoid, introrse-latrorse anthers (all from Tobe & Raven, in press.)

The pistil ends in (3–)4(–5) separate stylodia. The carpels each form a locule with 1–2 ovules in axile position.

The Anisophylleaceae (Tobe & Raven, in press) show a combination of frequent character conditions, from which there are various exceptions representing further evolutionary developments that contribute to elucidating the probable evolution within this small family (see cladogram in Tobe & Raven, in press). The endothelium is fibrous, the anther wall formation of the basic type, and the tapetum glandular with 2-nucleate or—by nuclear fusion—1-nucleate tapetal cells.

The pollen grains are tricolporate and, according to Vezey et al. (this volume), have a rather thin tectum with reticulate-punctate surface. Tobe & Raven (1987b) showed that the pollen grains are two-celled when dispersed.

The ovules are bitegmic or (*Anisophyllea* and *Combretocarpus*) unitegmic, with the inner integument in bitegmic ovules only two cells thick, a difference from the Rhizophoraceae; in bitegmic ovules the micropyle is formed by both integuments. The ovules are clearly crassinucellate; the primary archesporial cell cuts off a parietal cell that gives rise to a parietal tissue. The nucellar tissue persists longer than in Rhizophoraceae. No endothelium is formed. Embryo sac formation is of the *Polygonum* type or, in *Combretocarpus*, of the *Allium* type, the latter obviously an autapomorphy for that genus. Endosperm formation is nuclear. The endosperm is used up in the course of seed maturation. The embryo has a long hypocotyl and small to rudimentary cotyledons or no cotyledons at all. The latter conditions are possibly potentially valuable in the search for the relationships of Anisophylleaceae. (Information all according to Tobe & Raven, 1987b.)

Contrary to the Rhizophoraceae and Elaeocarpaceae, the seed coat of the mature seed is not exotegminal-fibrous but consists of the testal epidermis only (exotesta), as in *Poga*, of a multilayered testa (*Polygonanthus*), or of the multilayered or ultimately thin single integument (*Anisophyllea* and *Combretocarpus*, respectively) (Tobe & Raven, this volume). This variation makes difficult comparisons and conclusions on relationships based on seed coat structure.

Chemical information is somewhat incomplete. Aluminium accumulation is highly characteristic (Chenery, 1948), a major difference from Rhizophoraceae but a similarity to various Myrtales. The Anisophylleaceae are clearly tanniniferous plants. Ellagic acid is known in *Anisophyllea* (Lowry, 1968). Alkaloids are unknown.

The above evidence will form the basis for an attempt to evaluate approximate relationships of the Anisophylleaceae, which show no autapomorphy with strong significance comparable to that of the kind of sieve-element plastids in Rhizophoraceae. The homogeneity of Anisophylleaceae therefore rests on the combination of numerous, rather frequently occurring, and trivial character conditions. These include the similar states of wood characters (see above), accumulation of aluminium, the floral structures (epigyny, tri- or tetramery, presence of hypanthium, generally incised petals, presence of a disc, diplostemony, and separate stylodia), and the combination of general embryological characters (see above). Thus, multiple similarities rather than singularity binds together the four genera and support them as a monophyletic unit.

RELATIONSHIPS OF ANISOPHYLLEACEAE

Technically the Anisophylleaceae can be defined as follows: woody; vessel perforation simple; leaves alternate, exstipulate, simple, entire; flowers mostly tetramerous, actinomorphic, isomerous in all whorls but diplostemonous, with sepals and petals; filaments free from each other and from the corolla; anthers dehiscing with longitudinal slits; disc present; stylodia free; ovules 1–2 per locule, axile, anatropous, crassinucellate, with nuclear endosperm formation; fruit fleshy, indehiscent; seeds exendospermous, with straight embryo.

Such a combination of features is restricted to Anisophylleaceae but may coincide with that in Rosaceae as broadly defined to include Malaceae; however, it is not present in one and the same member of any Rosaceae.

Neglecting tetramery (in all whorls) does not increase the choice, but neglecting also absence of endosperm in the seed, a presumably advanced and recently derived character condition, also adds Flacourtiaceae and Anacardiaceae. Neglecting also the fruit type, the lack of stipules, and the free stylodia would bring some Myrtales in agreement with Anisophylleaceae as well, but then the anatomical peculiarities of Myrtales (intraxylary phloem and vestured pitting) are not considered either.

Thus, in gross morphology Anisophylleaceae are largely Saxifragalean–Rosalean in nature, and I agree with Cronquist (1981), who placed Anisophylleaceae in Rosales in the broad sense. Also chemical characters agree, largely with those in, for example, Rosaceae in the narrow sense. However, within the Rosales no obvious group agrees particularly well with the Anisophylleaceae, and the alternative families Flacourtiaceae and Anacardiaceae must be considered.

FLACOURTIACEAE

Flacourtiaceae comprise a very variable group of often cyanogenic plants with mostly stipulate leaves. Their flowers are nearly always hypogy-

TABLE 2. *Differences between Rhizophoraceae and Anisophylleaceae.*

Character	Rhizophoraceae	Anisophylleaceae
Leaves	opposite	alternate
Stipules	present, interpetiolate	lacking
Vessel perforation	usually scalariform	simple
Vessel diameter	narrow	wider
Sieve element plastids	with particular protein bodies	with starch only
Aluminium accumulation	none	present
Colleters	reported in several genera	none
Inflorescence	pauciflorous, cymules, solitary flower	multiflorous; panicle or panicle-derived
Merism	4-, 5- or > 5-merous	3- or 4-merous
Ovary, style	superior to inferior, a single style	inferior, separate stylodia
Tectum of pollen wall	relatively thick	relatively thin
Subepidermal floral laticifers	present, different types	none
Nucellar tissue	consumed early	persisting longer
Endothelium	present	none
Seeds	endospermous	exendospermous

nous, and the stamens are generally numerous. Furthermore, the ovary generally has parietal placentae. No single genus of Flacourtiaceae to my knowledge has the combination of character condition of the Anisophylleaceae, and it is solely due to the variability (or heterogeneity) of the Flacourtiaceae that it agrees, in most respects, with the Anisophylleaceae.

ANACARDIACEAE

Anacardiaceae are members of Sapindales. They are rich in tannins and have well-developed schizogenous or lysigenous ducts or channels with resins, which is not the case with the Anisophylleaceae. The leaves are variable in Anacardiaceae but are more frequently compound than simple, as in Anisophylleaceae. The small flowers are reminiscent of those in Anisophylleaceae but are more often pentamerous; they vary from hypo- or perigynous to epigynous and are often diplostemonous, with free stamens and a well-developed disc. The carpels are often solitary (sometimes several and free from each other) but when fused are generally three. The fruit is usually drupaceous. Anacardiaceae, apart from the resin canals, compound leaves, and numerical conditions of the flower (especially gynoecium), agree fairly well with Anisophylleaceae.

CONCLUSION

Anisophylleaceae are difficult to place, as most of their characteristics are of very common occurrence. Rosales(–Saxifragales–Cunoniales) seem to be the group in which they would be fairly well placed, but without obvious links. These orders have a clearly temperate(–boreal) concentration, which somewhat contrasts with the tropical concentration of Anisophylleaceae. The floral morphological (Tobe & Raven, 1987c) and embryological conditions in Anisophylleaceae agree completely with those common in Rosaceae sensu stricto, for example: exendospermous seeds and a bitegmic, crassinucellate ovule with nuclear endosperm formation. That in both families the ovules are bitegmic in some and unitegmic in other genera is a coincidence. The basic chromosome numbers, $x = 7$ or $x = 8$, are also present in Rosaceae sensu stricto, especially the former number (Raven, 1975).

It is probable that Anisophylleaceae comprise a rather isolated family evolved from ancestors shared between those in Rosales, Cunoniales, and Saxifragales. It is also probable that these were not very remote from the ancestors of Myrtales, although the last order is distinctive in several respects, including the anatomical features mentioned above.

PROPOSED CLASSIFICATION

Ordinal composition around Rhizophoraceae:

GERANIALES: Zygophyllaceae, Nitrariaceae, Peganaceae (position uncertain), Balanitaceae, Vivianiaceae, Geraniaceae, Ledocarpaceae, Biebersteiniaceae, Dirachmaceae, Ixonanthaceae, Humiriaceae, Hugoniaceae, Ctenolophonaceae, Erythroxylaceae, Linaceae, Lepidobotryaceae, Oxalidaceae

CELASTRALES: Celastraceae, Elaeocarpaceae, **Rhizophoraceae**

Ordinal composition around Anisophylleaceae:

CUNONIALES: Cunoniaceae, Baueraceae, Brunelliaceae, Davidsoniaceae, Eucryphiaceae

ROSALES: Crossosomataceae, Rosaceae, Neuradaceae, **Anisophylleaceae**, Malaceae, Amygdalaceae (plus perhaps some smaller families such as Rhabdodendraceae)

SAXIFRAGALES: Saxifragaceae, Penthoraceae, Vahliaceae, Francoaceae, Greyiaceae, Brexiaceae, Grossulariaceae, Iteaceae, Cephalotaceae, Crassulaceae, Podostemaceae.

A HISTORICAL AND TAXONOMIC SYNOPSIS OF RHIZOPHORACEAE AND ANISOPHYLLEACEAE[1]

Adrian M. Juncosa and P. Barry Tomlinson[2]

ABSTRACT

Even from its time of formal recognition by Robert Brown in 1814, the Rhizophoraceae has been known as a family with both terrestrial and mangal representatives so that the tendency to regard it as the "mangrove family" is inappropriate, even though one of its major subdivisions, the tribe Rhizophoreae, is made up exclusively of mangroves. This association of terrestrial and mangrove species adds a piquancy to the study of the systematics of the group because it allows the diagnostic usefulness of "adaptive" characters to be assessed. The progressive enlargement of our knowledge of the family is reviewed, including the status of Anisophyllea *and related genera, now regarded as constituting a separate family Anisophylleaceae. Brief tribal and generic diagnoses are provided, with generalized illustration of geographical distribution. Some portraiture of the more common genera is attempted.*

This symposium had as an objective the segregation of the small family Anisophylleaceae from the Rhizophoraceae (sensu lato), with a discussion of the evidence upon which this distinction was based (cf. Dahlgren, this volume). A further objective has been a discussion of where the two families might be placed in a natural system. Although the mangrove Rhizophoraceae are familiar to botanists and laymen alike, the systematic characteristics and even the existence of the inland genera are not well known. The Rhizophoraceae and Anisophylleaceae together include about 18 genera and some 140 species of tropical shrubs and trees (Table 1). The families exhibit a wide variety of character states and have had a checkered taxonomic history. It seems now generally agreed that the Anisophylleaceae are a distinct, probably unrelated family; for a detailed systematic comparison see our other contribution in this volume. Unless otherwise noted, "Rhizophoraceae" is therefore used sensu stricto, i.e., without the four genera now removed as Anisophylleaceae. In addition to describing this history, we present a synopsis of genera. No such complete synopsis appears elsewhere, so it should prove a useful reference for this symposium volume. A detailed comparison of the systematic and biological characteristics of the two families appears separately (Juncosa & Tomlinson, this volume).

TAXONOMIC HISTORY OF RHIZOPHORACEAE (SENSU LATO)

The family Rhizophoraceae, in a broad sense, originates with the genus *Rhizophora* of Linnaeus (1753), preceded by *Mangium* of Rumphius (1741–1755). Both of these authors used their generic names to designate a group of species growing in tropical tidal swamps, which modern ecologists would call "mangal" (Macnae, 1968). Of the seven species named by Linnaeus in *Rhizophora*, only one, *R. mangle* L., is still valid and forms the type species of the genus and hence of the family. *Mangium* has disappeared entirely, except in *Acacia mangium*, a terrestrial plant. A list of the Rumphian and Linnean names with their

TABLE 1. *Summary of genera of the Rhizophoraceae (s. str.) and Anisophylleaceae (after Ridley, 1922; Alston, 1925; Ding Hou, 1958; Melchior, 1964; Floret, 1974; van Vliet, 1976; Willis, 1973; Steyermark & Liesner, 1983). Tribal classification of Rhizophoraceae follows that accepted in the literature; recent studies indicate that changes are necessary (Tobe & Raven, this volume).*

Family or Tribe	Genus	Number of Species	Distribution
ANISOPHYLLEACEAE			
(= Anisophylleae)	*Anisophyllea*	25	Africa to South America and Malesia
	Combretocarpus	1	Borneo
	Poga	1	Africa
	Polygonanthus	2	Brazil
RHIZOPHORACEAE			
Gynotrocheae[1]	*Carallia*	9	Madagascar to Australia
	Crossostylis	12	South Pacific
	Gynotroches	1[2]	Indochina, Malesia, Pacific Islands
	Pellacalyx	8	Malesia to S China
Macarisieae[1]	*Anopyxis*	2	Africa
	Blepharistemma	1	India
	Cassipourea (including *Lasiosepalum* and *Weihea*)	55	Sri Lanka to Central America
	Comiphyton	1	Equatorial Africa
	Dactylopetalum[3]	15	Africa, Madagascar
	Macarisia	7	Madagascar
	Sterigmapetalum	7	South America
Rhizophoreae	*Bruguiera*	6	Africa to Australia
	Ceriops	2	Africa to Australia
	Kandelia	1	Malaysia to Japan
	Rhizophora	8[4]	pantropical

[1] Tobe & Raven (this volume) segregate *Crossostylis* as its own tribe and create two subtribes each in Macariseae and their modified Gynotrocheae.

[2] Ding Hou (1958) described much variation in *Gynotroches* and only reluctantly accommodated it in a single species. Juncosa & Tobe (this volume) describe some characteristics of two of the several distinct taxa.

[3] Floret (1976) presented evidence for the elevation of *Dactylopetalum* to generic rank.

[4] Includes putative hybrids or varieties (Tomlinson, 1986).

modern equivalents forms Table 2. This demonstrates an intrinsically ecological concept for their initial circumscription.

The family was formally designated (as the "order" Rhizophoreae) by Robert Brown in his account of the botany of Terra Australis (Brown, 1814) and included the genera *Rhizophora* Linnaeus, *Bruguiera* Lamarck, and *Carallia* Roxburgh "all of which are found in the equinoctial part of New Holland." Consequently, even at its erection the family already included plants of terrestrial as well as mangal habitats. Robert Brown drew attention to the "affinity of Rhizophoreae to Cunoniaceae" and rejected Jussieu's attempt to combine some of its elements with loranthaceous genera (cf. Dumortier, 1829). The subsequent development of our knowledge of the family is summarized in Table 3.

Endlicher (1840) subdivided the family into Legnotidae (*Cassipourea* and *Dryptopetalum* = *Gynotroches*) and Rhizophoreae sensu stricto, which still included *Carallia*. Blume (1849) raised these two divisions to family status but transferred *Carallia* to Legnotidae so that the first recognition of the Rhizophoreae (not in Brown's sense) as "mangrove Rhizophoraceae," i.e., a named taxon capable of ecological designation, is from this date, even though Blume's "families" have scarcely been recognized by subsequent authors. Corner (1976) did recognize Legnotidaceae in his description of seeds of dicotyledons. Bentham & Hooker (1865), treating the Rhizophoraceae as a family, maintained Rhizophoreae and Legnotidae as tribes but added Anisophylleae as a third tribe to include the terrestrial genera *Anisophyllea* and *Combretocarpus*.

This system was essentially followed by Baillon (1876), who split the Legnotidae into two separate

tribes, Macariseae and Barraldeieae (= Gynotrocheae) from *Barraldeia* (= *Carallia*). Ridley (1922) raised the three tribes to families (his "orders," viz. Rhizophoraceae, Legnotidae, and Anisophylleae) but considered only the Malayan genera.

Schimper (1898) retained the traditional one-family concept but departed dramatically from the general consensus by splitting the family on morphological characters that he considered to be more fundamental than the structure of the fruit and seedling, since he considered their specializations to be features adapting the plants to their habitat (Anpassungsmerkmal) and therefore comparable to those found in other isolated mangrove taxa like *Aegiceras, Avicennia, Lumnitzera,* and *Sonneratia*. This may be seen as a complete reversal of the Linnean view. Schimper developed an elaborate subdivision, cutting across ecological characteristics as follows:

subfamily I. Rhizophoroideae
  tribe 1. Gynotrocheae
    subtribe 1a. Gynotrochinae [*Crossostylis* (as *Crossostyles*), *Gynotroches, Rhizophora, Ceriops, Kandelia*]
    subtribe 1b. Carallinae [*Pellacalyx, Bruguiera, Carallia*]
  tribe 2. Macarisieae [*Blepharistemma, Dactylopetalum, Macarisia, Weihea, Cassipourea*]
subfamily II. Anisophylloideae [*Anisophyllea, Combretocarpus*]

This arrangement has been summarily rejected by all subsequent authors, in particular it leads to Ding Hou's statement (1958), which might well be placarded in all institutes of systematic botany: "Schimper's clearly wrong classification provides again a good example of what danger is involved if a taxonomist introduces pre-occupied theoretical ideas into classification." In fairness to Schimper, it should be pointed out that he had a better idea of fruit and seed construction than most of his predecessors, since he recognized that the family Rhizophoraceae, which Brown had characterized as exalbuminous, did indeed possess well-developed endosperm (Juncosa, 1982), and that *Bruguiera* was appreciably different from the other mangrove taxa in some basic features. However, the sum of all vegetative features and especially of wood anatomy (Marco, 1935; van Vliet, 1976) shows that the habitat distinctiveness of the Rhizophoreae, even though it can be said to be primarily based upon "adaptive" or "ecological" characteristics, is well founded at the systematic level. The family therefore provides an interesting example for phyletic study since the Rhizophoreae are clearly derivative and must have had an ancestry in taxa that are now represented by the terrestrial genera. The most recent accepted intrafamilial classification (Table 1) was initially presented by Melchior

(1964). It recognizes three tribes: Macarisieae, with a center of distribution in Africa; Gynotrocheae, centered in Malesia; and Rhizophoreae, also centered in Malesia.

Monographs and partial revisions of varying utility exist for some genera of Rhizophoraceae. Alston (1925) discussed the largest genus, *Cassipourea*, including within it *Dactylopetalum*, *Weihea*, and *Lasiosepalum*. The related genus *Comiphyton* was described by Floret (1974), who subsequently discussed relationships of African Macarisieae further (Floret, 1976). *Sterigmapetalum* was recently revised by Steyermark & Liesner (1983). Several systematic treatments of *Rhizophora* or portions thereof exist (Salvoza, 1936; Ding Hou, 1960; Breteler, 1969, 1977). Yet only in the western Pacific, where the plants have been studied largely in the field rather than as dried material, is our understanding of the taxa adequate (Tomlinson, 1978; Duke & Bunt, 1979), although many basic questions about distribution, hybrids, and specific limits still remain unanswered. Excellent revisions of other Malesian genera, both mangrove and inland, are found in Ding Hou (1958). Our present understanding of the mangrove Rhizophoraceae is summarized in Tomlinson (1986).

In looking at the history of this family, one is impressed by the relative recentness of our present taxonomic and nomenclatural understanding. For example, the clarification of the full range of morphology in *Bruguiera* only comes with Ding Hou (1958); *Ceriops decandra* was correctly designated for the first time in this monograph. The difference between the two species of *Ceriops* is quite striking when floral function is considered. Some African taxa have been discussed by J. J. Floret (1976), while the New World taxa have been treated incompletely by a few authors (e.g., Prance et al., 1975).

One might conclude that any discussion of the phylogeny of this family is premature in the absence of detailed information about many species, but the situation reflects our ignorance of tropical plant families generally. If we can devote at least as much time to observation as we are doing to speculation about phylogenies, then our understanding is likely to improve.

AFFINITIES WITH OTHER FAMILIES

Rhizophoraceae (sensu lato) have traditionally been placed in the Myrtales (Bentham & Hooker, 1865; Melchior, 1964; Takhtajan, 1980), although more recently they have sometimes been aligned with Cornales (Cronquist, 1968; Thorne, 1976). These assignments and the long-obsolete suggestions of affinities with Loranthaceae or Santalaceae were based on the incorrect assumption that Rhizophoraceae (s. str.) characteristically have an inferior ovary; on the contrary, this is a rare and derived condition in the family. Furthermore, there are many fundamental vegetative differences between Rhizophoraceae (s. str.) and all of the aforementioned groups. Suggestions of relationship with Rubiaceae, Cunoniaceae, or Dialypetalanthaceae are based solely on the common possession of interpetiolar stipules and are as indefensible as are most systematic judgments based upon a single character. Cronquist's (1981) separation of Anisophylleaceae and Rhizophoraceae and assignment of the latter to its own order, Rhizophorales, is a wiser phylogenetic policy but still begs the question of affinities. We strongly favor Dahlgren's approach that leads to the surprising but very well-supported suggestion, proposed and discussed in detail elsewhere in this volume, of affinities between Rhizophoraceae, Celastraceae, Elaeocarpaceae, and possibly several other families.

FIELD RECOGNITION OF RHIZOPHORACEAE

Because of the great infrafamilial variation in most morphological characters, the family diagnosis, given below for completeness, is unwieldy and nearly useless to both field and herbarium botanists. Much of the year the mangrove genera are easily recognized by the hypocotyls protruding from the fruits. Vegetatively, the family is recognized by having opposite (or verticillate) leaves with interpetiolar stipules; the leaves are generally bitter-tanniniferous and usually minimally toothed in inland genera. In mangal, only one nonrhizophoraceous genus has interpetiolar stipules (to only 3 mm long—the weak-stemmed Old World shrub *Scyphiphora* (Rubiaceae)). Inflorescences are axillary and basically cymose, condensed in many common genera. The sole diagnostic floral feature, present in all species of which we are aware and otherwise known only in Rhamnaceae, is that each petal (fringed in all but two genera) individually encloses either a single antipetalous stamen or a group of 2–6 stamens, depending mainly upon whether the androecium is diplostemonous or polyandrous. Rhamnaceae are easily distinguished by their isomerous stamens and entire petals and of course many other characters.

FAMILY RHIZOPHORACEAE R. BROWN

Shrubs or trees (to 50 m) of dry to wet forests or mangrove swamps; leaves opposite or verticillate, toothed, crenate, or entire. Stipules interpetiolar, valvate and pubescent or imbricate and gla-

[4] Non-Malaysian taxa not considered.

brous, always bearing colleters. Inflorescences axillary, cymose, dichotomous, or fasciculate. Flowers actinomorphic, bisexual or rarely unisexual, clearly articulated at juncture with pedicel. Calyx valvate, 4–many-lobed; petals equaling the number of sepals, usually with both a terminal arista and filiform appendages on the two lobes (rarely entire), each petal individually enclosing 1–5 stamens. Androecium diplostemonous to polyandrous, the filaments sometimes connate at base; nectariferous ring ("disc") intrastaminal, entire or lobed. Ovary superior to inferior, 2–many-carpellate (locules often incompletely or not at all separated by septae at anthesis); stigma capitate or with pronounced lobes, generally papillate. Ovules 2 or many per carpel, anatropous, usually apically inserted. Fruit capsular or baccate; seeds 1–many, naked, arillate, or winged, albuminous. Embryo green, usually straight, with laminar cotyledons and epigeal germination, or with thick cotyledons (or cylindrical cotyledonary body) and viviparous germination.

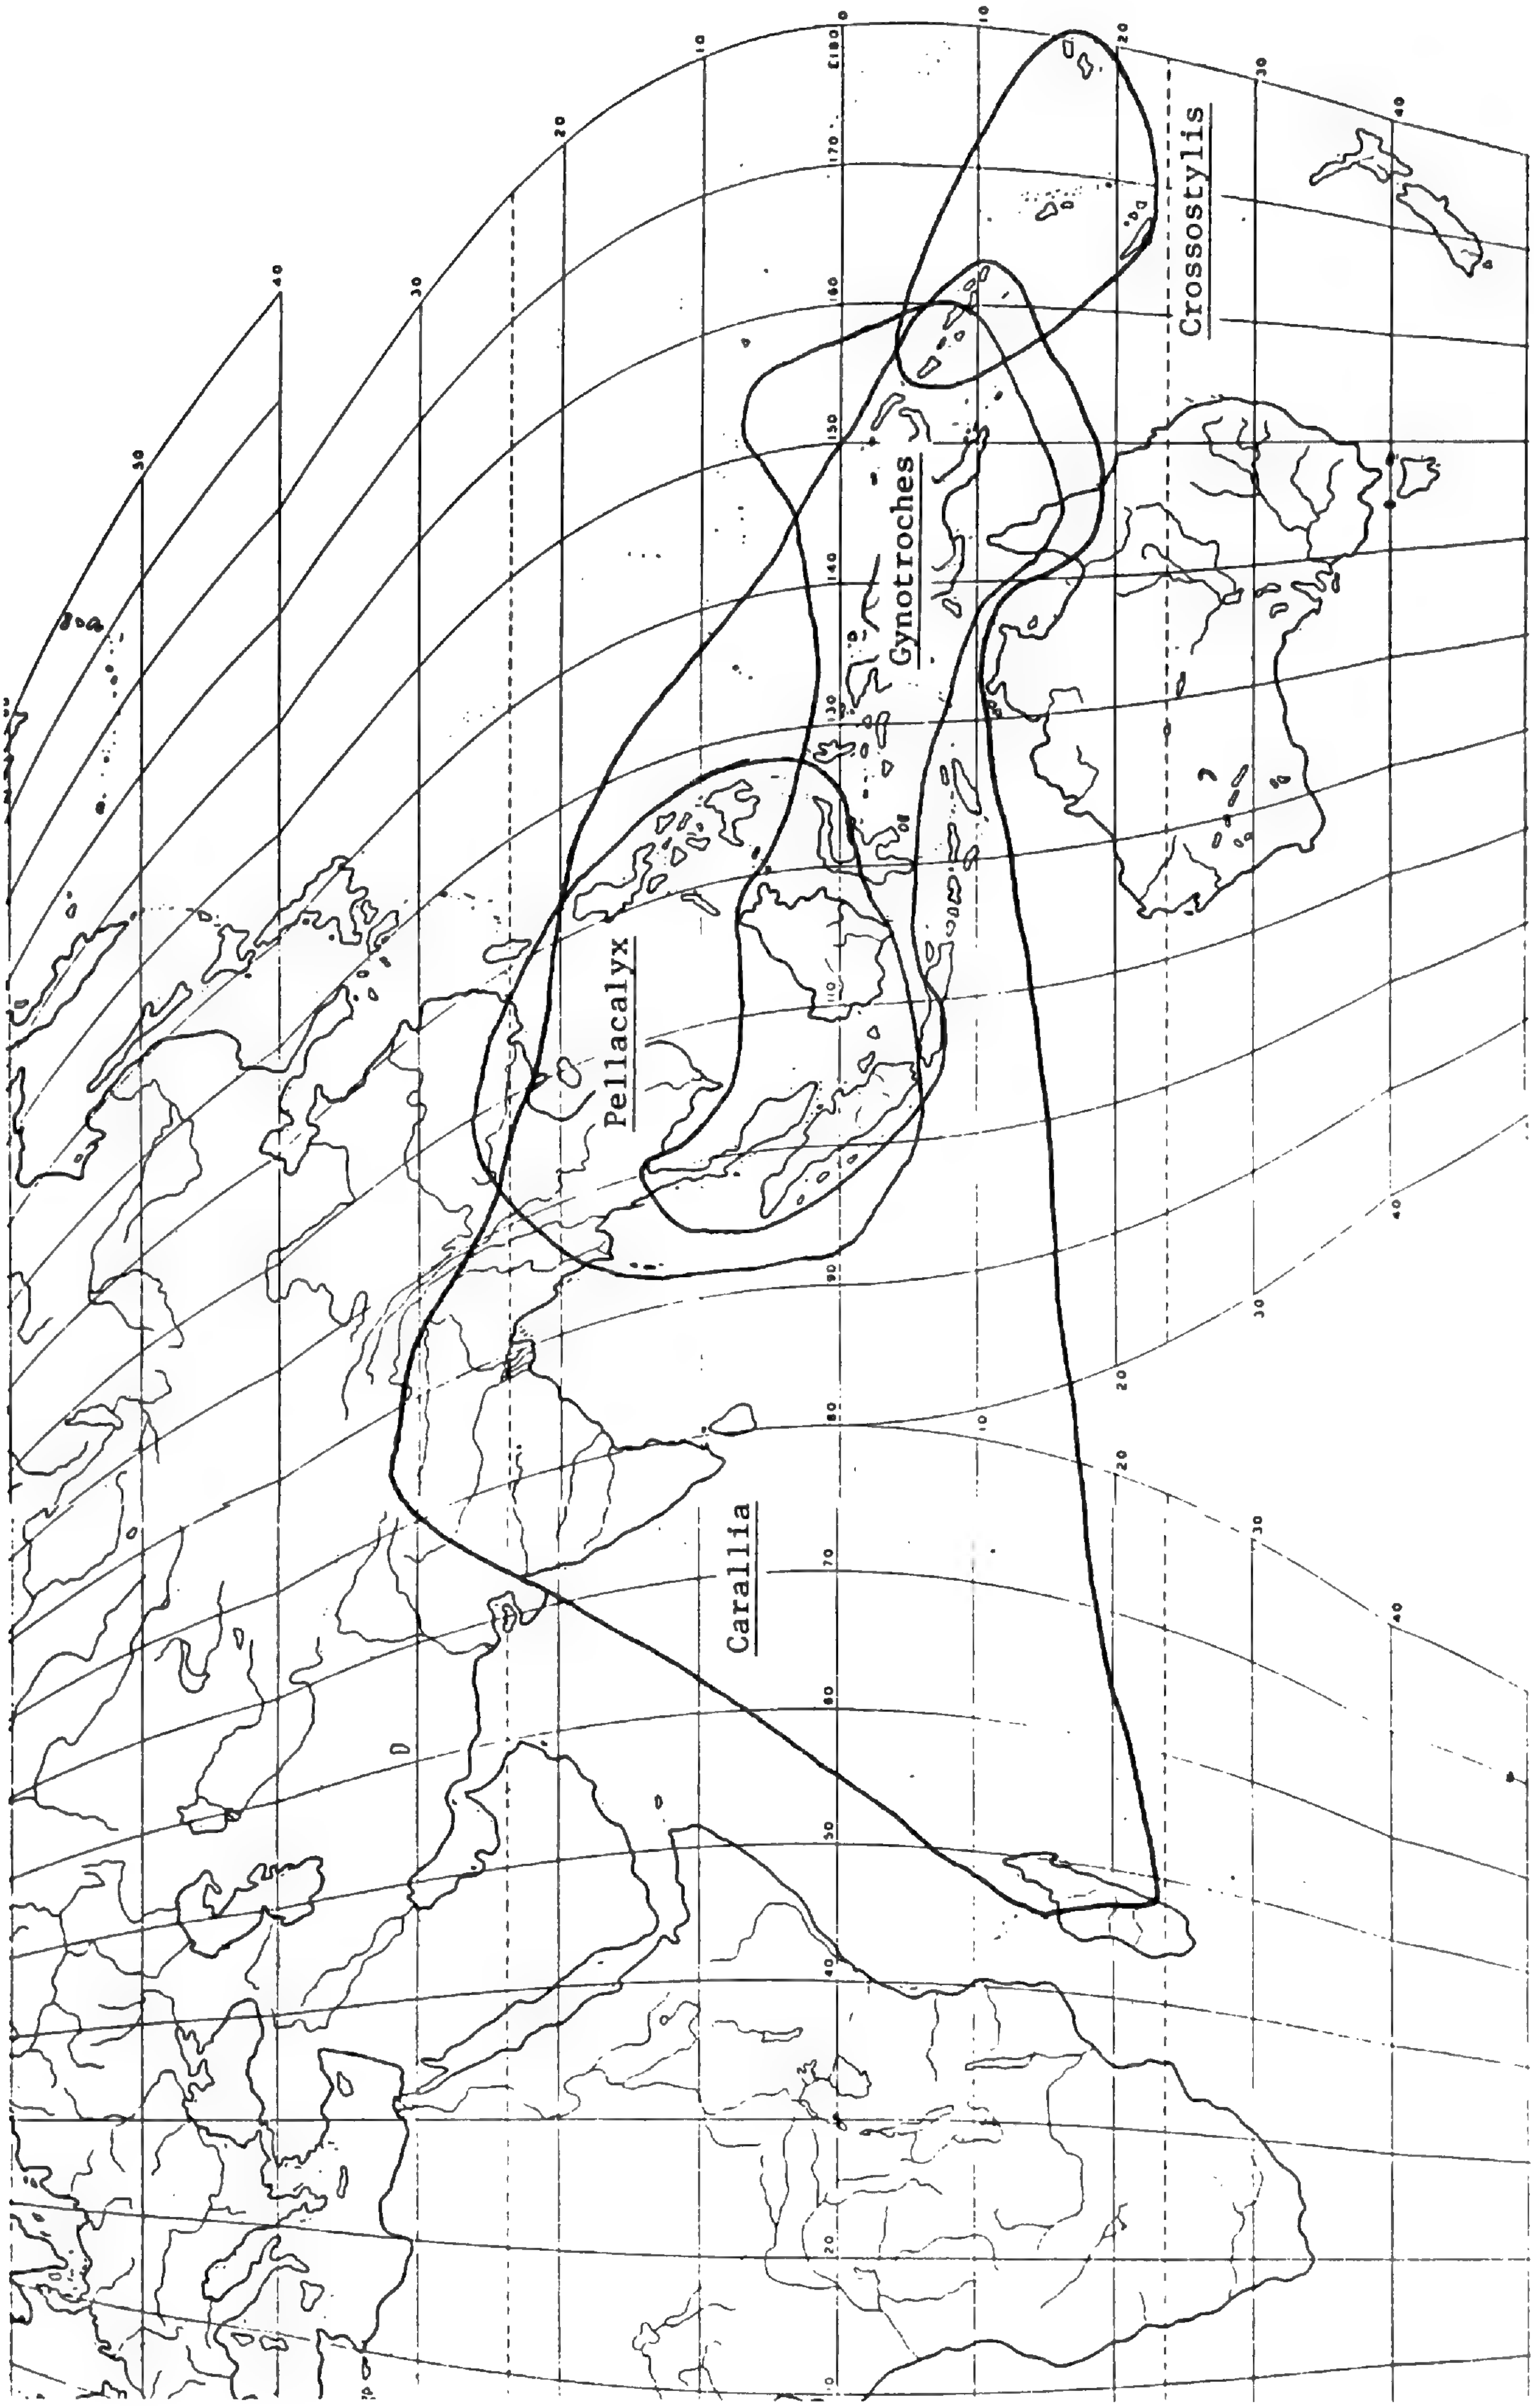
Genera. 15 (names listed by tribes); about 145 species.

Distribution. Pantropical.

In the synopsis that follows, genera are organized into the traditionally recognized tribes (e.g., Melchior, 1964), despite evidence already in hand that suggests some rearrangements (Tobe & Raven, this volume). Complete diagnoses are not given; instead, only some of the more distinctive characteristics of each tribe or genus are mentioned. References are likewise selectively cited. Listing of tribes and genera is alphabetical.

TRIBE GYNOTROCHEAE

Shrubs to large trees, some species weedy and characteristic of highly disturbed vegetation. Prominent aerial roots known in all genera but *Pellacalyx*. Leaves bijugate (not decussate), generally crenate. Stipules glabrous and imbricate (except in *Pellacalyx*). Flowers bisexual (except in *Gynotroches*); stamens twice the number of petals; ovary



Crossostylis
Gynotroches
Pellacalyx
Carallia

inferior (except superior in *Gynotroches*), 5- or many-carpellate; ovules 2 or many per carpel (locules incompletely separated). Fruit ± baccate, 1–many-seeded; seeds naked (except arillate in *Crossostylis*). This highly variable tribe has been the source of much confusion and is undoubtedly paraphyletic. Its proposed subdivision by Tobe & Raven (this volume) aids in clarification.

Genera. *Carallia, Crossostylis, Gynotroches, Pellacalyx.*

Distribution. Centered in Malesia, except *Crossostylis* (South Pacific) (Fig. 1).

Carallia Roxb., 9 species (Brandis, 1911; Ridley, 1922; Ding Hou, 1958). Figure 2.

Distribution. Indochina, Malesia, Philippines to New Guinea; *C. brachiata* also ranges to Madagascar, India, Nepal(!), S China, Solomon Islands, and N Australia.

Stilt roots reported only in *C. brachiata*. Large stalked glands (up to 5 mm) present outside stipules in several (all?) species. Inflorescences usually lax-cymose. Flowers 5–8-merous, diplostemonous, the ovary fully inferior. Seeds 1–several. Embryologically similar to Rhizophoreae.

Crossostylis J. R. & G. Forst., about 12 species (Smith, 1981). Figures 3, 4.

Distribution. S Pacific Islands.

Inflorescences dichotomous. Largest flowers in the family (to 6 cm wide) in *C. grandiflora* (Fig. 4). Petals with very reduced appendages, even appearing entire at maturity. Stamens variable in number, sometimes basally connate and bearing odd appendages that retain the copious nectar in pendulous flowers. Ovary multicarpellate (up to about 20), nearly superior to inferior; stigma with long lobes. Fruit dehiscent or a partially dehiscent "salt-shaker" capsule.

This genus shares some characteristics (e.g., appendaged seeds) with Macarisieae, but many others with Gynotrocheae. It is placed in its own tribe, Crossostylieae, by Tobe & Raven (this volume).

Gynotroches Blume, 2–4 species (Ding Hou, 1958; Backer & Bakhuizen, 1963). Figures 5, 6.

Distribution. Burma through Malesia to Micronesia and Melanesia.

Weedy tree; branches often drooping. Plants dioecious. Inflorescences fasciculate. Flowers 4–5-merous, diplostemonous (Fig. 6). Ovary superior, 4–5-carpellate, with 3–8 ovules per locule; stigmatic lobes sometimes elongate. Fruit a berry; seeds several to many.

The most recent revision (Ding Hou, 1958) recognizes only one species (*G. axillaris* Blume) but points out that the variation in floral characters is such that with further study several distinct species will be recognized. Juncosa & Tobe (this volume) provide some details separating two of these taxa.

Pellacalyx Korth., 8 species (Ding Hou, 1958). Figure 7.

Distribution. Burma and South China to Malesia.

Some species weedy; branches often drooping. Stipules valvate, the edges folded sharply inward. Indumentum of stellate hairs, unique among Rhizophoraceae. Pairs of bracteoles fused into a toothed cup. Number of stamens and of carpels twice the number of petals, this usually 4 or 5. Each carpel or locule with 8–25 ovules.

Despite its distinctive indumentum and superficially very different flowers, this genus shares many vegetative and embryological synapomorphies with *Gynotroches*; the two are clearly sister genera.

TRIBE MACARISIEAE

Shrubs to large (50 m) trees, generally of moist primary forest; but some species found in dry or deciduous forest. Stilt roots absent or weakly developed. Leaves toothed, at least in juvenile growth phases, verticillate or opposite, decussate in bud but often reoriented on branches. Stipules valvate, pubescent, also bearing colleters. Inflorescences fasciculate or lax-cymose. Flowers bisexual, except in *Sterigmapetalum* and *Blepharistemma* (?). Androecium diplostemonous (polyandrous only in *Cassipourea*). Ovary superior in four or five of the six genera, not in only two as sometimes stated; locules 2–6. Fruit a capsule, sometimes indehiscent; seeds arillate or winged.

Detailed information is lacking for most genera, and characterizations reported here are based largely upon the literature, much of which is very

---

7

incomplete and not illustrated. This basal tribe is the most poorly known group of Rhizophoraceae, largely due to the unavailability of fixed material and the rarity of certain key taxa. The three subgenera of *Cassipourea* are distinguished by several characters of calyx, androecium, and petal appendages, although three species exhibit combinations of character states of more than one subgenus (Floret, pers. comm.). *Dactylopetalum*, here re-elevated from a subgenus of *Cassipourea* to generic rank, and *Blepharistemma* are dubiously distinct at the generic level. Anatomical and monographic work in progress promises to clarify the relationships of all these arillate-seeded Macarisieae. Distinctions between the winged-seeded genera (*Anopyxis, Macarisia,* and *Sterigmapetalum*) are clear.

Genera. Anopyxis, Blepharistemma, Cassipourea, Comiphyton, Dactylopetalum, Macarisia, Sterigmapetalum.

Distribution. Centered in Africa, extending to Madagascar and India (Sri Lanka) and to South and Central America (Fig. 8).

Anopyxis (Pierre) Engl., 1–3 species (Sprague & Boodle, 1909; Hutchinson & Dalziel, 1954; Irvine, 1961).

Distribution. Tropical Africa.

Tallest inland genus (to 50 m), often dominant. Leaves opposite or in whorls of 3. Calyx, petals, and ovary 5-merous. Stamens 10, filaments connate over their entire length. Petals sometimes entire. Fruit woody, indehiscent (?); seeds winged.

Blepharistemma Wall. ex Benth., 1 species (Schimper, 1898; Gamble, 1919).

Distribution. SW India.

Bracteoles absent (?); flowers polygamodioecious, 4-merous. Ovary 3-locular; fruit fleshy, indehiscent (?); seeds arillate.

Cassipourea Aublet (including subgenera *Weihea* and *Lasiosepalum*), about 55 species (Alston, 1925). Figures 9, 10.

Distribution:

subgenus *Cassipourea*: tropical Americas, West Indies, West Africa.
subgenus *Lasiosepalum*: West Africa.
subgenus *Weihea*: Africa, Madagascar, India, Sri Lanka.

Many species occurring in dry habitats; commonly shrubby, also some tall (30 m) trees (Fig. 9). Inflorescences usually condensed. Flowers (4–)5(–6)-merous. Stamens indefinite in number (15–40), in one (or more?) whorls. Ovary superior, 3(–4)-locular. Seeds 1–4; aril white, yellow, or orange.

Comiphyton Floret, 1 species (Floret, 1974, 1976).

Distribution. Gabon to E border of Zaire; not yet known from the belt defined by 2°N or S, thus one of the most narrowly equatorial ranges of any plant.

Distinguished from *Cassipourea* by its inflorescence, diplostemonous androecium, anthers, and placentation (Floret, 1974, 1976); not sharply differentiated from *Dactylopetalum*.

Dactylopetalum Benth., about 15 species (Alston, 1925; Floret, 1976).

Distribution. Equatorial Africa, Madagascar.

After consideration of remarks by Floret (1976) and other literature (Bentham & Hooker, 1865; Oliver, 1871; Dale & Greenway, 1961), we prefer to recognize this genus as distinct from *Cassipourea*; distinguishing characteristics include the diplostemonous androecium, 2-carpellate ovary, and indehiscent (?) fruit.

Macarisia Thouars, 7 species (Schimper, 1898; Arènes, 1954).

Distribution. Madagascar.

Diplostemonous, 4–5-carpellate, seeds winged.

Sterigmapetalum Kuhlmann, 7 species (Steyermark & Liesner, 1983).

←

FIGURES 2–7. *Habit and flowers of Gynotrocheae.—2. Fully open flowers of* Carallia borneensis *growing in Brunei. Those at left opened the previous day and are now in their pistillate phase (stigmas receptive); those at right are at (staminate) anthesis.—3.* Crossostylis grandiflora *growing in New Caledonia in lowland rain forest, typical habitat for inland Rhizophoraceae.—4. Flowers of* Crossostylis grandiflora, *some at anthesis, others past. Buds are white to red, petals white.—5.* Gynotroches *sp. growing by a stream in Sarawak, E Malaysia, showing opposite bijugate leaves reoriented into one plane on horizontal or drooping branches.—6. Flowers of* Gynotroches *sp.; they were being visited (pollinated?) by numerous small ants.—7. Flowers and young fruits of* Pellacalyx cristatus *growing in Sarawak; overall habit in this genus is similar to that of* Gynotroches.

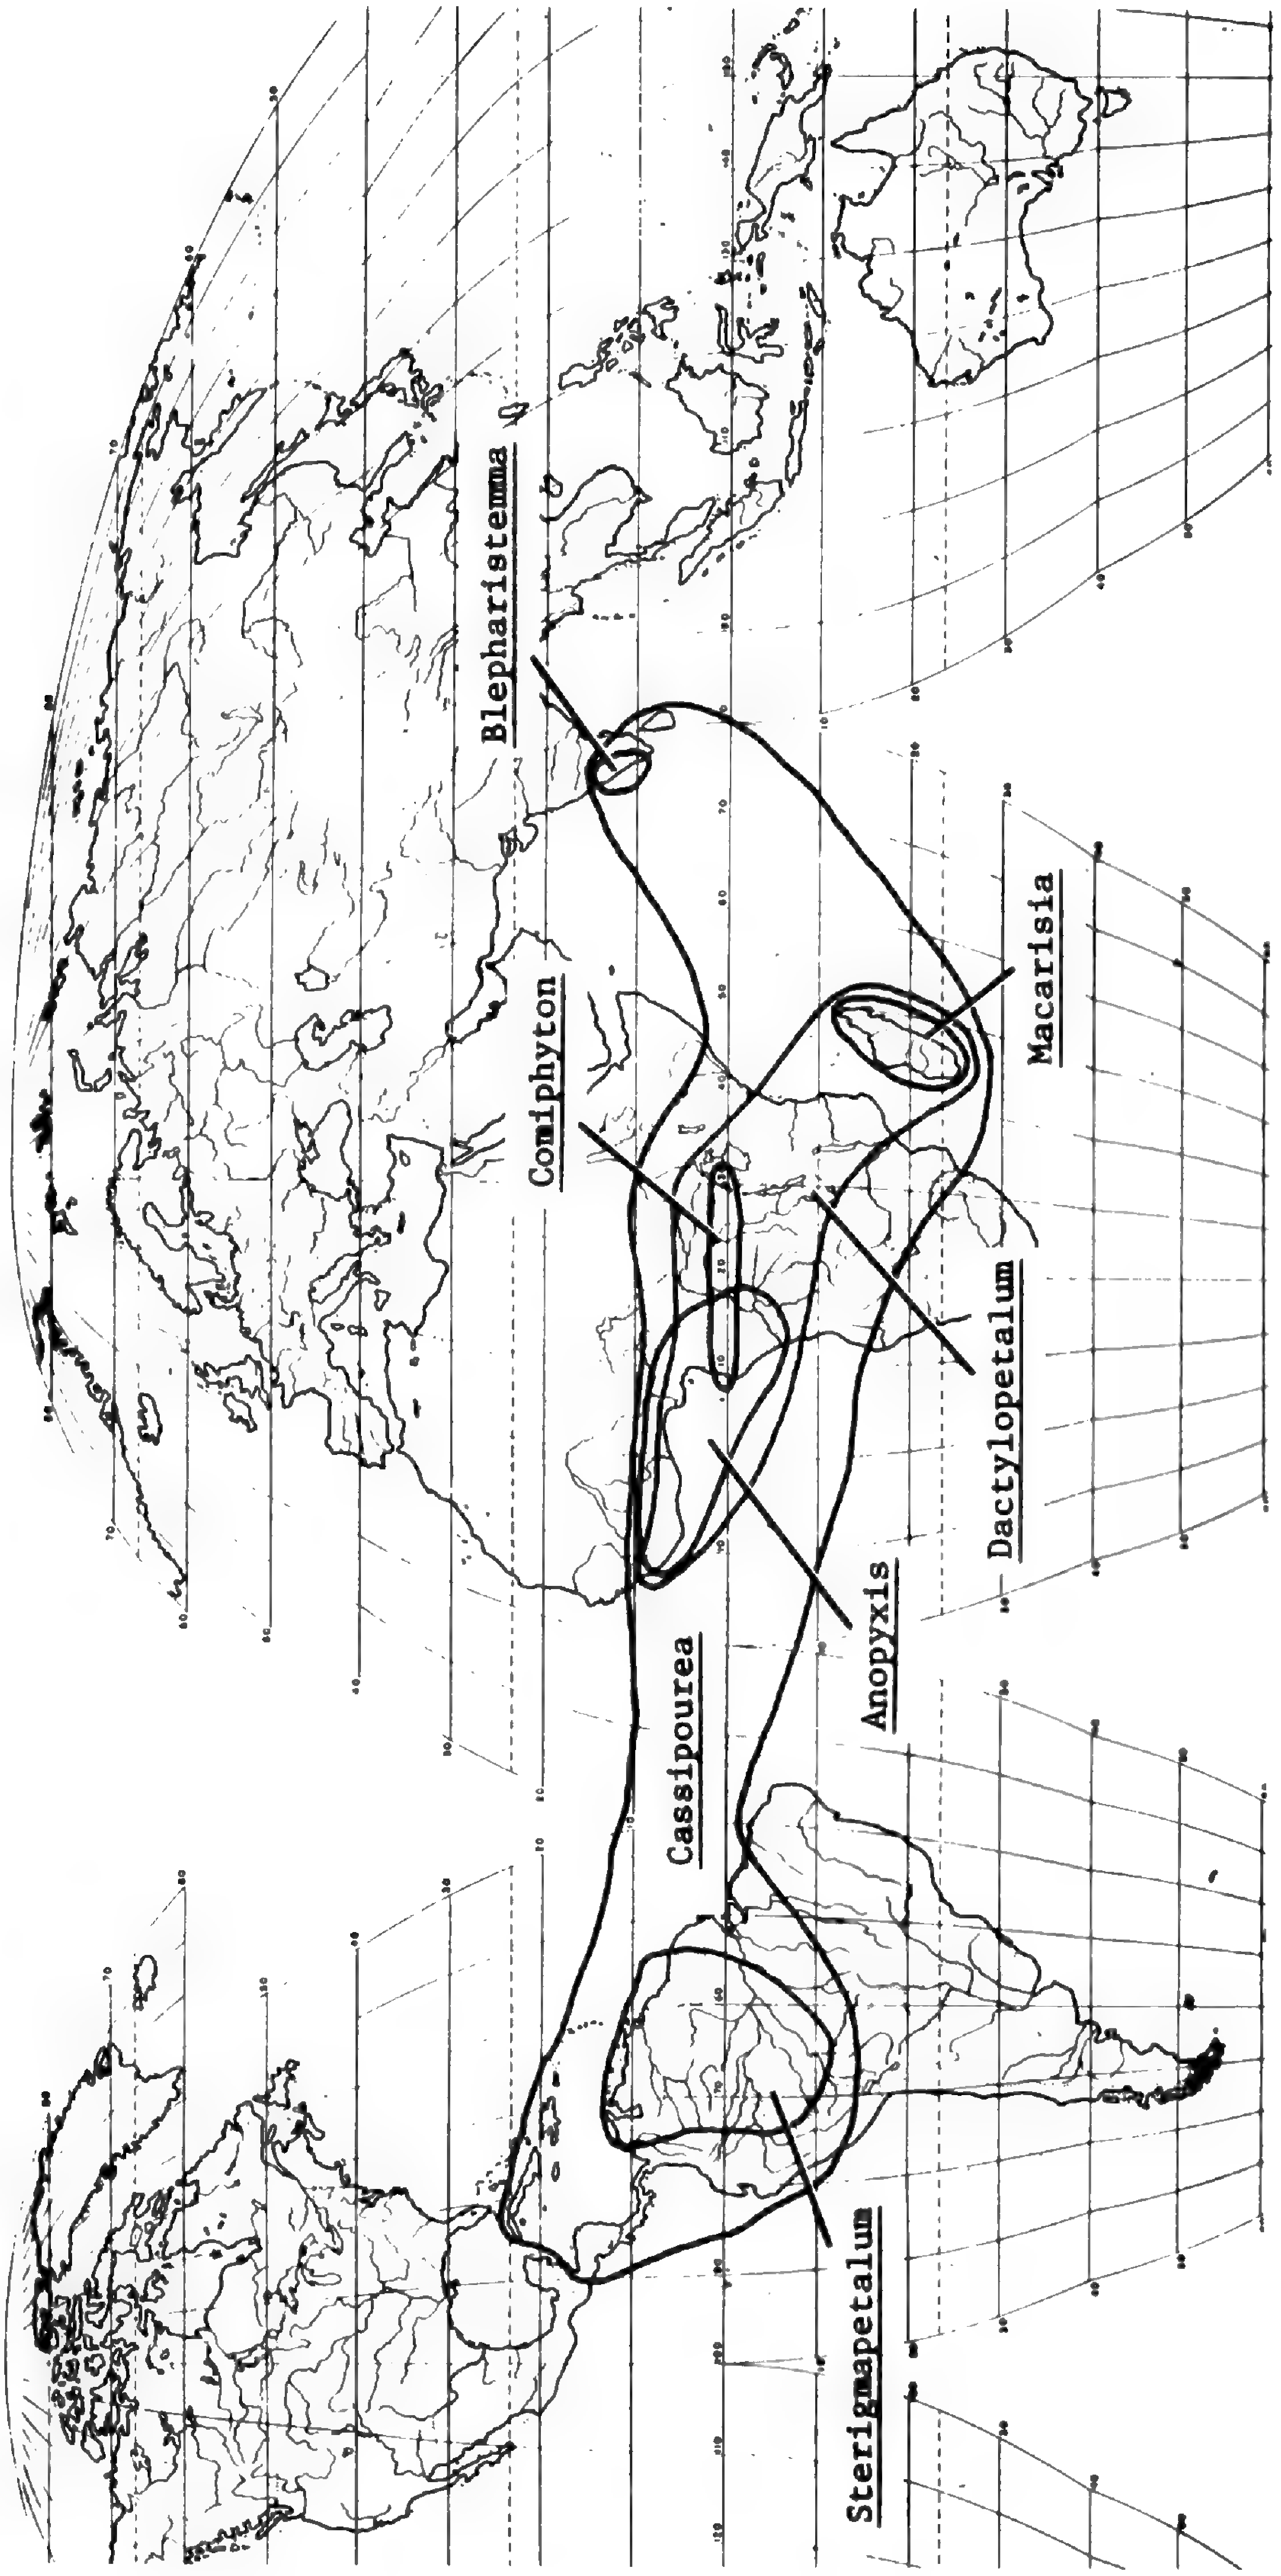

FIGURE 8. *Geographical distribution of genera of Macarisieae.*

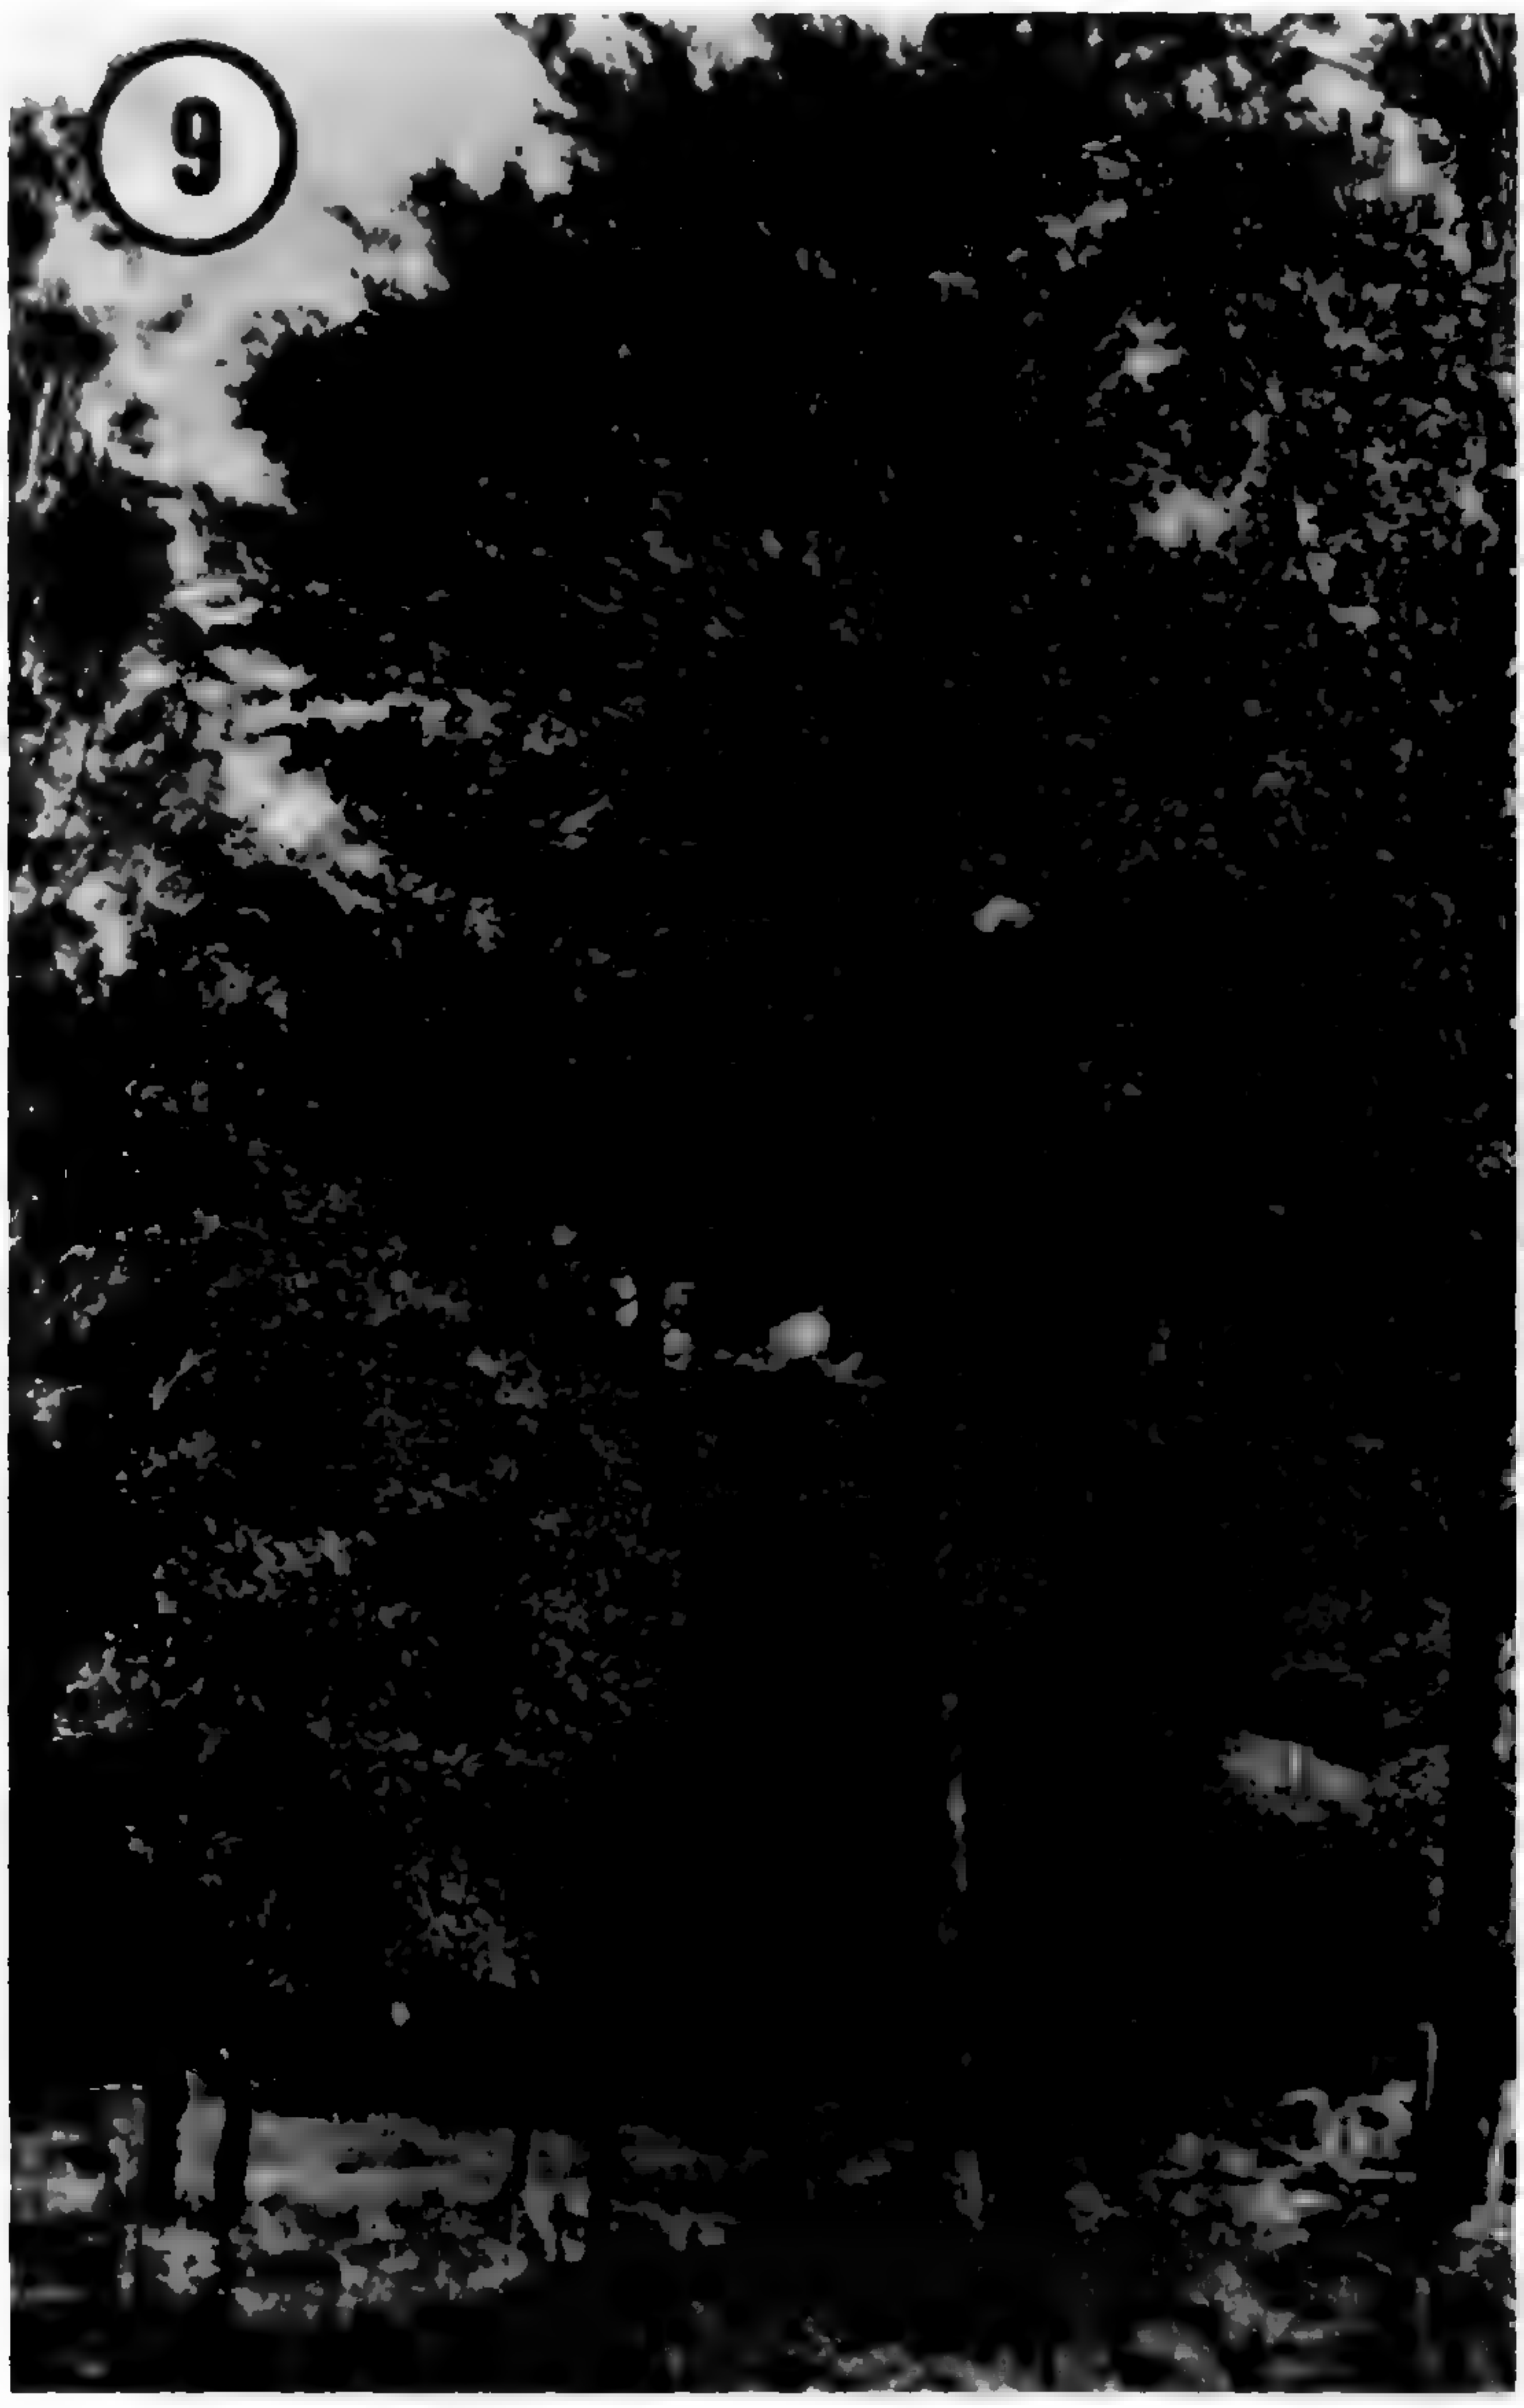

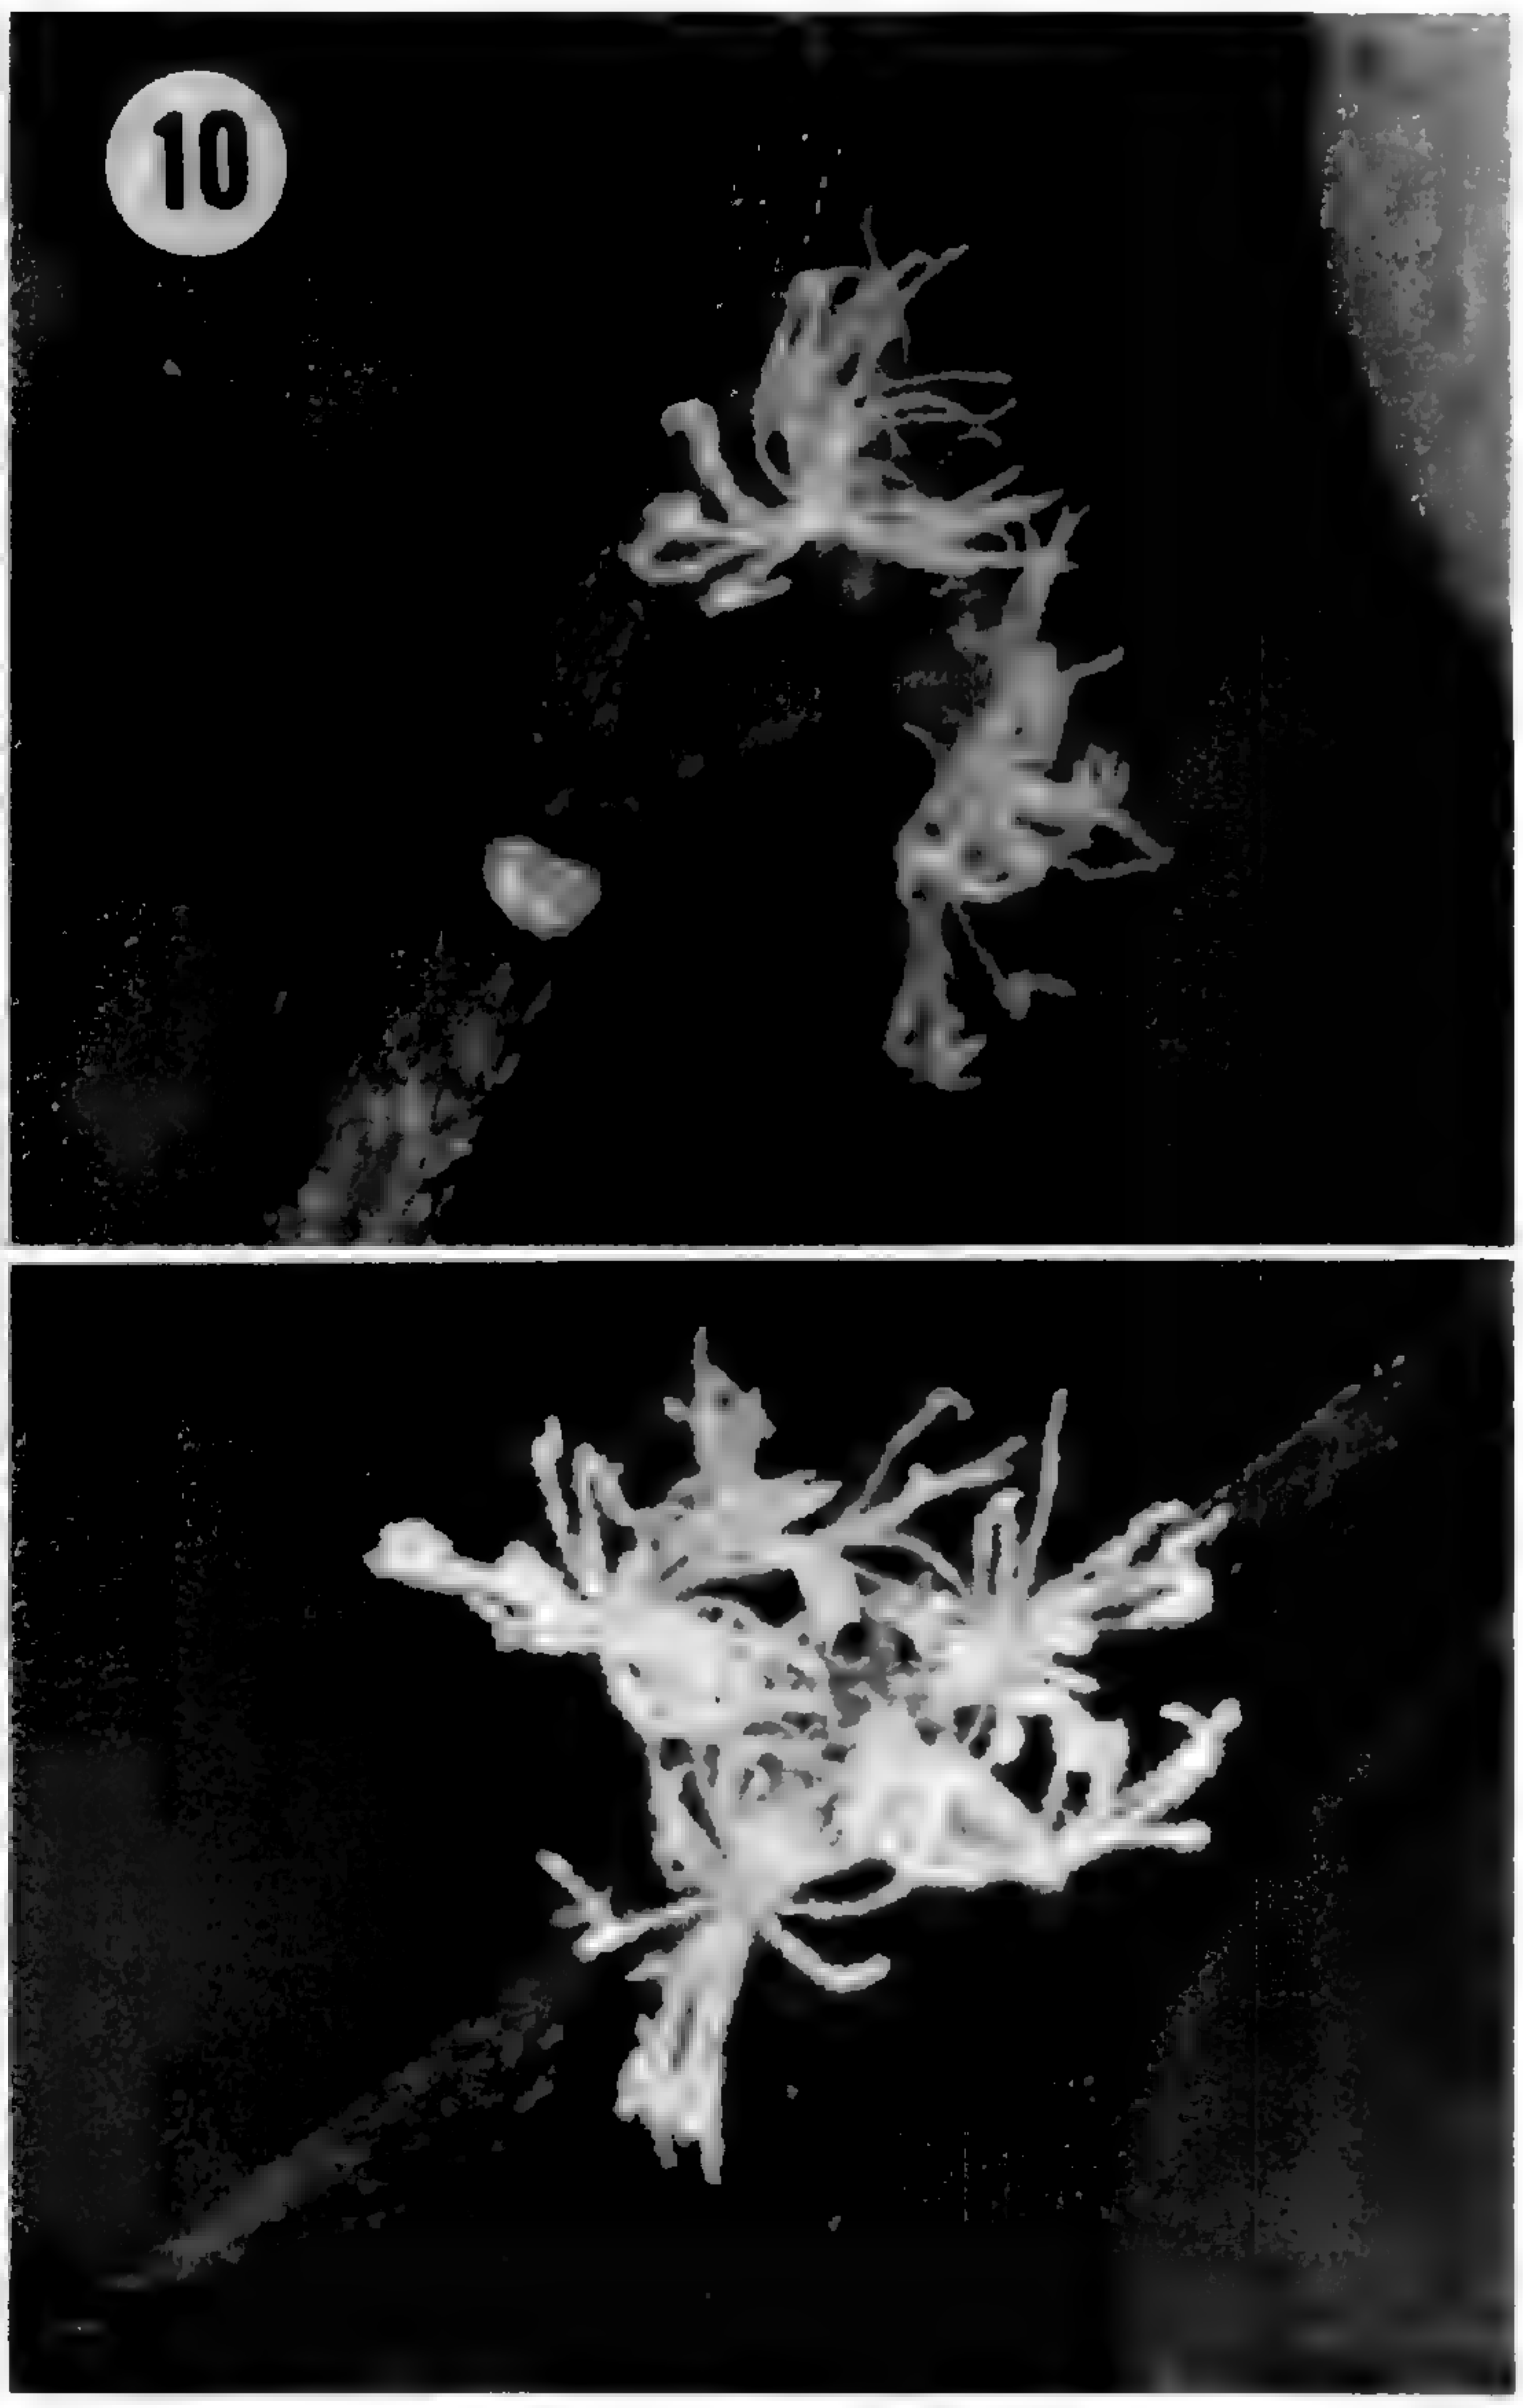

FIGURES 9, 10. *Habit and flower of* Cassipourea *(Macarisieae)*.—*9.* Cassipourea *sp. growing by pasture on Monteverde, Costa Rica. Smooth unbuttressed bole and dense crown are typical of the genus.*—*10. Flower of* Cassipourea *sp. cf.* killipii *(Chocó, Colombia) at anthesis, showing both side and top views; plumose petal appendages greatly increase apparent size of flower.*

Distribution. NW South America.

Plants dioecious. Leaves usually verticillate. Flowers 4–6-merous, diplostemonous. Seeds winged.

TRIBE RHIZOPHOREAE

Shrubs or trees of mangrove swamps; flowering plants 1.5–50 m tall. Aerial stilt roots always produced, prominent only in *Rhizophora*. Leaves entire, bijugate. Inflorescences variable, generically diagnostic. Flowers 4–multimerous, mostly diplostemonous, the petals variously specialized for diverse pollination mechanisms. Ovary half to fully inferior, 2–3-carpellate; ovules 2 per carpel. Fruit baccate, fibrous, 1-seeded. Germination viviparous, the huge seedling axis (to 1 m) emerging from both seed coat and fruit up to 9 months before abscission.

This familiar tribe is unfortunately morphologically atypical of the family; this has led to considerable confusion in phylogenetic decisions.

Genera. *Bruguiera, Ceriops, Kandelia, Rhizophora.*
Distribution. Pantropical (Fig. 11).

Bruguiera Lam., 6 species (Ding Hou, 1957, 1958). Figure 12.

Distribution. SE Africa through Malesia to Pacific Islands and Northern Australia.

Inflorescences cymose or reduced to 1–3 flowers, sometimes ebracteolate. Flowers polymerous, diplostemonous; ovary deeply inferior, 3-carpellate. Each petal encloses two stamens, releasing them explosively when stimulated. Petal appendages often reduced, the petals variably pubescent abaxially.

Ceriops Arn., 2 species, 1 variety (Ding Hou, 1958). Figures 13, 14.

Distribution. SE Africa through Malesia to Australia.

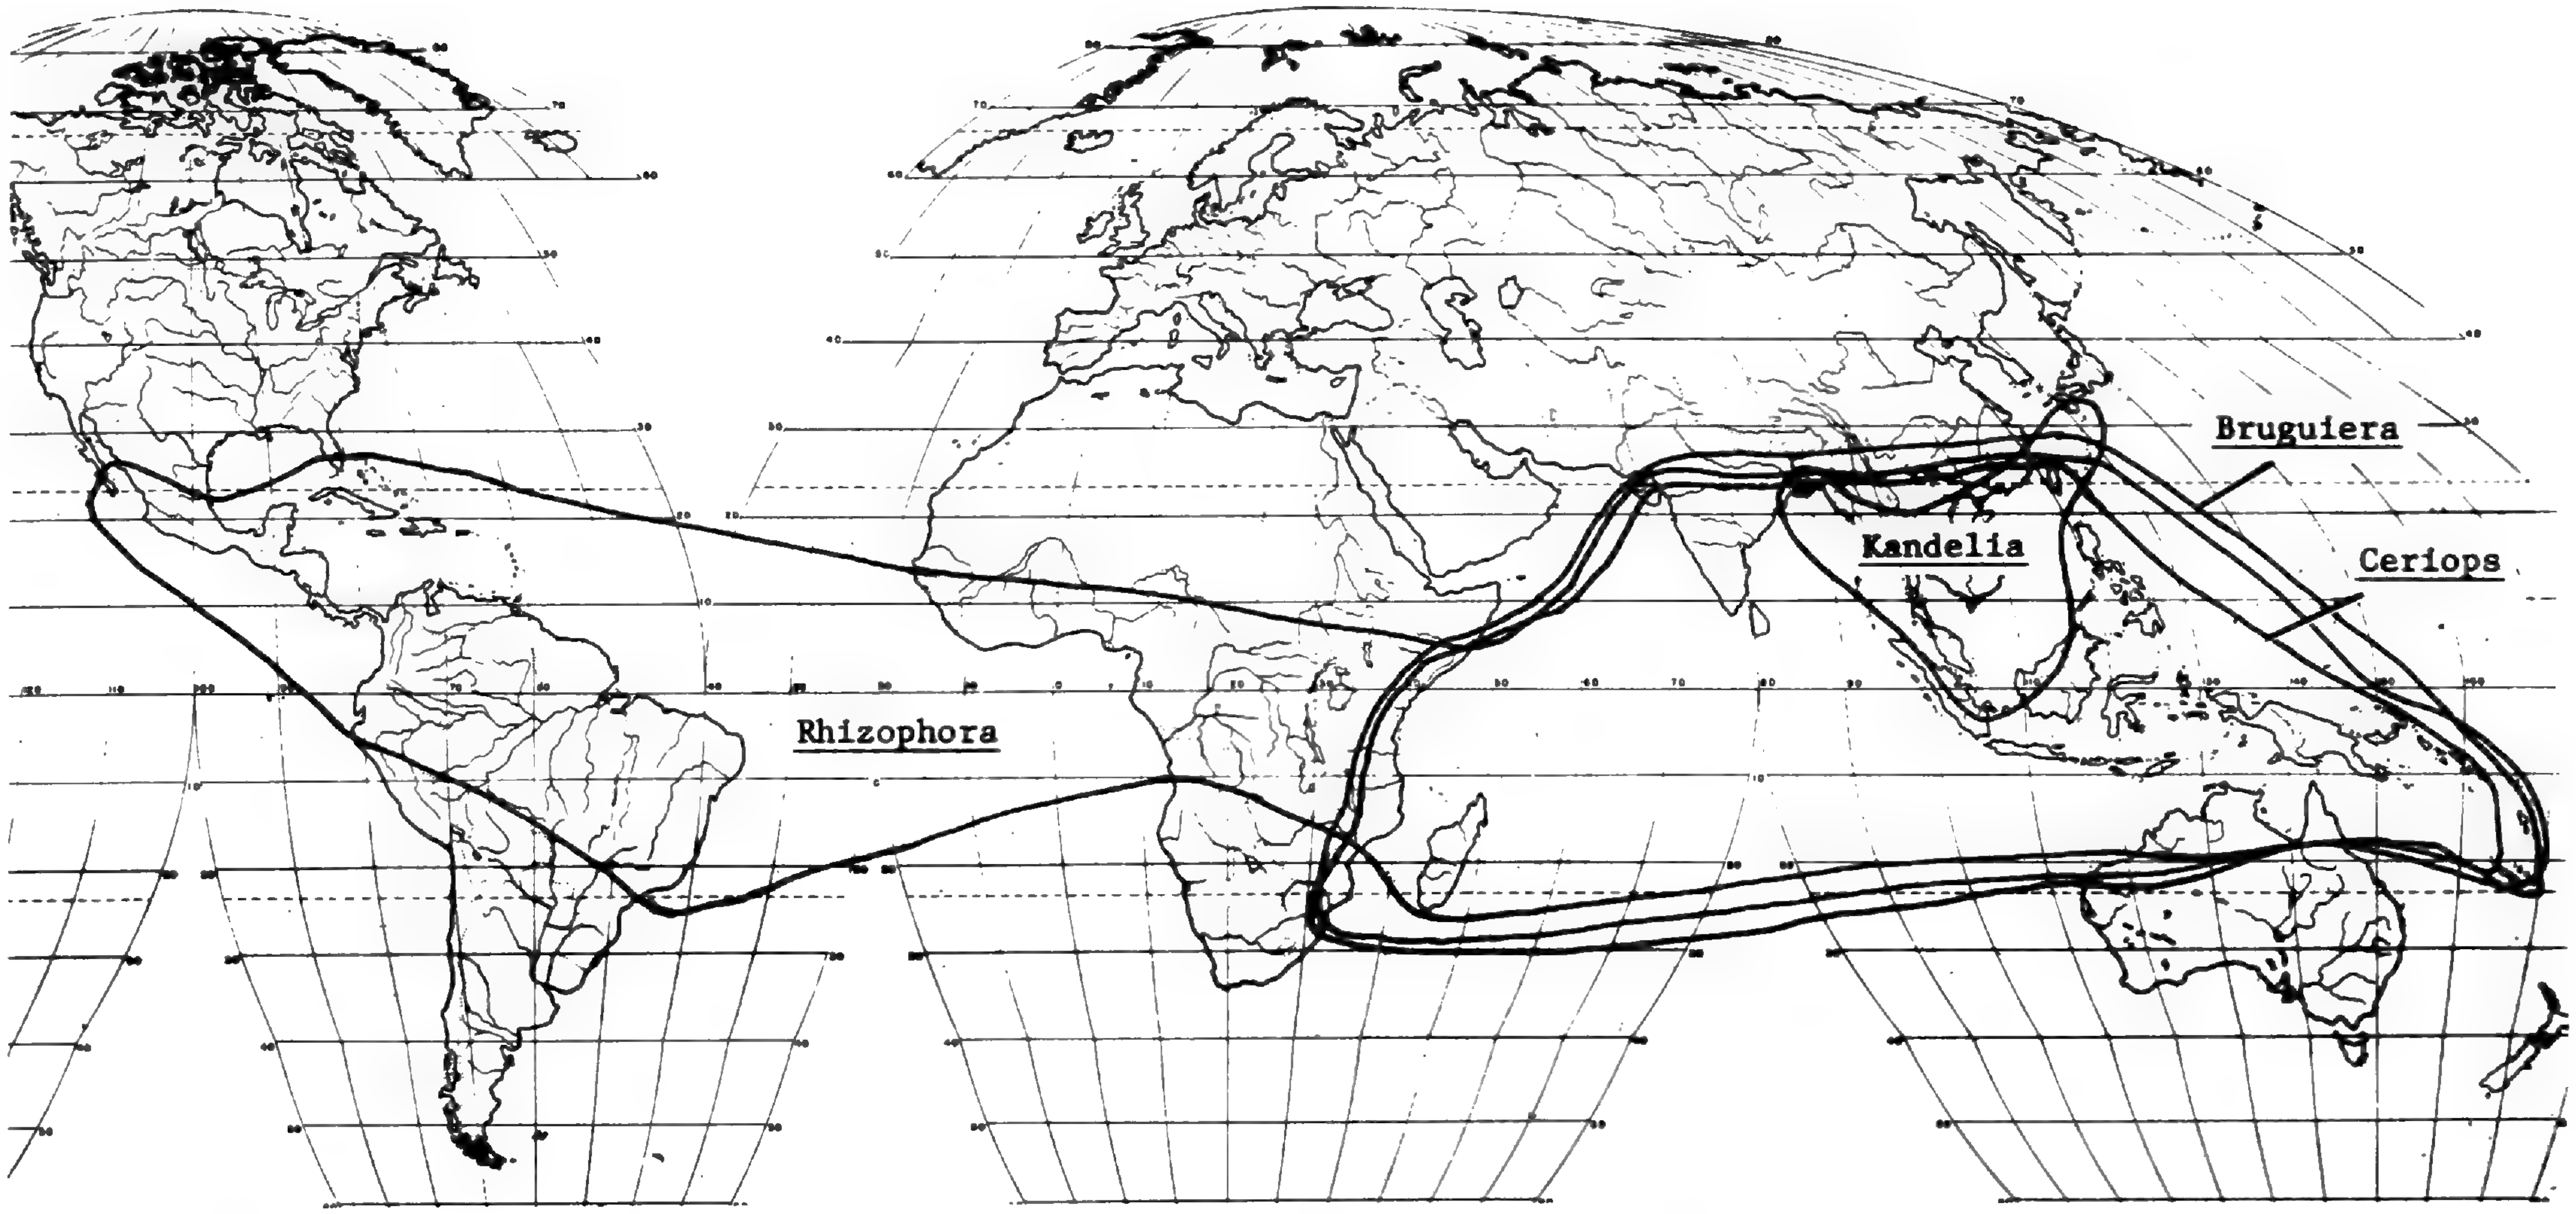

FIGURE 11. *Geographical distribution of genera of tribe Rhizophoreae.* Rhizophora *and* Bruguiera *have been introduced and are becoming naturalized in Hawaii (not shown).*

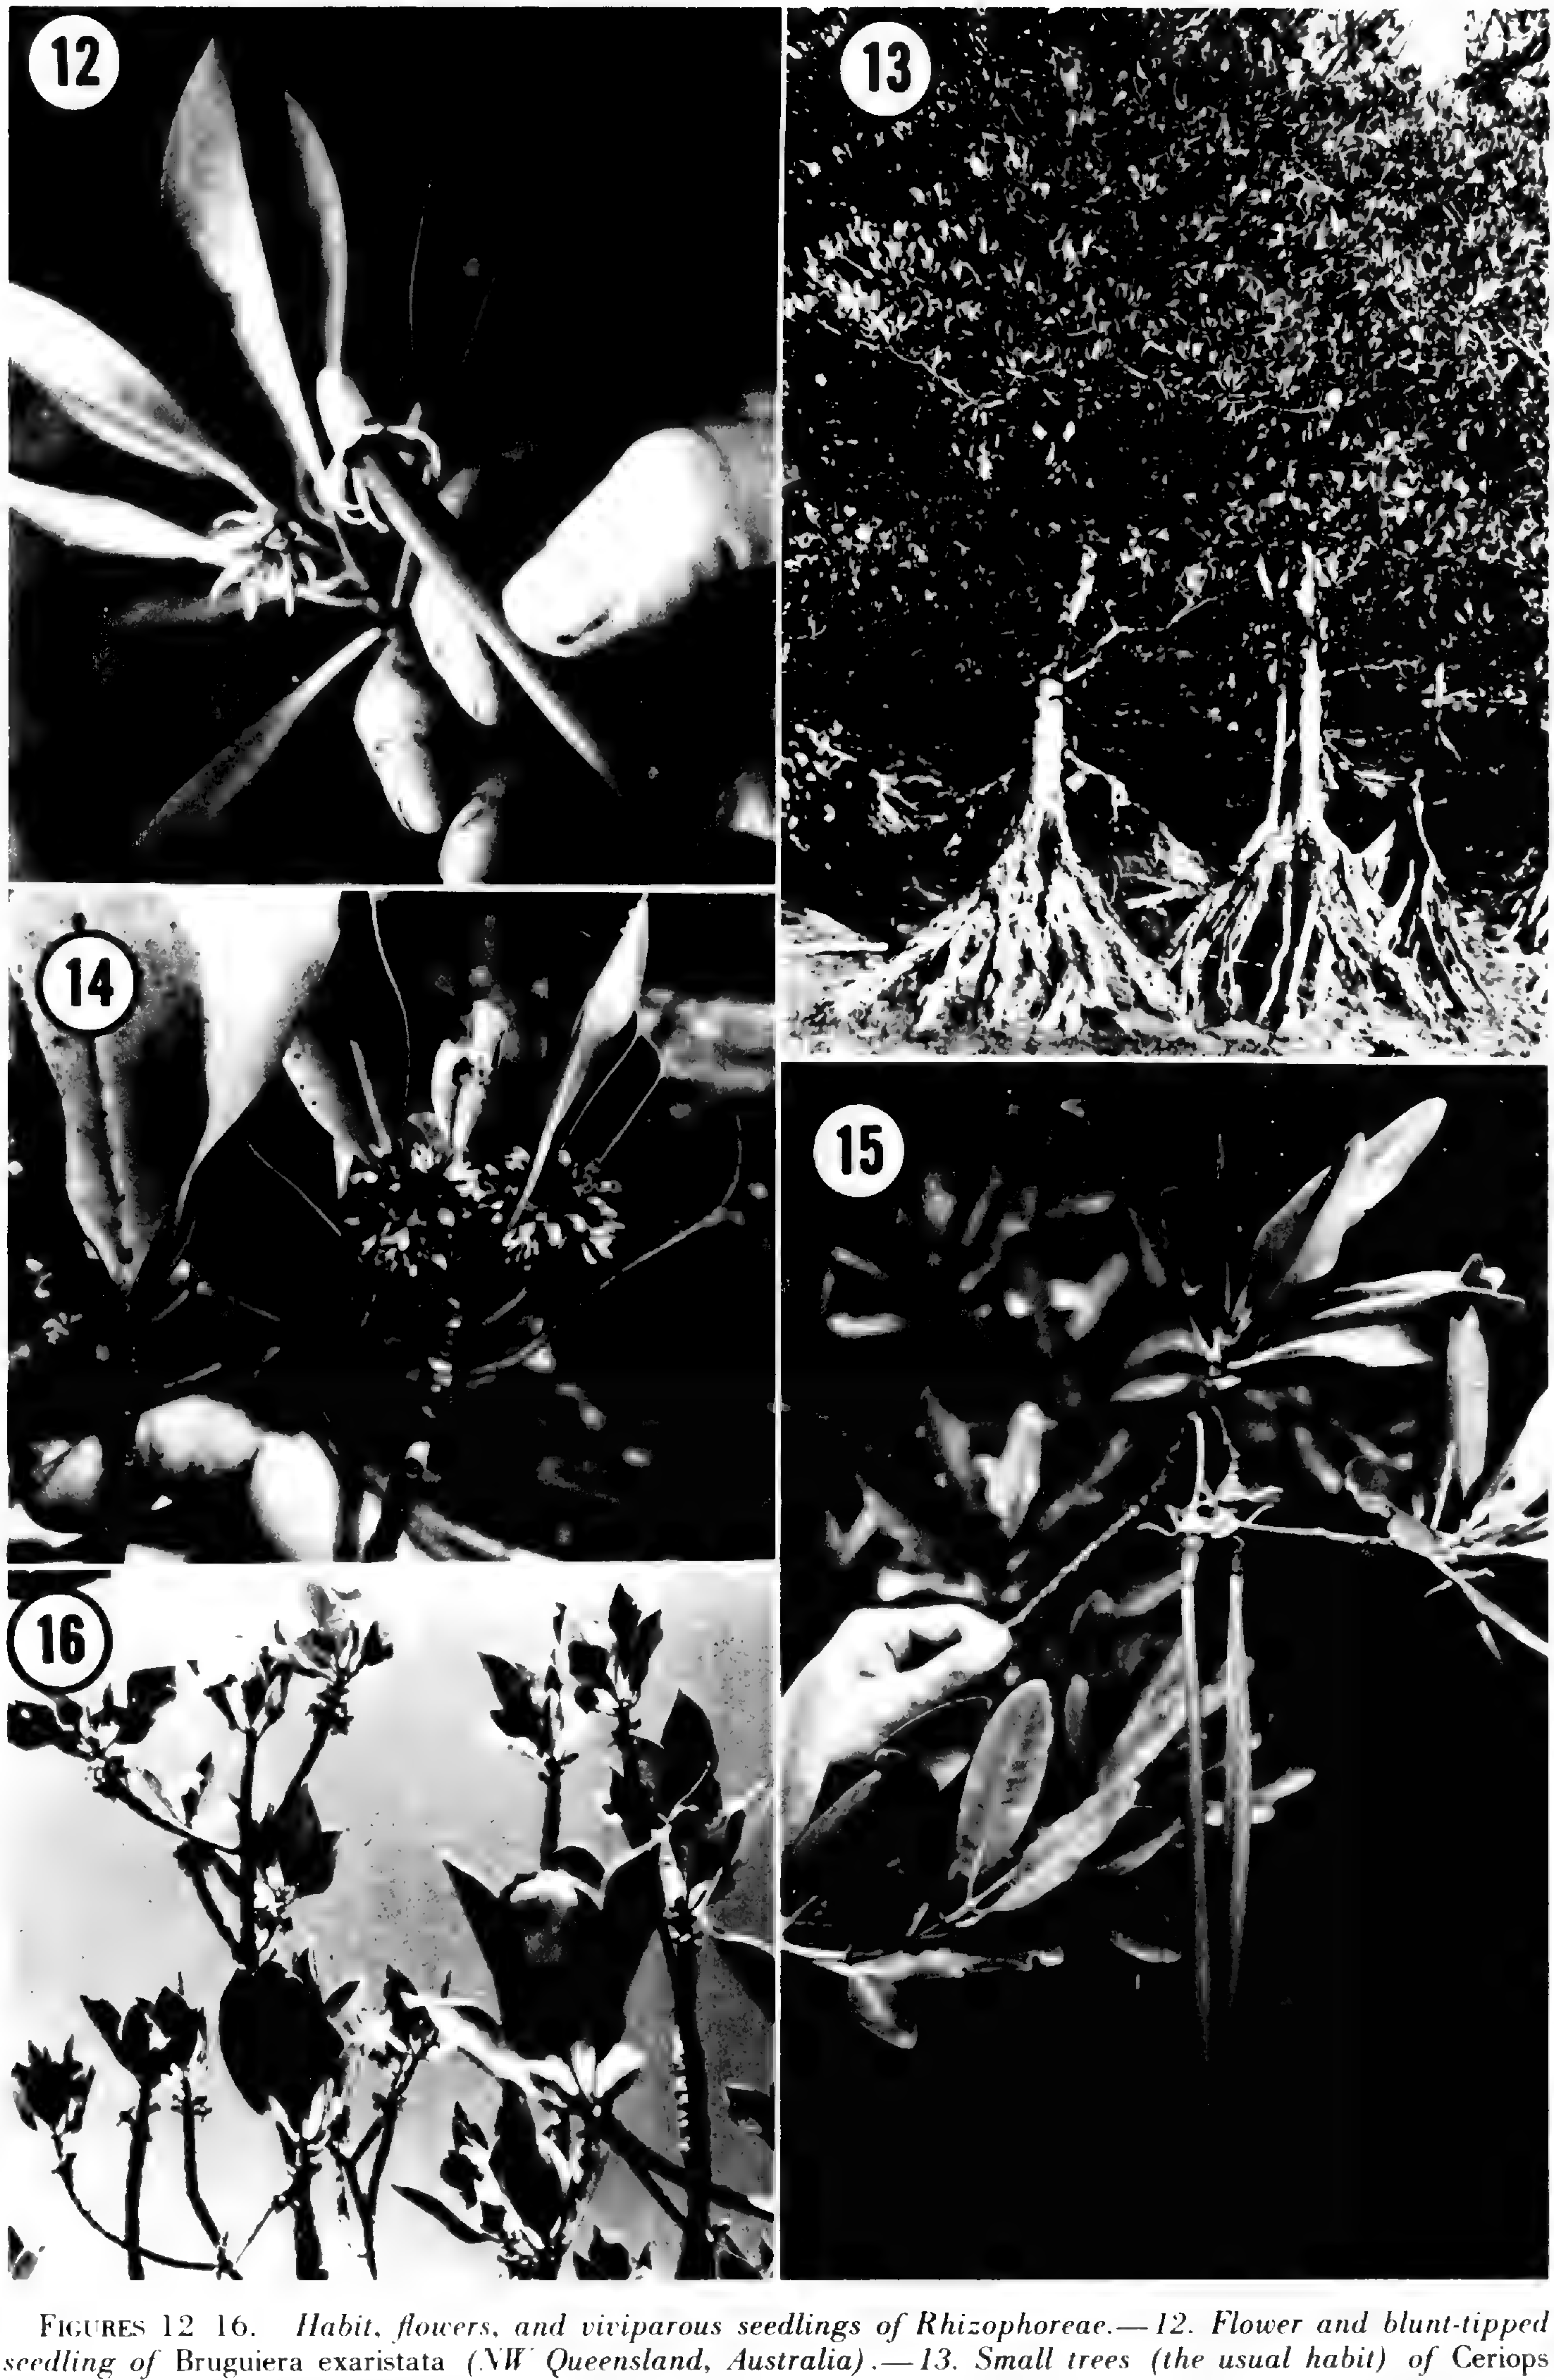

FIGURES 12–16. *Habit, flowers, and viviparous seedlings of Rhizophoreae.—12. Flower and blunt-tipped seedling of* Bruguiera exaristata *(NW Queensland, Australia).—13. Small trees (the usual habit) of* Ceriops tagal *(Sarawak), showing low cone of stilt roots that coalesce to form buttresses; leaves of this very drought- and salt-tolerant species are curled and upright.—14. Branch tip with fasciculate inflorescences of* Ceriops tagal *(Sarawak).—15. Branch tip of* Kandelia candel *(Sarawak) with mature viviparous seedlings. The long-acuminate seedlings of this genus have a mode of establishment unlike that of other Rhizophoreae.—16. Habit of* Rhizophora apiculata *(New Caledonia). In this species, highly adapted to anemophily, flowers are borne well below leaves, and petals and dehisced stamens may abscise before the flower opens.*

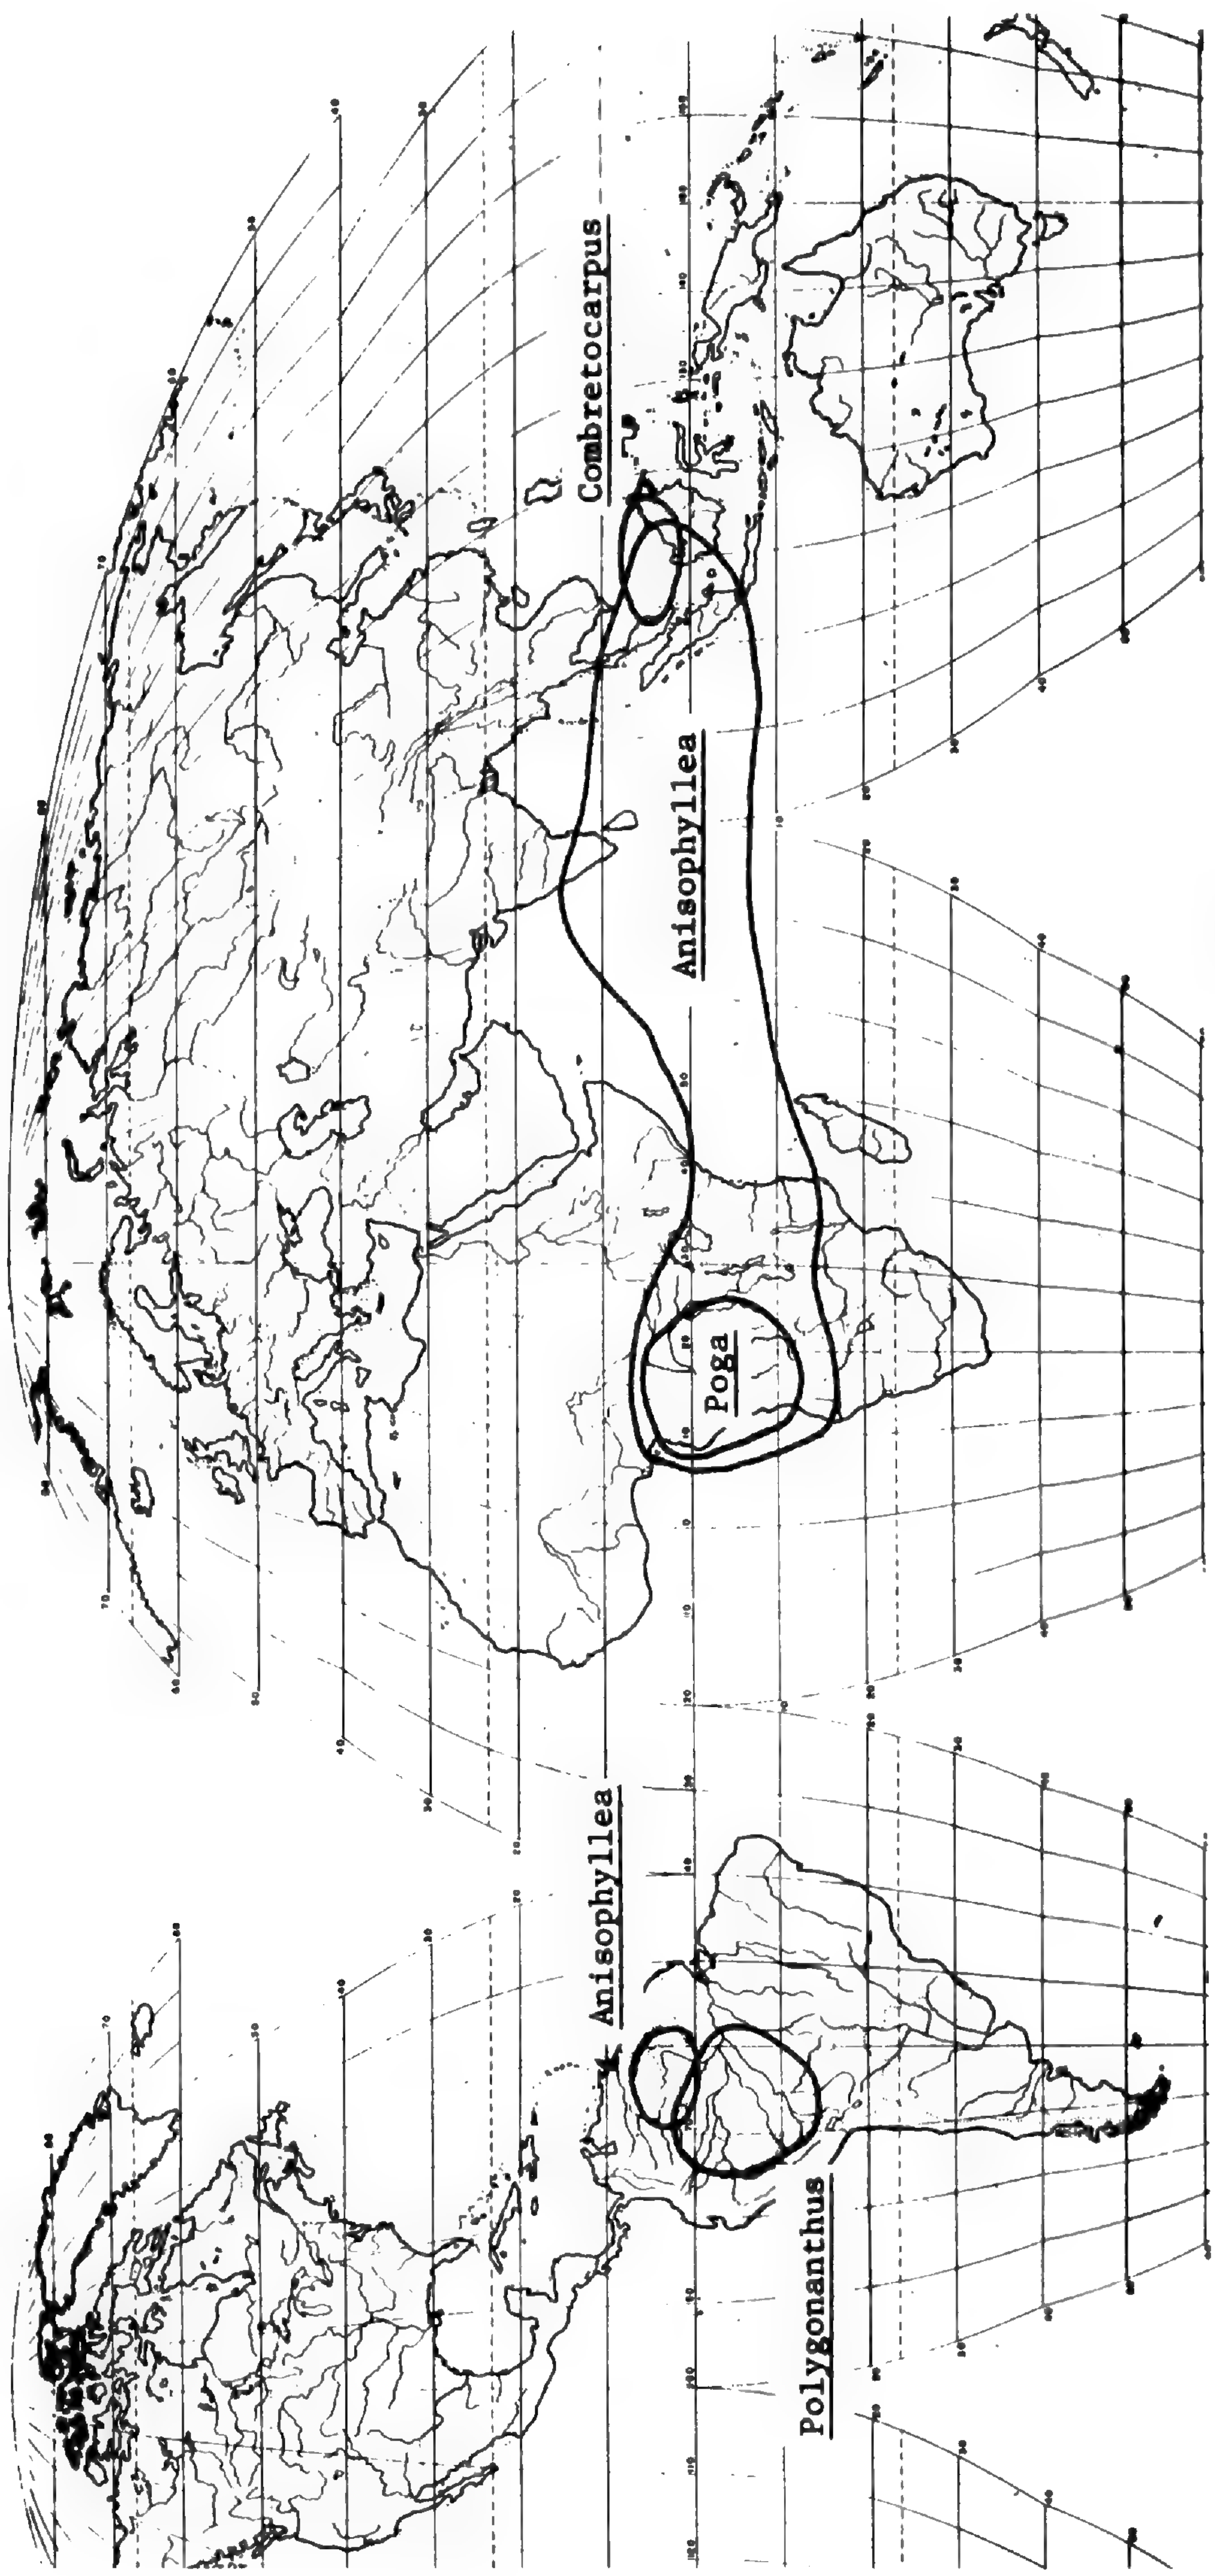

FIGURE 17. *Geographical distribution of genera of family Anisophylleaceae. In Peninsular Malaysia,* Combretocarpus *may now be extinct.*

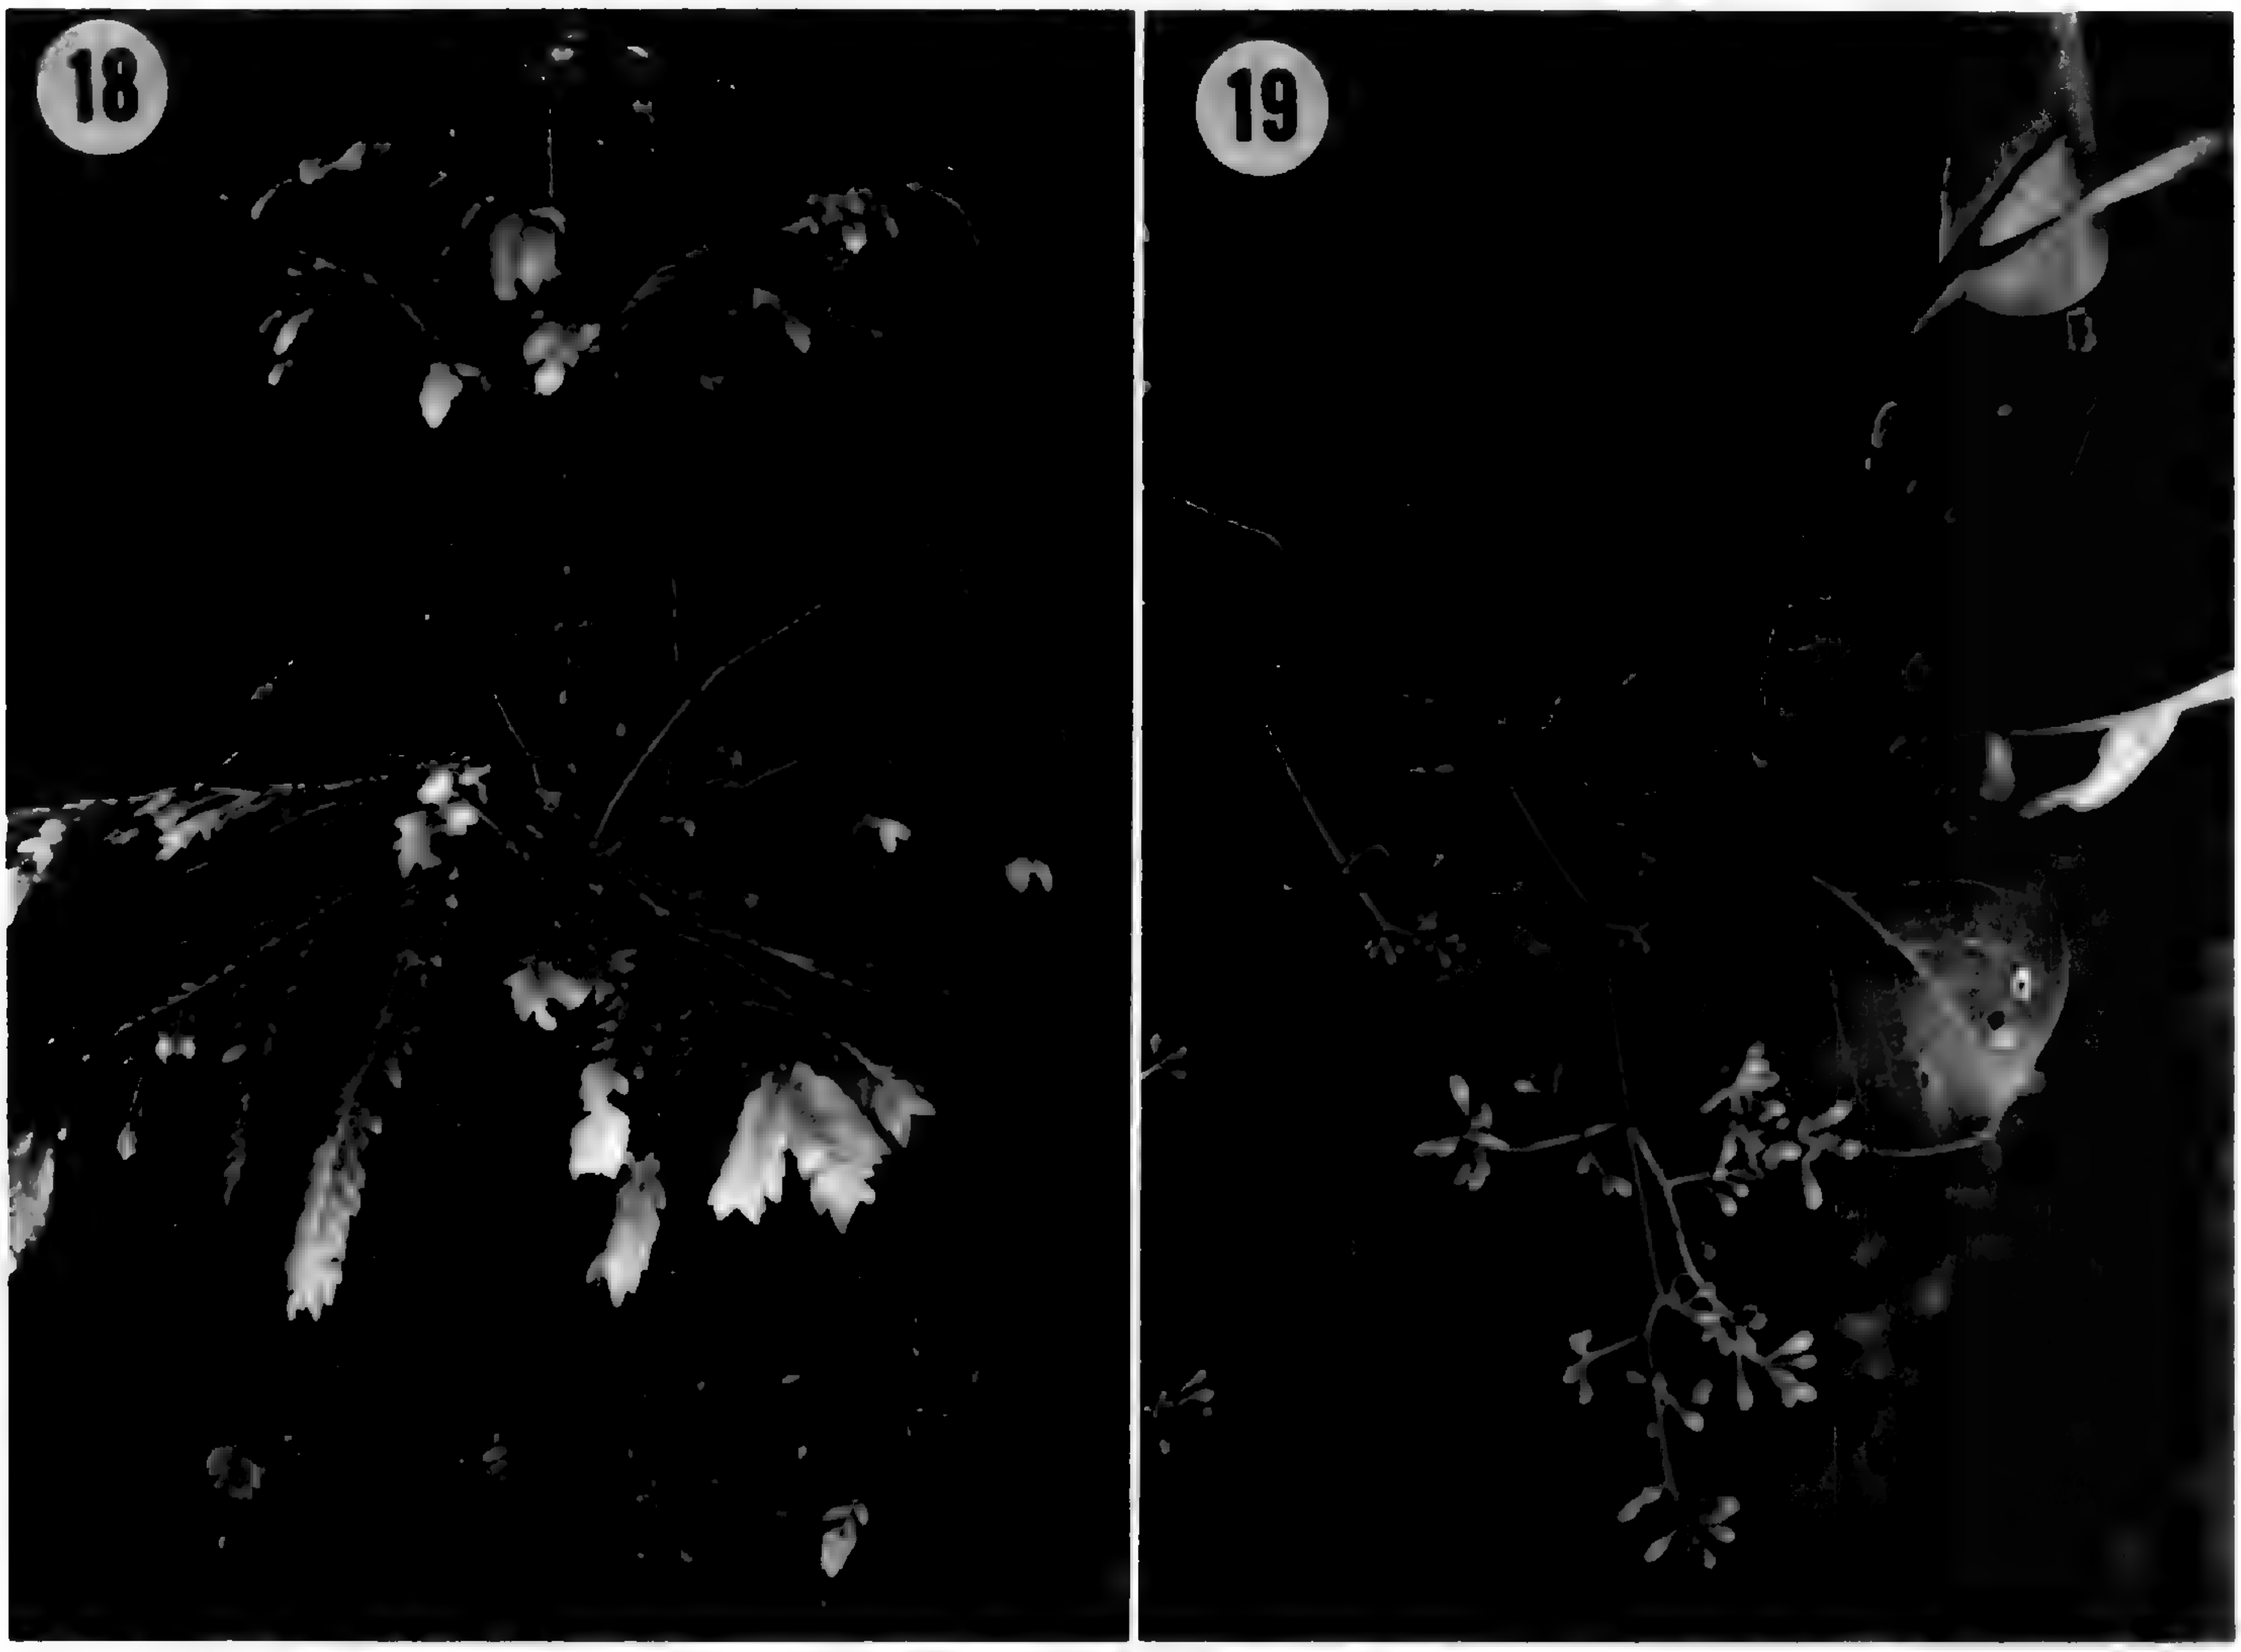

FIGURES 18, 19. *Habit and inflorescence of Anisophylleaceae.—18.* Anisophyllea disticha *(Brunei), a common understory shrub in Malaysia; large trees in this genus have similar architecture and phyllotaxis, albeit less obvious.—19. Foliage and paniculate inflorescence of* Combretocarpus rotundatus *(Also from Brunei).*

Most salt-tolerant genus of the tribe; frequently shrubby; bark pale (unlike all other genera of the tribe). Inflorescences fasciculate (Fig. 14), trichasial changing to monochasial. Flowers pentamerous, diplostemonous; ovary half-inferior, 3-carpellate. Hypocotyl generally ridged.

Kandelia (DC.) Wight & Arn., 1 species (Ding Hou, 1958). Figure 15.

Distribution. Bangladesh to S Japan, through Indochina to Malaysia, Sumatra, Borneo. Characteristically found on riverbanks.

Inflorescences dichotomous; bracteoles connate and corky. Flowers 4–5-merous; petals to 2 cm, 3–7-lobed nearly to base; stamens about 30; ovary half-inferior, 3-carpellate. Hypocotyls long-acuminate.

Rhizophora L. Either 8 species or 4 species, 2 distinct varieties, 3 hybrids (Salvoza, 1936; Ding Hou, 1958; Tomlinson, 1978). Figure 16.

Distribution. Pantropical, barely extending to subtropics.

Large stilt roots. Inflorescences dichotomous, bracteoles of most species tiny. Flowers 4-merous; ovary half-inferior, 2-carpellate. Petals entire (this unique in the family) but usually densely pubescent, the edges barely enclosing each antipetalous stamen. Stamens 8, in two whorls, except 3 times the number of petals in *R. apiculata*; multilocellate in all species. Wind pollinated.

FAMILY ANISOPHYLLEACEAE RIDLEY

Trees and shrubs of wet primary forest; leaves alternate, dimorphic (except in *Combretocarpus*), exstipulate or with highly reduced stipular homologues. Inflorescences axillary, racemose to paniculate. Flowers mostly unisexual (plants monoecious), except bisexual in *Combretocarpus*. Calyx and petals valvate, 3–5-merous. Petals lobed or laciniate (except entire in *Polygonanthus*). Androecium diplostemonous. Nectary crenate. Ovary inferior, 3–

4-locular, the styles separate. Ovules 1–2 per carpel. Fruit a drupe or dry, winged (*Combretocarpus*), usually 1-seeded. Endosperm lacking; embryo with reduced or no cotyledons. Germination hypogeal.

Genera. Anisophyllea, Combretocarpus, Poga, Polygonanthus.

Distribution. South America, Africa, India to Malesia (Fig. 17).

Anisophyllea R. Brown ex Sabine, 25 species (Hutchinson & Dalziel, 1954; Ding Hou, 1958). Figure 18.

Distribution. South America, Africa, India to Malesia.

Shrubs 1.5 m tall through large trees. Axes strongly differentiated; plagiotropic branches of most species anisophyllous, with unique tetrastichous phyllotaxy (Fig. 18). Serial axillary buds numerous. Staminate and pistillate flowers either in separate inflorescences or mixed, often not strongly heteromorphic, usually 4-merous. Drupes 2–15 cm, usually 1-seeded.

Combretocarpus Hook. f., 1 species (Ding Hou, 1958). Figure 19.

Distribution. Borneo.

Large tree of peat swamps. Leaves isomorphic, distichous. Inflorescence paniculate (Fig. 19). Flowers bisexual, usually trimerous. Petals linear or irregularly 3–4-lobed. Fruit winged.

Poga Pierre, 1 species (Hutchinson & Dalziel, 1954).

Distribution. Equatorial Africa.

Large tree. Leaves anisophyllous. Inflorescences on specialized leafless branches. Flowers unisexual, strongly heteromorphic. Fruits with 3–4 edible oily seeds.

Polygonanthus Ducke, 2 species (Prance et al., 1975).

Distribution. Brazil (Amazonia).

Small trees. Leaves anisophyllous. Flowers unisexual, strongly heteromorphic; petals unlobed, nearly linear.

SYSTEMATIC COMPARISON AND SOME BIOLOGICAL CHARACTERISTICS OF RHIZOPHORACEAE AND ANISOPHYLLEACEAE[1]

Adrian M. Juncosa[2] *and*
P. Barry Tomlinson[3]

ABSTRACT

Systematic and biological characteristics of Rhizophoraceae and Anisophylleaceae are detailed. Comparison of a wide variety of vegetative and reproductive characters reveals virtually no points of agreement between the two families. Characters such as the basically diplostemonous androecium are of such wide occurrence in choripetalous dicotyledons as to be phylogenetically insignificant. One apomorphy found in both families, divided or appendiculate petal margins, occurs in several unrelated families also and is judged to be a homoplasy. Cladistic analysis of Rhizophoraceae shows that, not surprisingly, information now in hand about most Macarisieae is inadequate to resolve the relationships of the genera and clades of this tribe. The remainder of the proposed phylogenetic tree is very robust and shows that, as traditionally circumscribed, tribe Gynotrocheae is paraphyletic. Carallia *is evidently the inland genus most closely related to the mangroves.* Bruguiera, *although characterized by several remarkable autapomorphies, is the most primitive of the mangrove genera, and* Rhizophora *is the most derived.*

The Rhizophoraceae (used sensu stricto throughout this article) and Anisophylleaceae have often been treated as a single family, although some recent phylogenetic treatments of the angiosperms have placed them separately (Cronquist, 1981; Dahlgren, 1980), as originally suggested by Ridley (1922). We believe that this lack of consensus stems largely from the absence of detailed information on a wide variety of systematic characters of the two families, rather than from differences in interpretation. Detailed discussions of several specific suites of characters, such as pollen and leaf architecture, appear elsewhere in this volume, so we have emphasized other, mostly morphological, characters that are either not widely understood for these two families or not generally considered in systematic comparisons. A summary of the systematic differences between Rhizophoraceae and Anisophylleaceae in these characters forms Table 1.

Despite the fact that most botanists are somewhat familiar with the mangrove Rhizophoraceae, particularly the genus *Rhizophora*, the biology of these plants is widely misunderstood. Accordingly, in a second section of this article, we discuss some of the biological adaptations to the mangrove habitat that are found in Rhizophoraceae, with as much comparative reference to the inland genera as the current state of our knowledge permits.

SYSTEMATIC COMPARISON

DISTRIBUTION AND HABITAT

Rhizophoraceae and Anisophylleaceae are tropical families of shrubs and trees; only a few species of mangrove Rhizophoraceae stray beyond 22° lat-

itude, and then only on coastlines with warm currents. Taxa of both families occur in most of the major moist-tropical floristic regions. The preponderance of genera with only one or two species and the narrow geographic ranges of those genera (Juncosa & Tomlinson, this volume) suggest that both may be relictual families.

For its size, the Rhizophoraceae have an exceptionally wide ecological and geographic range. The mangrove taxa are found on virtually all tropical coasts, and inland species grow in many moist forest types, both primary and successional. A few species, mostly in the genus *Cassipourea*, grow in drier habitats. Several genera of Rhizophoraceae (both inland and mangrove) may form very large trees (to 50 m), but most species are small trees and may begin flowering at heights of only 1–2 m.

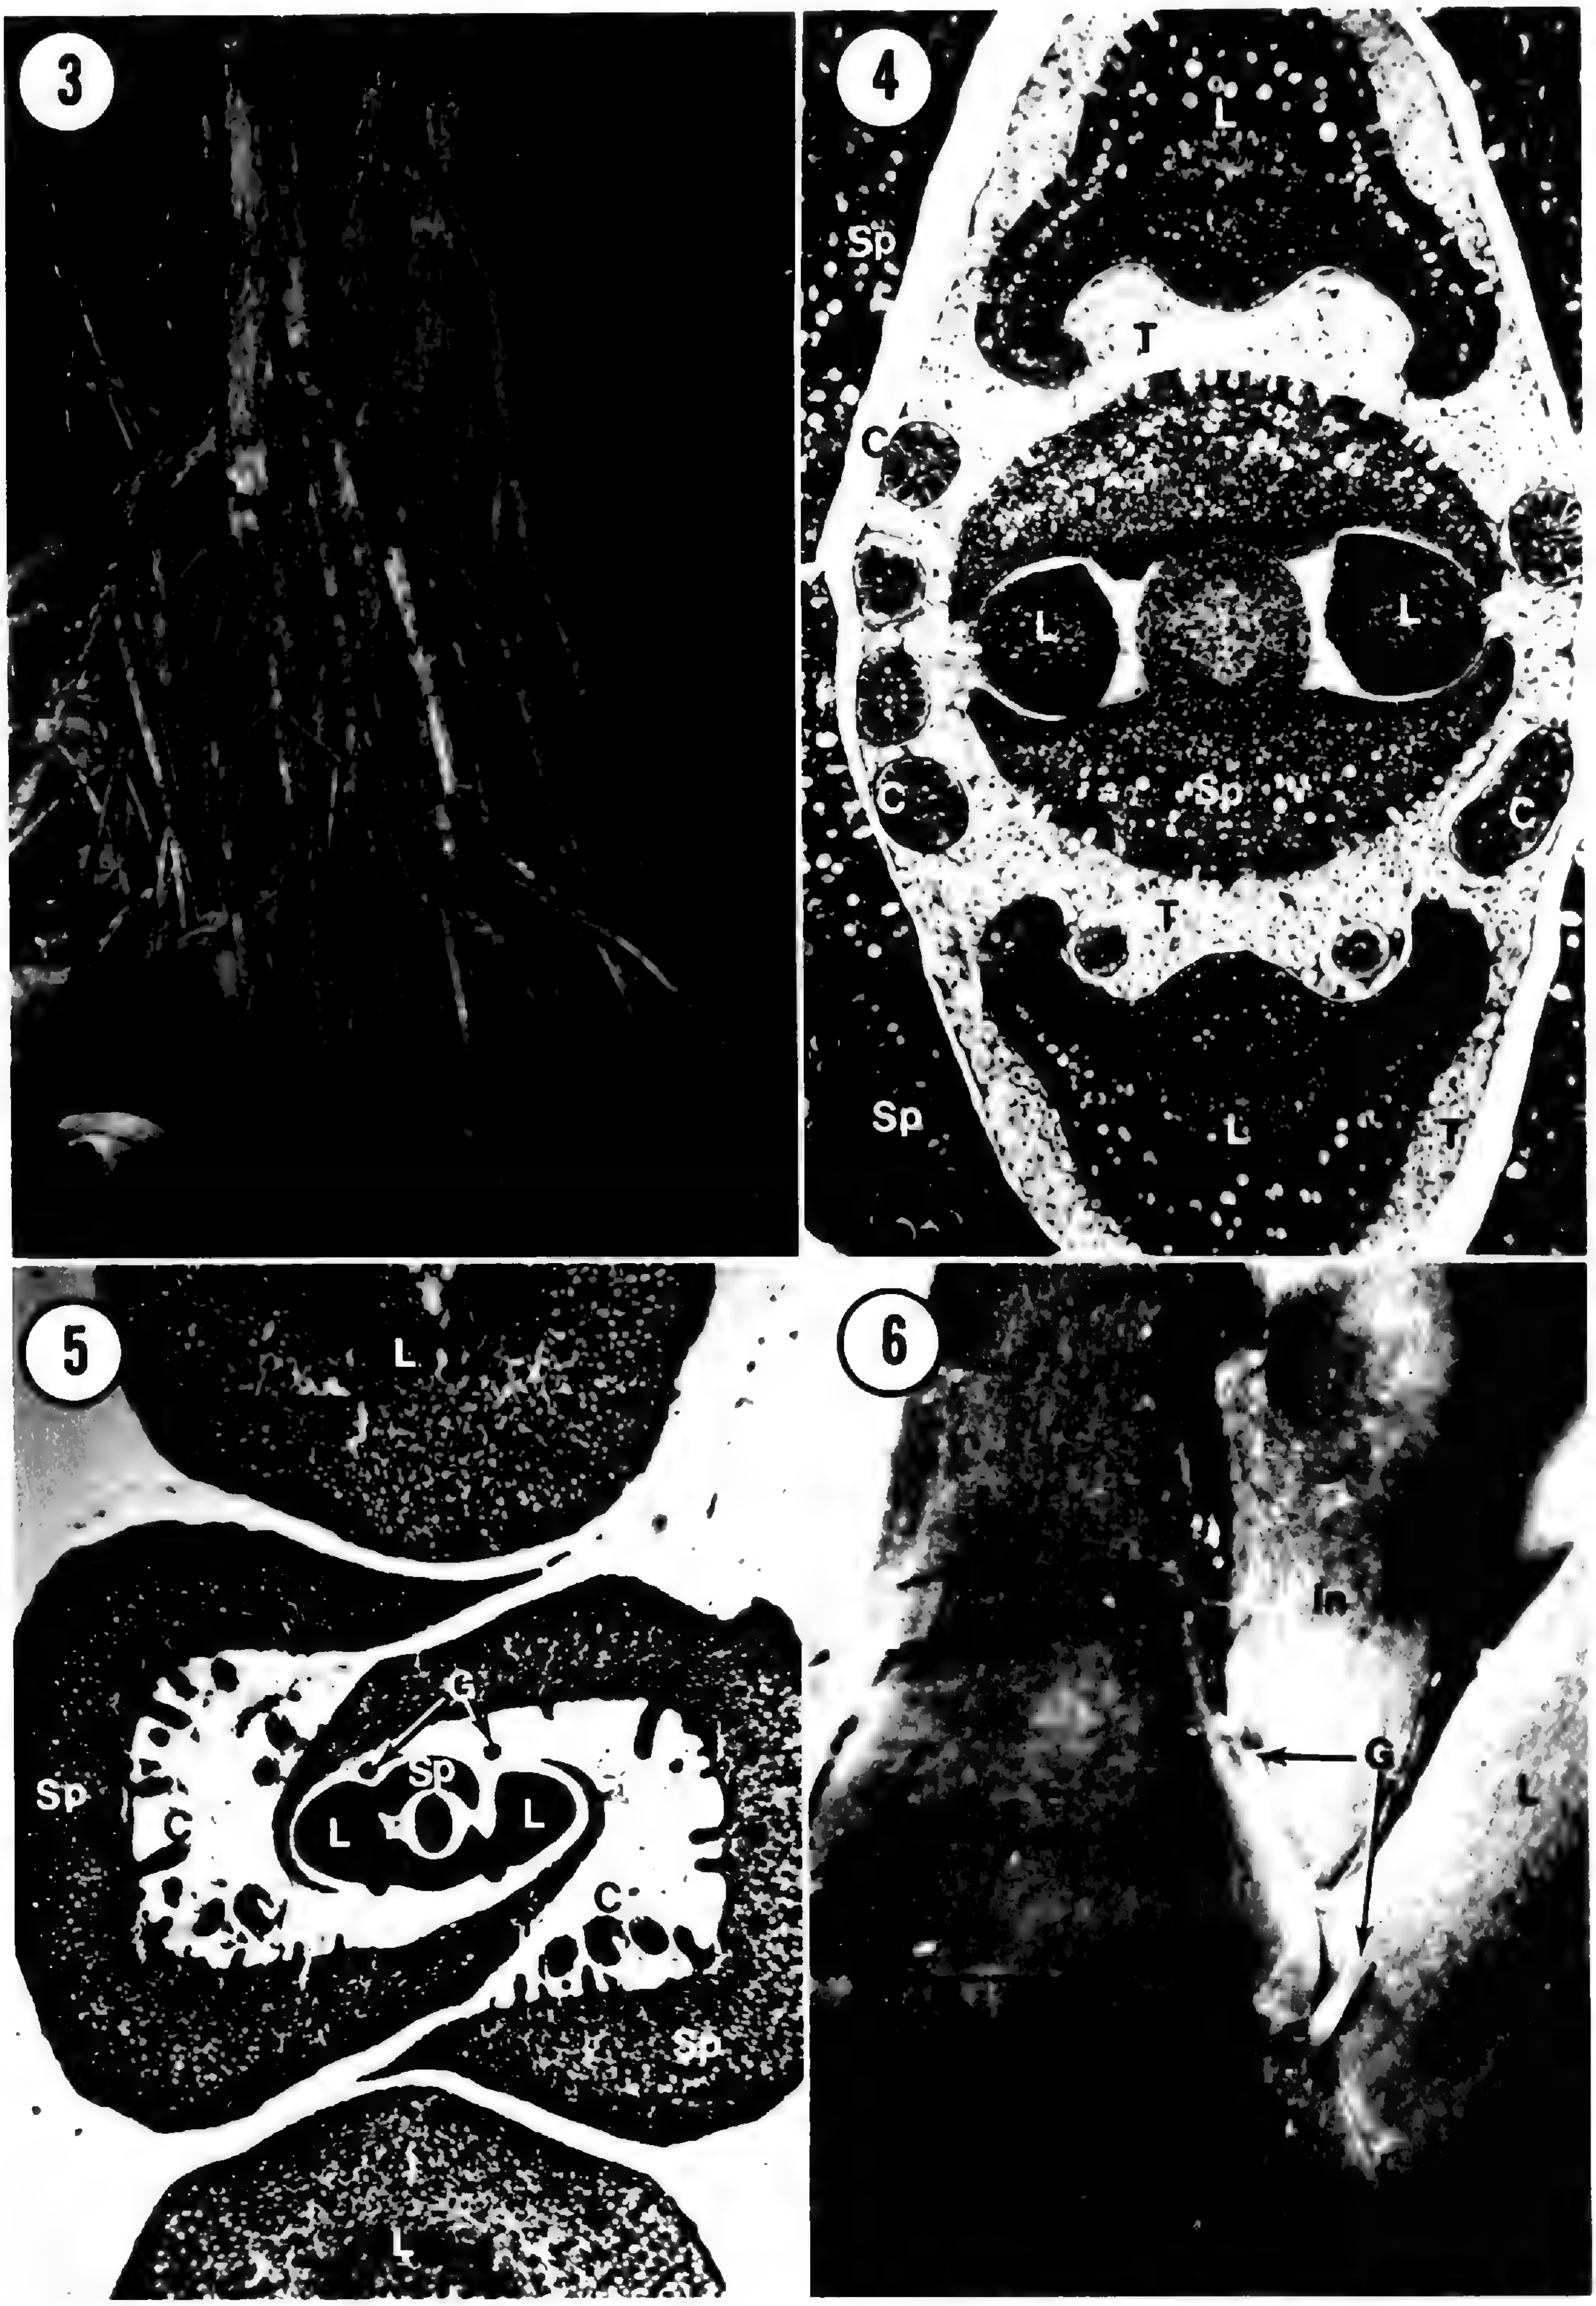
Anisophylleaceae are characteristically large trees of wet lowland primary forest, although the genus *Anisophyllea* also includes some elegant small shrubs (e.g., *A. disticha*). *Combretocarpus* is a dominant tree of Bornean (fresh water) peat swamp forest, apparently now extinct in peninsular Malaysia (F. S. P. Ng, pers. comm., 1981).

AERIAL ROOTS

Members of at least seven genera of Rhizophoraceae characteristically form aerial stilt roots, which have been described in greatest detail for the mangrove taxa (Troll, 1943). The genus *Rhizophora* ("root-bearer") is justly famous for its remarkable stilt roots (Fig. 1), the development, anatomy, and function of which were not understood until recently (Gill & Tomlinson, 1971, 1977; Scholander et al., 1955). *Ceriops tagal* and species of *Bruguiera* also form stilt roots on the hypocotyl and base of the trunk, which coalesce to form the fluted, conical trunk base that is seen in older plants (Fig. 2).

Among the inland genera, *Gynotroches* and *Crossostylis* (Gynotrocheae) normally form thick stilt roots on the lower trunk; *Crossostylis grandiflora* is known as "palétuvier de montagne" in New Caledonia for this reason (Fig. 3). At least one species of *Carallia*, *C. brachiata*, forms abundant stilt roots in peat swamps (Ding Hou, 1958). Thus, prominent aerial roots occur in three of the four genera of Gynotrocheae, the inland tribe that is probably most closely related to the mangroves. Although aerial roots in Rhizophoraceae may be formed more abundantly in swamps (e.g., in *Gynotroches*), they are not limited to plants found in that habitat; *Crossostylis grandiflora* is characteristically found in hilly sites. It may well be the humidity of the air rather than the inundation of the soil that is a factor in the development of aerial roots in inland taxa.

Another root character that is not often considered in systematic analyses is the presence of root hairs. These are formed on roots of *Cassipourea* seedlings but are not found in any of the members of the Gynotrocheae or Rhizophoreae that we have studied. Absence of root hairs from Rhizophoreae



FIGURES 3–6. *Stilt roots and vegetative bud morphology of inland Rhizophoraceae.—3. Stilt roots of* Crossostylis grandiflora, *one of at least three inland genera in which they occur (New Caledonia).—4. may have a simple functional explanation if, as suggested by Tomlinson (1986), the endodermis is the site of the salt excluding mechanism, rendering an elaborated root surface unnecessary. Consequently, the root surface instead is elaborated by production of capillary rootlets (Attims & Cremer, 1967). This does not account for the absence of root hairs from Gynotrocheae, however.

Only one genus of Anisophylleaceae is known to possess any kind of aerial roots. *Combretocarpus* sometimes produces unique, diminutive (1–4 cm), negatively geotropic aerial roots on the trunk, usually 1–2 m above the soil (or water) level. However singular these may be, they bear no resemblance to the stilt roots of Rhizophoraceae, neither in development nor in mature anatomy and morphology, and cannot be considered a synapomorphy between the two families.

WOOD ANATOMY

A more detailed consideration of the wood anatomy of Rhizophoraceae and Anisophylleaceae appears elsewhere (Keating & Randrianasolo, this volume), but several specific points merit brief mention here. Indisputably, wood anatomical character states are very variable within Rhizophoraceae (Marco, 1935; van Vliet, 1976); however, we deem it poor systematic practice to use this variability as license to draw a relationship between the woods of these two families without any consideration of adaptive significance of wood structure. A number of significant differences could be discussed, but we wish to cite only a few. All Anisophylleaceae have alternate intervessel pitting with coalescent apertures, which are not found in any Rhizophoraceae. A limited amount of alternate pitting occurs in some species of *Carallia*, clearly as a specialization that has arisen within that genus and is thus not relevant to interfamilial relationships. The narrow vessels and scalariform perforation plates of Rhizophoreae are distinctive and related to the low negative pressures induced by the saline environment, as discussed in Tomlinson (1986).

At the request of P. Baas, E. Wheeler (pers. comm.) compared wood anatomical characteristics of Anisophylleaceae with those of the Gynotrocheae and her computerized data base of 5,000 species. Although the character set was not specified and clearly did not include coalescent apertures, absent from Rhizophoraceae (van Vliet, 1976), the coded characters of woods of Anisophylleaceae match those of at least some species of *Carallia* and, to a lesser extent, *Gynotroches* and *Crossostylis*. Significantly, woods of Anisophylleaceae are similar neither to those of the mangrove genera nor, more importantly, to those of any Macarisieae. Therefore, if the wood anatomical similarities between Anisophylleaceae and *Carallia* were taken as synapomorphies, it would then be necessary to include the Anisophylleaceae as a subtribe of Gynotrocheae (see Fig. 27), which in turn requires us to hypothesize parallel reversals in at least 20 (probably closer to 50) vegetative, chemical, embryological, floral, fruit, seed, embryo, and seedling characters (see Table 1 and Dahlgren, this volume). As this is both extremely unparsimonious and biologically completely implausible, we conclude that the similarities in wood anatomy represent homoplasies and are not systematically significant in this case.

PHYLLOTAXY AND NODAL ANATOMY

Phyllotaxis is the one systematic difference between Rhizophoraceae and Anisophylleaceae that seems to be widely known: Rhizophoraceae have opposite leaves with interpetiolar stipules, whereas most Anisophylleaceae have alternate, exstipulate leaves. Certain additional details may ultimately prove helpful in understanding infrafamilial systematics.

In all Rhizophoraceae, the interpetiolar stipules bear colleters that secrete gummy substances onto the buds. In *Rhizophora stylosa*, this secretion contains galactose (Primack & Tomlinson, 1978), but whether its primary function is to deter herbivory (either through direct toxicity to insects or by attracting insectivorous birds) or merely to lubricate the expanding leaves while protecting them from desiccation is uncertain.

There are tribal distinctions in bud morphology within Rhizophoraceae. In *Cassipourea*, the stipules are valvate and pubescent (in addition to bearing colleters), and the leaves are truly decussate, that is, successive pairs of leaf primordia are initiated at exact right angles to one another (Fig. 4). Some reorientation of the leaves may occur during and after expansion. However, the usual descrip-

tion of phyllotaxis in all Rhizophoraceae as decussate holds only for the tribe Macarisieae and for *Pellacalyx* (Gynotrocheae). Tomlinson & Wheat (1979) showed that phyllotaxis in all genera of Rhizophoreae is actually bijugate, with successive leaf pairs offset by angles of 70°–80°. Except for *Pellacalyx*, which has many autapomorphic features, all genera of Gynotrocheae also have bijugate phyllotaxy (Fig. 5). At least several species of *Carallia* bear extrastipular glands in addition to the colleters (Fig. 6). Interestingly, all genera with bijugate phyllotaxy have imbricate stipules, whereas those with decussate leaves have valvate stipules.

As discussed in greater detail later, overall tree architecture in Rhizophoraceae is variable, to some extent in relation to habitat differences. However, the basic architectural character of systematic interest is that the trunk and branches are only minimally or not at all differentiated; plagiotropic axes may be lacking altogether.

Anisophylleaceae are universally characterized as having alternate, exstipulate leaves, but at least one species of *Anisophyllea*, *A. disticha*, has structures interpretable either as minute stipules or large glands (Figs. 8, 11). The phyllotaxy of plagiotropic branches of this genus is unique among angiosperms: there are four orthostichies of leaves, two of reduced leaves on the upper side, and two of full-sized leaves along the lower side (Figs. 7–9). Orthotropic axes, in contrast, bear helically arranged reduced leaves in a conventional 2/5 helix (Figs. 10–12; Vincent & Tomlinson, 1983); thus, differentiation of axes is pronounced, at least in this genus.

Based primarily on study of herbarium material, Ding Hou (1958) stated that anisophylly of this kind is characteristic of only two species of *Anisophyllea*. However, our fieldwork shows that anisophylly is also the rule in plagiotropic axes of at least *A. cinnamomoides*, *A. ferruginea*, *A. griffithii*, and *A.*, sp. nov. Ding Hou (1958), but that the reduced leaves in these species are sometimes very small and caducous and hence are rarely seen in herbarium specimens. (Their scars, ordinarily lacking axillary buds, can often be detected.) It thus seems likely that both anisophylly and the unique tetrastichous phyllotaxy are uniform for Asian species of the genus. *Anisophyllea cinnamomoides*, which forms a moderate-sized tree, has the same architecture as a sapling that has been described in detail for adult *A. disticha* (Vincent & Tomlinson, 1983). Consequently, one may interpret the latter species as a permanently juvenile form. Herbarium study of virtually all other described species of the genus revealed that anisophylly occurs in all but a group of two or three closely related species (Juncosa, pers. obs.), a conclusion corroborated by the field studies of Floret (pers. comm.). He additionally communicated that in at least one rhizomatous shrubby species of a habitat subject to both severe seasonal drought and periodic fires, axis differentiation is seasonal rather than architectural.

Our knowledge of phyllotaxy and architecture in other genera of Anisophylleaceae is even poorer than in *Anisophyllea*; no reference mentions anisophylly in the other three genera. It does occur in *Poga* and *Polygonanthus*, although the strict alternation of leaf types seen in *Anisophyllea* is not preserved in all parts of the axes of *Polygonanthus*: several small leaves occur in succession at the bases of some branches, but these reduced leaves may be lacking distally (Juncosa, pers. obs.).

A more detailed discussion of leaf anatomy appears elsewhere in this volume, but a few characters bear mention here. It is not generally understood that in most inland Rhizophoraceae, juvenile and usually also the adult leaves are variously toothed or crenate, not entire as is usually stated. Only in Rhizophoreae are the leaves consistently entire, one of many characters in which derived states (within the family) are exhibited by the specialized mangrove genera. Other leaf characteristics of this tribe, such as the succulent hypodermal layer, terminal tracheids, and frequently abundant sclereids, are probably all adaptations to the mangrove hab-

itat. An achlorophyllous hypodermal layer is also found in at least three genera of Gynotrocheae, but not in *Cassipourea* (Macarisieae), so that character may be of phylogenetic significance as well.

Nodal anatomy also seems to distinguish the two families, as the Rhizophoraceae are characterized by multilacunar nodes with split-lateral traces (Howard, 1970, 1979), whereas Anisophylleaceae have unilacunar nodes (*Anisophyllea*: Geh & Keng, 1974; Vincent & Tomlinson, 1983; *Combretocarpus*: Juncosa, unpubl. obs.).

INFLORESCENCE

The inflorescence in Rhizophoraceae is fundamentally cymose, both in open-branched and fasciculate forms. Flowers of large-flowered species of *Bruguiera* are solitary, presumably by reduction. The first branching event is dichasial (sometimes trichasial in *Ceriops* and in *Carallia brachiata*); subsequently, branching is usually monochasial (Fig. 13). In *Rhizophora*, *Kandelia*, and *Crossostylis*, inflorescences bifurcate throughout (Fig. 14), but the division appears to be pseudodichotomous. Although the apices terminating the sympodial units do not develop into flowers in these genera, their vestiges can often be found (Fig. 15). Interestingly, both open-branching and fasciculate forms (in which the branch internodes do not elongate; Fig. 16) are found in all three tribes. It therefore appears that condensation of the inflorescence evolved in parallel three times. A single bract subtends each branch, thus there is a pair of bracts at each node, even when further development of one of the two branches is suppressed in the monochasial portions of the inflorescence. Pairs of bracteoles also subtend each flower. The bracteoles bear colleters similar in distribution, development, and mature anatomy to those of the stipules and secrete a sticky, rubbery coating over the floral primordia. In *Pellacalyx*, the pairs of bracts are fused into a toothed cup-shaped structure superficially resembling an epicalyx, but subtending minute axillary buds in addition to the terminal flower (Fig. 17).

Inflorescences in the Anisophylleaceae are paniculate or racemose and usually somewhat open-branched. A single bract subtends each branch and flower. In *Anisophyllea disticha*, male and female flowers occur in separate inflorescences, but in most other species and genera in the family, the two floral types are mixed in all inflorescences. Thus, although the differences are to some extent an extension of the phyllotactic differences of the vegetative shoots, there is no inflorescence character state common to both Rhizophoraceae and Anisophylleaceae.

FLORAL MORPHOLOGY AND DEVELOPMENT

In most Rhizophoraceae the flowers are bisexual, but exceptions are found in both inland tribes. *Gynotroches* (Gynotrocheae) is dioecious; in male flowers, the ovary and ovules develop and at least the early stages of megagametogenesis occur, but the style atrophies distally instead of elongating. In female flowers, anthers and sporogenous tissue develop, but normal microsporogenesis seems to be interrupted shortly after meiosis. At least some species of *Crossostylis* (Gynotrocheae) are polygamodioecious, with many individuals bearing only functionally female flowers (Smith, 1981). Among the Macarisieae, *Blepharistemma* and *Sterigmapetalum* are reported to be polygamodioecious and dioecious, respectively, but developmental details are lacking.

Although mature floral structures in Rhizophoraceae are remarkably diverse, especially in relation to contrasted pollination mechanisms (Juncosa & Tomlinson, 1987), early developmental stages are generally very similar. Floral characters that unify the family include petal development and mature morphology, the generally diplostemonous androecium, and the presence of laticifers.

These generalizations are based upon study of nine of the fourteen genera of the family, including all genera of tribes Gynotrocheae and Rhizophoreae and one of Macarisieae (*Cassipourea*). Inasmuch as the mature morphology of flowers of Macarisieae varies very little, especially in comparison with that of genera of the other two tribes, this survey may be taken as encompassing nearly all aspects of floral evolution in the family.

Petals in rhizophoraceous taxa are fundamentally bifid, with a prominent terminal arista, and they enclose groups of one or more stamens individually, rather than forming a whorl that collectively surrounds the androecium as a whole (Fig. 18). This distinctive petal vernation is to our knowledge found in only one other family of dicotyledons, Rhamnaceae. Usually, several to many filamentous appendages develop on the distal margins of the two main lobes of the petal (Fig. 19). Mature petals of *Crossostylis* appear to lack appendages, but this results from the suppression of development of appendages that are initiated in exactly the same mode and position as in other genera. This may also be the case in *Anopyxis*, which is described as having entire petals. Only in *Rhizophora*, the most specialized genus in the family, are the marginal petal appendages truly absent, even though

petals still bear a terminal arista and enclose individual stamens. Although fringed petals are found in a number of other families, including Anisophylleaceae, their mature morphology and probably also early development do not resemble those of petals of Rhizophoraceae.

Another distinctive characteristic of rhizophoraceous flowers is the presence of a layer of laticiferous cells in the ovary and calyx. These cells may form a more or less continuous layer (*Cassipourea* and Rhizophoreae; Fig. 20) or may grow radially, usually dividing periclinally (*Crossostylis* and *Carallia*; Fig. 21). In *Gynotroches* and *Pellacalyx*, the laticifers are further modified into disconnected canals or idioblastic cells. In most genera, the epidermis surrounding the laticiferous layer divides periclinally, becoming 5–7-seriate.

The androecium in most Rhizophoraceae is diplostemonous, and the antisepalous whorl of stamens is ordinarily initiated earlier than the antipetalous whorl. Nearly all Macarisieae and at least one genus in each of the other two tribes exhibit this basic floral pattern, which we believe to be ancestral for the family. However, significant modifications have arisen in parallel in all three tribes. For example, in *Carallia* and *Pellacalyx* (Gynotrocheae), the antipetalous stamens are initiated earlier than the antisepalous stamens (Juncosa, in press). Also, one genus in each of the three tribes has polyandrous flowers, probably a homoplasy (see Fig. 27). This indirect conclusion, based upon the likely cladistic relationship of the genera, is also supported by the diversity of developmental pathways that give rise to the numerous stamens in these three genera. In *Kandelia*, the polyandrous mangrove genus, the supernumerary stamens result from the initiation of about five stamens on a large common primordium that also produces a petal (Juncosa & Tomlinson, 1987). In the distantly related inland genus *Cassipourea* (Macarisieae), additional stamens are not initiated together with the petals, but the vasculature of each petal is closely associated with that of several nearby stamens. In several species of *Crossostylis*, the groups of stamens are found opposite the sepals instead of the petals (Smith, 1981).

All Rhizophoraceae have a single style and stigma, although in *Gynotroches* the stigmatic lobes may be rather long. The separate stigmatic lobes may be discernable at gynoecial initiation (e.g., *Gynotroches, Pellacalyx*), or the gynoecium may arise as a single toroidal primordium (e.g., *Carallia, Bruguiera*). Most Macarisieae have fully superior ovaries, but two genera of this tribe and most other genera in the family have half-inferior or completely inferior ovaries. Details of the development and vasculature of the ovary appear in Juncosa (in press). The occurrence of a superior ovary in female flowers of *Gynotroches* is probably a reversion from the half-inferior condition, which occurs in the functionally male flowers of the same genus. (As detailed above, unisexuality occurs in this genus by very late-developmental changes; the basic morphology of the two kinds of flowers is quite similar.) Additional support for this hypothesis comes from the diversity of placentation types in *Gynotroches* (Ding Hou, 1958); placentation in all other genera of Rhizophoraceae is invariably apical-axile.

Rhizophoraceae typically have 3–5 carpels (whether the locules are completely separate or not) and only two ovules per carpel, but an increase in the total number of ovules and seeds has evolved in several ways. In *Crossostylis*, this is achieved by multiplication in the number of carpels, up to as many as 20. In *Gynotroches* there are only five carpels, but each contains up to eight ovules. In *Pellacalyx* both the number of carpels and the number of ovules in each is increased.

The presence of a floral disc is often used as a systematic character, but an imprecise understanding of the initiation and development of this organ

may have led to considerable confusion and misinterpretation in the study of angiosperm phylogeny. In Rhizophoraceae, a nectarial ring arises inside the androecium late in floral development (Juncosa & Tomlinson, 1987). Thus, the stamens are not inserted on this ring, nor is it part of the androecium (Fig. 22). This important distinction is clearly illustrated by the genus *Bruguiera*, in which the androecium is initiated as a toroidal primordium, upon which separate stamen primordia later develop. Later, a separate toroidal primordium is initiated internally (centripetally) to the androecium and ultimately develops into the nectary. Some significant modifications to this basic pattern occur in certain inland genera in tribe Gynotrocheae, but the oft-cited character state "stamens inserted on a disc" is certainly incorrect for nearly all Rhizophoraceae.

Unfortunately, detailed information on development of flowers of Anisophylleaceae is not available, but descriptions of their mature morphology (Ding Hou, 1958; Tobe & Raven, 1987b) reveal several major differences from Rhizophoraceae. Petals of several genera of Anisophylleaceae are fringed (*Poga*, *Anisophyllea*) or weakly divided (*Combretocarpus*), but the distinctive morphology described above for Rhizophoraceae does not occur here. In particular, the prominent terminal arista is absent, and even in the few cases where the petals are bifid (some species of *Anisophyllea*), they do not individually enclose one or more stamens. Other floral differences are seen in gynoecial morphology. The several styles are separate all the way to their bases in all Anisophylleaceae. The inferior ovary is evidently ancestral for the family (not superior, as in Rhizophoraceae). The morphology of the nectary in Anisophylleaceae is unusual. The mature nectary is both inter- and intrastaminal and is cleft to its base in many places (Fig. 23). Information on its development is lacking, but it is safe to speculate that it is likely to be very different from that of nectaries of Rhizophoraceae.

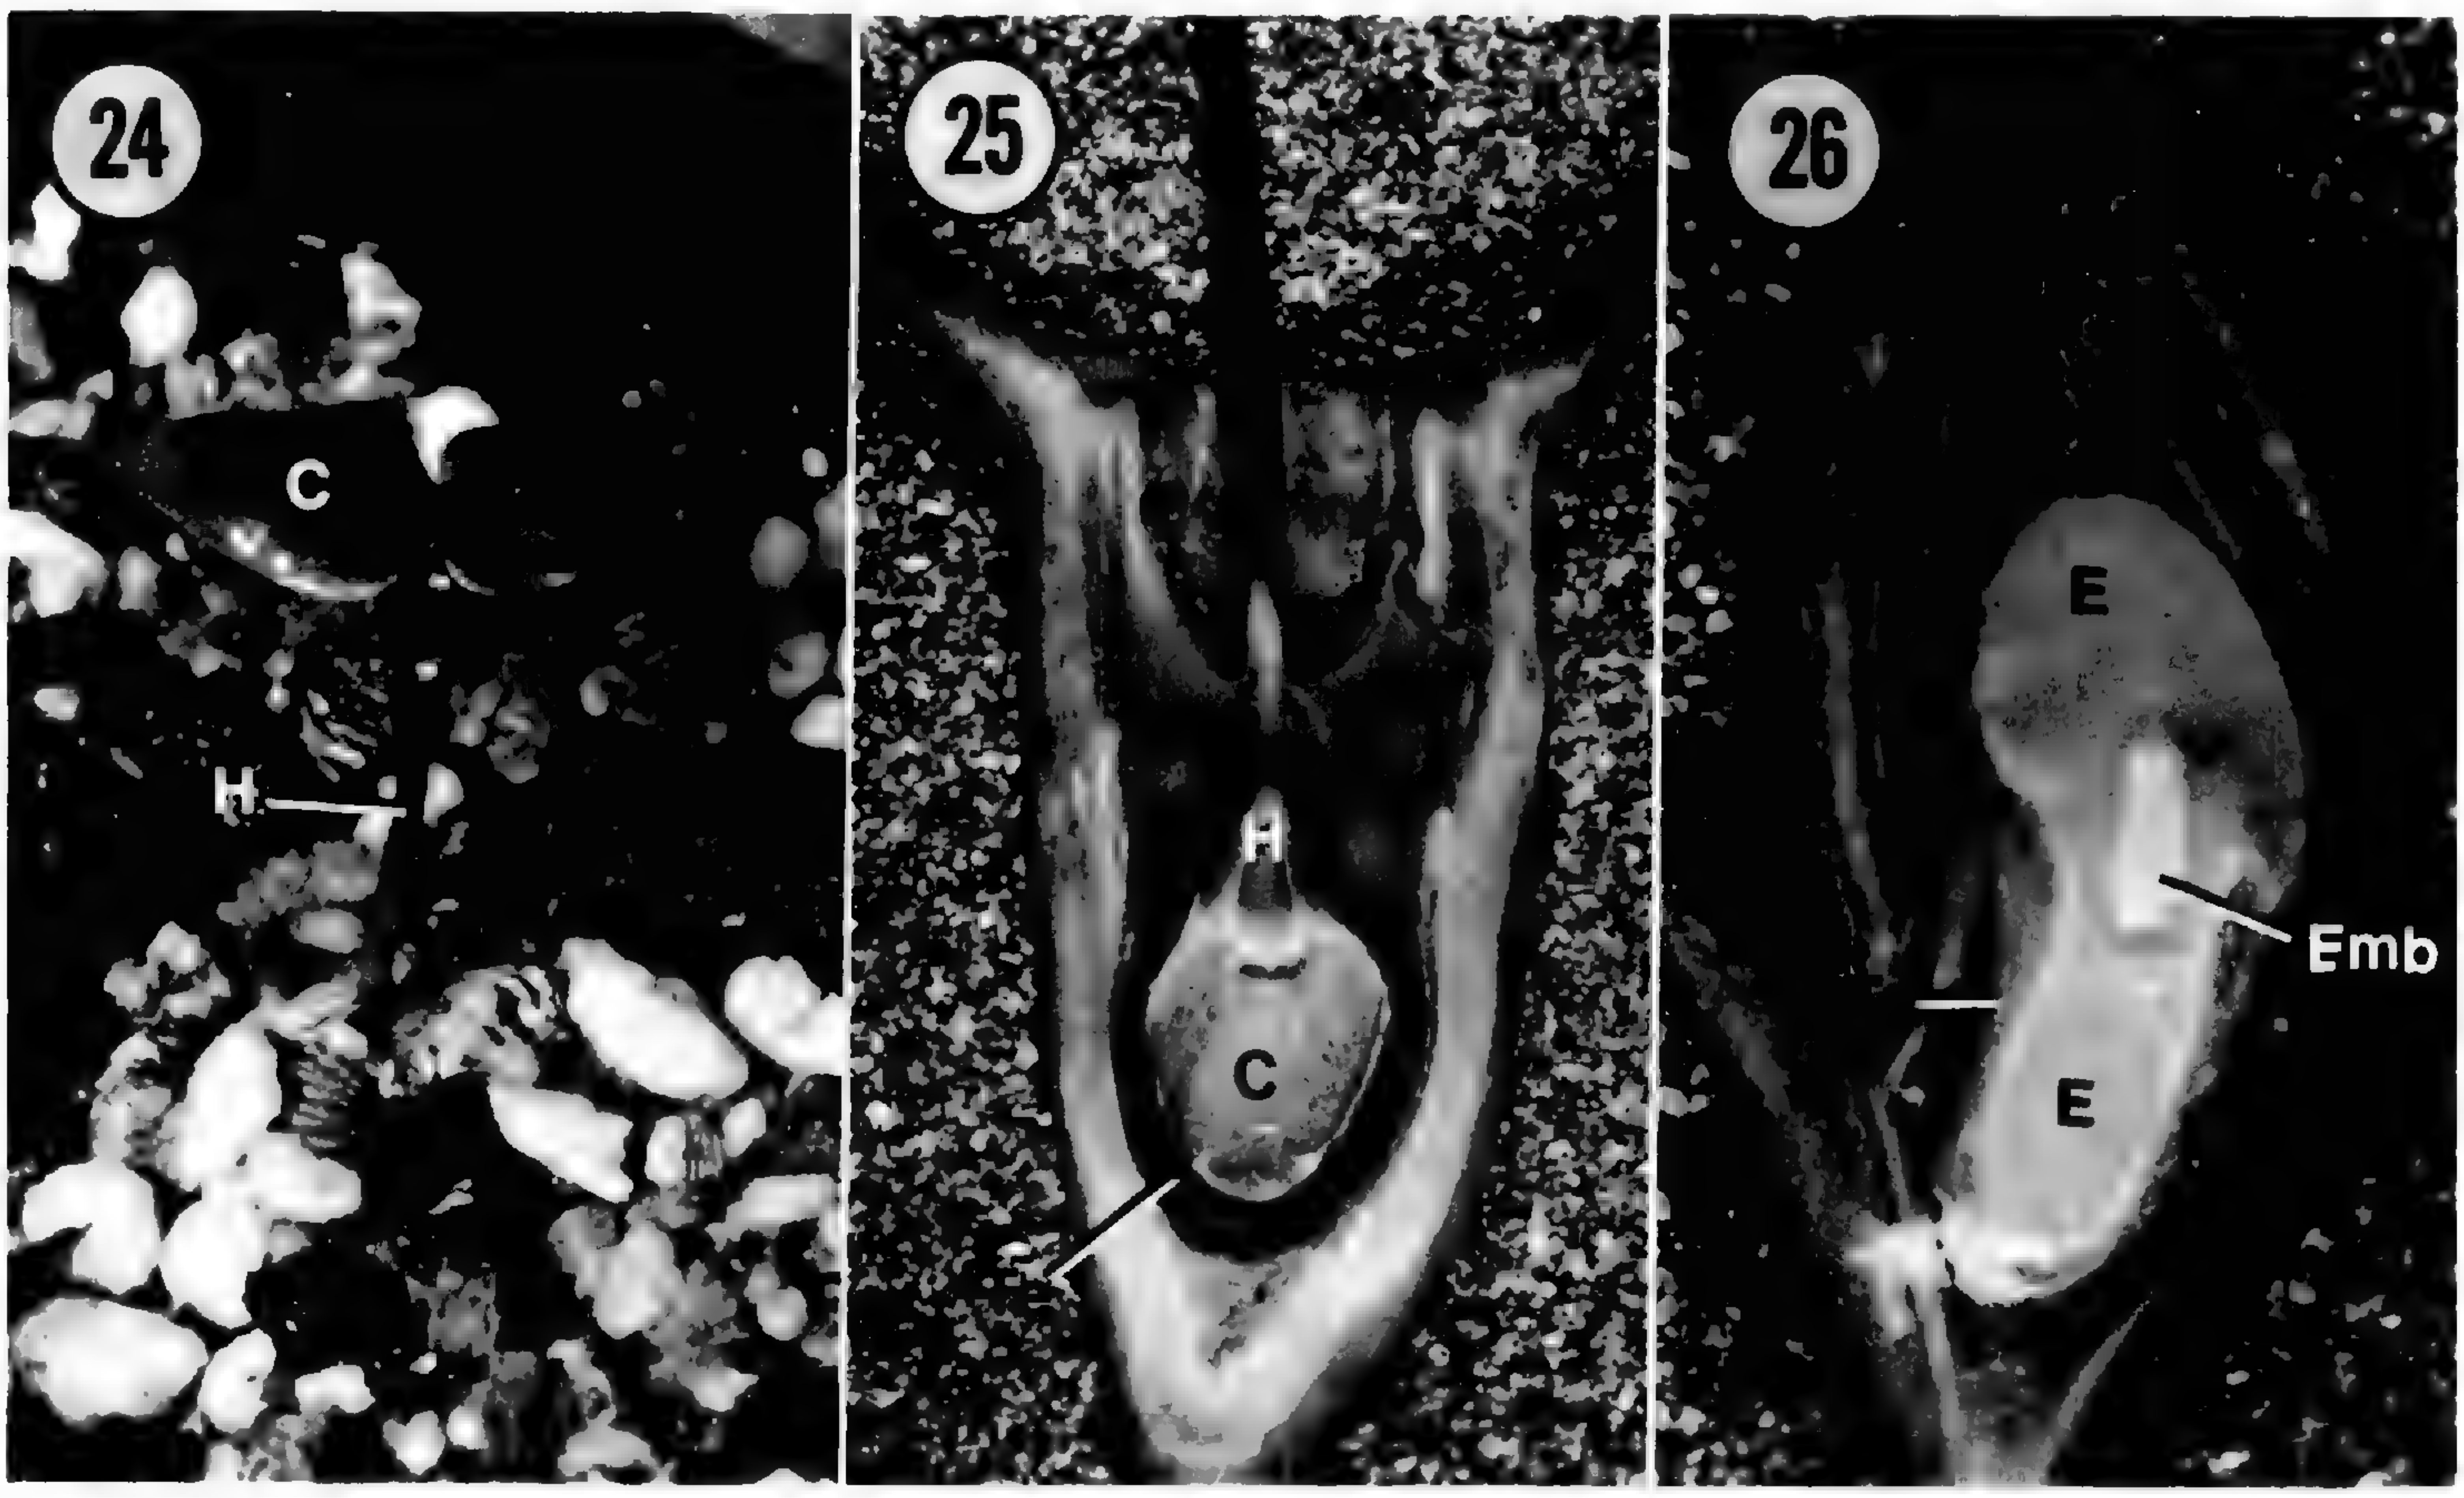
FRUIT AND SEED

Within the Rhizophoraceae, a clear evolutionary trend can be seen in fruit structure. All Macarisieae have capsular fruits, although these vary in their degree of sclerification and in how readily they dehisce. The tough-fleshy capsules of *Cassipourea elliptica* (Sw.) Poir., for example, often (always?) drop from the trees unopened, dehiscing on the ground as they dry slightly; the arillate seeds are then carried off in great numbers by leaf-cutter ants. Field observation on the Osa Peninsula of Costa Rica revealed that the ants carry the seeds into the nest, remove the arils, and discard the stripped seeds (Juncosa, pers. obs.). This may seem an unadaptive destination, but Prance (pers. comm.) correctly pointed out that the dispersal function is satisfied by those seeds dropped along the way by accident or as a result of such common disturbances as rain showers. In *Cassipourea*, presence of the aril does not inhibit germination. The comparatively large (3.5 cm), woody capsules of *Anopyxis* have been described as indehiscent, but we imagine that the description was based on immature fruits; it seems overwhelmingly likely that a canopy tree with winged seeds would also have dehiscent fruits. Consideration of the probable cladistic relationship of genera yields the interesting conclusion that some or all of the arillate-seeded genera were derived from winged-seeded ancestors. The homology of wing and aril is established by Tobe & Raven (this volume) on the basis of comparative morphology of mature seeds; these authors consider the aril to represent the ancestral condition, primarily because of its strong correlation with a superior ovary. Fruits of *Crossostylis* (Gynotrocheae) are also capsular, often only partly dehiscent, the small seeds falling out through the slots.

Fruits of all Gynotrocheae other than *Crossostylis* and those of all Rhizophoreae are baccate, and the seeds are naked. In *Gynotroches* and *Pellacalyx*, the many small seeds are embedded in a nearly homogeneous juicy berry. In *Carallia* and in Rhizophoreae, a distinctive loose spongy region develops below the ovules, allowing for the rapid early expansion of the seed(s). In *Ceriops*, *Kandelia*, and *Rhizophora* the superior portion of the ovary develops greatly in fruit.

The seed coats of all Macarisieae and most Gynotrocheae are characterized by a sclerified exotegmen (Corner, 1976; Juncosa, 1984a and unpubl.; Tobe & Raven, 1987b), but this structure is absent from seeds of *Carallia* and the Rhizophoreae. That this absence probably represents an evolutionary loss is supported by developmental evidence: the outer epidermis of the inner integument of *Carallia* ovules is histologically distinctive, as in other inland genera, but the cells fail to expand and sclerify.

Fruits of most Anisophylleaceae are drupaceous, unlike those of any Rhizophoraceae. The fruit of *Combretocarpus* is light and three-winged, so it is not surprising that the development of a heavily sclerified endocarp is suppressed. The seed coats of Anisophylleaceae lack a sclerified exotegmen and differ in other respects from those of Rhizo-



FIGURES 24–26. *Seedling germination in Rhizophoraceae.—24. Epigeal germination in* Cassipourea elliptica.—*25. Viviparous germination by growth of hypocotyl in* Bruguiera exaristata.—*26. phoraceae (Tobe & Raven, 1987a). Seeds of Anisophylleaceae also lack endosperm (Floret, 1979), which is present in all Rhizophoraceae.

EMBRYO AND GERMINATION

As far as is known, all inland Rhizophoraceae have epigeal germination and foliaceous cotyledons (Fig. 24) (*Cassipourea*: Juncosa, 1982a, b, 1984a; *Carallia, Pellacalyx,* and *Gynotroches*: Geh & Keng, 1974; Ng, 1980; Ng & Sanah, 1979; Ng, pers. comm.). Development of the embryo to a large seedling while still attached to the parent plant (vivipary) characterizes the Rhizophoreae and offers interesting material for comparative study. Germination morphology in these (mangrove) genera has been classified as "Durian-germination," in which the hypocotyl elongates, but the cotyledons remain hidden (Ng, 1978). Both outgroup comparison (with all inland Rhizophoraceae) and comparative developmental morphology indicate that this is a modification of ancestral epigeal germination.

Among the Rhizophoreae, cotyledonary morphology varies. *Bruguiera* species have two or three cotyledons, which are thick and fleshy and remain permanently within the seed coat throughout the viviparous seedling development. The development of these cotyledons and their median-plus-split-laterals vasculature reveals their foliaceous ancestry; they also subtend axillary buds (Juncosa, 1984b). In the more advanced Rhizophoreae, however, the cotyledons arise as a single toroidal primordium and form a solid cylindrical body, sometimes becoming 2–3-lobed distally; it is vascularized by many separate traces, evenly spaced. Vasculature of the cotyledonary body of *Kandelia* is intermediate between that of *Bruguiera* and that of *Ceriops* and *Rhizophora.*

In addition to being the only genus in the tribe with separate cotyledons, *Bruguiera* also exhibits the intermediate condition in the evolution of vivipary: the embryo grows to fill the seed completely, then germination occurs by elongation of the hypocotyl, much as in the nonviviparous inland genera (Fig. 25). Endosperm is not involved in viviparous germination. However, in *Ceriops, Kandelia* and *Rhizophora,* the micropyle is forced open by growth of the endosperm, which in *Rhizophora* may even carry the undifferentiated proembryo partially or entirely out of the seed (Fig. 26). In all genera, the cotyledonary body subsequently grows to fill the seed coat, with only a thin layer (usually one cell thick) of intervening endosperm. This persistent endosperm forms transfer cells (Juncosa, 1982a, b). A considerable amount

TABLE 1. *Summary comparison of Rhizophoraceae and Anisophylleaceae. Refer to text for important details and exceptions.*

	Rhizophoraceae (14 genera)	Anisophylleaceae (4 genera)
Growth	continuous	rhythmic
Branch differentiation	minimal	extreme
Wood	very heterogeneous	large vessels, alternate pitting with coalescent apertures
Aerial stilt roots	formed in Gynotrocheae and Rhizophoreae	not formed
Phyllotaxis	leaves opposite (bijugate or decussate)	leaves alternate (distichous or tetrastichous)
Stipules	present, interpetiolar	vestigial or absent
Leaf morphology	toothed margins in inland genera	entire margins
Nodal anatomy	tri- or multilacunar, split laterals	unilacunar
Inflorescences	cymose (dichasial changing to monochasial)	racemose (to paniculate)
Floral histology	subepidermal laticifers	no laticifers
Petals	bifid, fringed, with terminal aristata, convolute	sometimes fringed or divided, not folded
Ovary	superior to inferior	inferior
Fruit	capsular to baccate	drupaceous or winged
Seed coat	sclerified exotegmen in most inland genera	sclerified exotegmen absent
Seed	albuminous	exalbuminous
Cotyledons	laminar (modified in mangroves)	minute or absent
Germination	epigeal or viviparous	hypogeal
Sieve-tube plastids	Pv-type	S-type
Chromosome number	$n = 14, 18, 21, 32$	$n = 7, 8$

of endosperm emerges from the seed coat in all three genera. In *Rhizophora,* this endosperm merely forms a collar around the (intercalary) meristematic upper portion of the hypocotyl (Juncosa, 1982a), but in *Ceriops* and *Kandelia* it grows invasively into the ovary wall, forming an irregularly branched haustorium.

Embryo anatomy and germination in Anisophylleaceae differ sharply from that of any Rhizophoraceae. The embryo in Anisophylleaceae has a massive hypocotyl, with the cotyledons represented by minute scales (*Anisophyllea*) or even entirely absent, not even detectable under microscopic examination (*Poga*; Floret, 1979). Germination is hypogeal, with all of the morphological characteristics associated with that growth habit (e.g., earliest epicotyledonary leaves cataphylls, not foliaceous as in epigeal germination). In *Anisophyllea disticha,* shoots may arise from both ends of the seed (Geh & Keng, 1974). Regrettably, anatomical information is lacking.

CYTOLOGY

Chromosome numbers are often regarded as systematically important, but only a few genera of these two families have been counted. Rhizophoreae uniformly have $n = 18$ (Sidhu, 1968; Yoshioka et al., 1984). *Crossostylis* has $n = 14$ (Tobe & Raven, pers. comm.); *Anopyxis,* $n = 32$ (Mangenot & Mangenot, 1958). Counts of $n = 18$ and $n = 21$ have been reported in *Cassipourea* (Weiss, 1973; Juncosa, unpubl.); further data from this large genus are urgently needed. Chromosomes throughout Rhizophoraceae are extremely small, most of them being about 1 μm long.

Chromosome numbers in Anisophylleaceae have been counted only in sectioned material (Tobe & Raven, 1987a) but show quite different numbers ($n = 7, 8$), which have not yet been observed in Rhizophoraceae.

Other systematic characters that have recently proved revealing include sieve-tube plastids. Behnke (1982) found that Anisophylleaceae have S-type (starch-containing) plastids, whereas Rhizophoraceae have the rare PVc-type, in which crystalline protein inclusions are found. Further discussion of this and several important chemical characters appear in Dahlgren (this volume).

SYSTEMATIC CONCLUSIONS

A summary of the systematic characters of Anisophylleaceae and Rhizophoraceae (Table 1) re-

TABLE 2. *Characters used in cladistic analysis (Fig. 27). See text for full descriptions of many of the one-word character states.*

	Condition		
Character	Ancestral (00)	Derived (01/10)	More Derived (11)
1. Stilt roots	absent	present	
2. Root hairs	present	absent	
3. Phyllotaxy	decussate	bijugate	
4. Stipule vernation	valvate	imbricate	
5. Leaf margin	serrate	entire	
6. Hypodermis	absent	present	
7. Salt-tolerant?	no	yes	
8. Inflorescence	open-branched	fasciculate	
9. Terminal flower	present	absent	
10. Breeding system	hermaphroditic or monoecious	dioecious	
11. Floral laticifers	one layer	radially expanded	idioblastic[1]
12. Petal arista	as laterals	differentiated	
13. Lateral appendages	present	abort	never initiated
14. Petal orientation	reflexed	erect	
15. Androecium	diplostemonous	polyandrous	
16. Hypanthium[2]	absent	present	
17. Ovary position	superior	half-inferior	inferior
18. Locule formation	enclosure	schizogeny	
19. Carpels	5	3/many	2
20. Ovules per locule	2	5–8	
21. Receptacle	solid	spongy	
22. Exotegmen	present	vestigial	absent
23. Nucellus	crassinucellate	tenuinucellate	
24. Integument	not vascularized	vascularized	
25. Seed appendage	wing[3]	aril[3]	none
26. Seeds per fruit	several to many	1	
27. Fruit	dehiscent	baccate	
28. Cotyledons	separate	connate	
29. Cotyledonary node	unilacunar	trilacunar	multilacunar
30. Extra-ovular endosperm	absent	present	
31. Endosperm transfer cells	absent	present	
32. Viviparous?	no	yes	
33. Germination process	by hypocotyl	by endosperm expansion	
34. Seedling establishment	by radicle	by lateral roots	

Autapomorphy	Genus
35. Multimery	*Bruguiera*
36. Explosive pollination system[4]	*Bruguiera*
37. Cotyledonary axillary buds	*Bruguiera*
38. Coleorhiza	*Bruguiera*

41. Stellate pubescence	*Pellacalyx*
42. Trichosclereids	*Rhizophora*
43. Anemophily	*Rhizophora*
44. Multilocellate anthers	*Rhizophora*
45. Abortion of first epicotyledonary leaves	*Rhizophora*

[1] The idioblastic laticifers or mucilage cells of *Gynotroches* and *Pellacalyx* are here interpreted as derived from the radially expanded ones of other Gynotrocheae. They may actually be instead a cell type *sui generis* within the family, but this has no effect whatever on the cladogram.

[2] Used here as a perianth/androecium character, independent of ovary position.

[3] Separate analyses were carried out with the aril as the ancestral condition, but the resulting trees were essentially topologically equivalent and equally (not more) parsimonious.

[4] Evolved independently in *Ceriops tagal*; not present in *C. decandra*.

veals virtually no points of agreement. The very few points of vegetative similarity are clearly homoplasies—for example, entire leaves in tribe Rhizophoreae and in Anisophylleaceae. The most frequently cited floral character state common to both families is fimbriate petals (e.g., Tobe & Raven, 1987a), but this also occurs in many dicotyledonous families and is even a diagnostic character of several of these (e.g., Cunoniaceae, Elaeocarpaceae). Moreover, as emphasized above, the petals of Rhizophoraceae have a unique pattern of development and mature morphology and vernation. The ancestral androecial condition in both Rhizophoraceae and Anisophylleaceae is diplostemonous, but this can hardly be regarded as a synapomorphy, as it is found in many other apopetalous dicotyledons. We feel that the overwhelming number of differences in all aspects of growth, anatomy, and reproductive cycle of Rhizophoraceae and Anisophylleaceae make it clear that these two families are not at all closely related. It is to be hoped that the data assembled in addressing this question will also aid in assigning them to their correct phylogenetic positions.

Although more information about the poorly known African genera of Macarisieae will be required before the family can be rigorously revised, a well-supported cladogram (Fig. 27) has been derived from analysis of the 45 characters listed in Table 2. Many other characters that we were unable to study in crucial taxa, or the coding of which could not be satisfactorily resolved, or whose states were unknown in as many as half of the genera, were not included in this preliminary analysis. For the sake of consistency, all anatomical character states noted were derived from our own observations. Computer analysis was carried out using the Phylogeny Inference Package (PHYLIP; Felsenstein, 1985); the PENNY branch-and-bound algorithm was utilized to ensure that all most parsimonious trees were found. Characters were weighted equally and all reversals were permitted. Primarily due to the paucity of characters distinguishing genera of Macarisieae, numerous alternative most-parsimonious trees were found, but all were essentially topologically equivalent and reflected only different placements of the clades and genera of this tribe. Specifying the ancestral condition of the seed appendage as arillate, as would be indicated by comparison with the hypothetical out-groups (Dahlgren, this volume), neither resolves this point nor results in a more parsimonious tree. We emphasize again that more characters from a variety of aspects of the plants are required in order to elucidate the relationships of the Macarisieae.

A complete character analysis and discussion of generic relationships will be presented elsewhere, but several comments are appropriate here. Tribe Gynotrocheae is clearly paraphyletic and is maintained here and in our synopsis (Juncosa & Tomlinson, this volume) merely for convenience. Despite the occurrence of arils in *Crossostylis*, a character traditionally given much weight, it is clear that this genus is much more closely related to other Gynotrocheae than it is to Macarisieae. It is also evident that *Carallia* is more closely allied to the mangroves than is any other inland genus. In fact, *C. borneensis* shares several additional characters with the mangroves (vascularized integument, frequently single-seeded fruits, complete disappearance of exotegmic cell layer, etc.) that we have conservatively regarded as homoplasies at present. If the extra-stipular glands, the only apomorphy distinguishing the genus, do not occur in all species, then the genus may have to be regarded as paraphyletic, with *C. borneensis* and possibly other species placed further up on the clade leading to Rhizophoreae.

It is instructive to note which characters are homoplastic in Rhizophoraceae. Polyandry occurs in *Kandelia*, *Crossostylis*, and in two subgenera of *Cassipourea*, all independent origins of this character. As described above, this is also reflected in the different modes of development of the additional stamens or, in the case of species of *Crossostylis* not yet studied developmentally, in the positions of those stamens. Condensation of inflorescences also arose at least three times, as did the suppression of later development of the lateral appendages of the petals; this is hardly surprising, considering the minor developmental changes that are involved. Traditionally, the number of carpels or locules and the position of the ovary have been regarded as systematically important, but it is clear that substantial changes in both of these characters have occurred within the Rhizophoraceae. However, the trend from a superior ovary to half-inferior to inferior is reversed only once, in the female flowers of *Gynotroches*. In these, a secondary expansion of the superior portion of the ovary occurs, accommodating the increased number of ovules. Male flowers of the genus also form an ovary and (slightly fewer) ovules, but the ovary is half-inferior. In our judgment, the agreement between the unbiased cladistic analysis and the developmental evidence strongly supports our systematic conclusions.

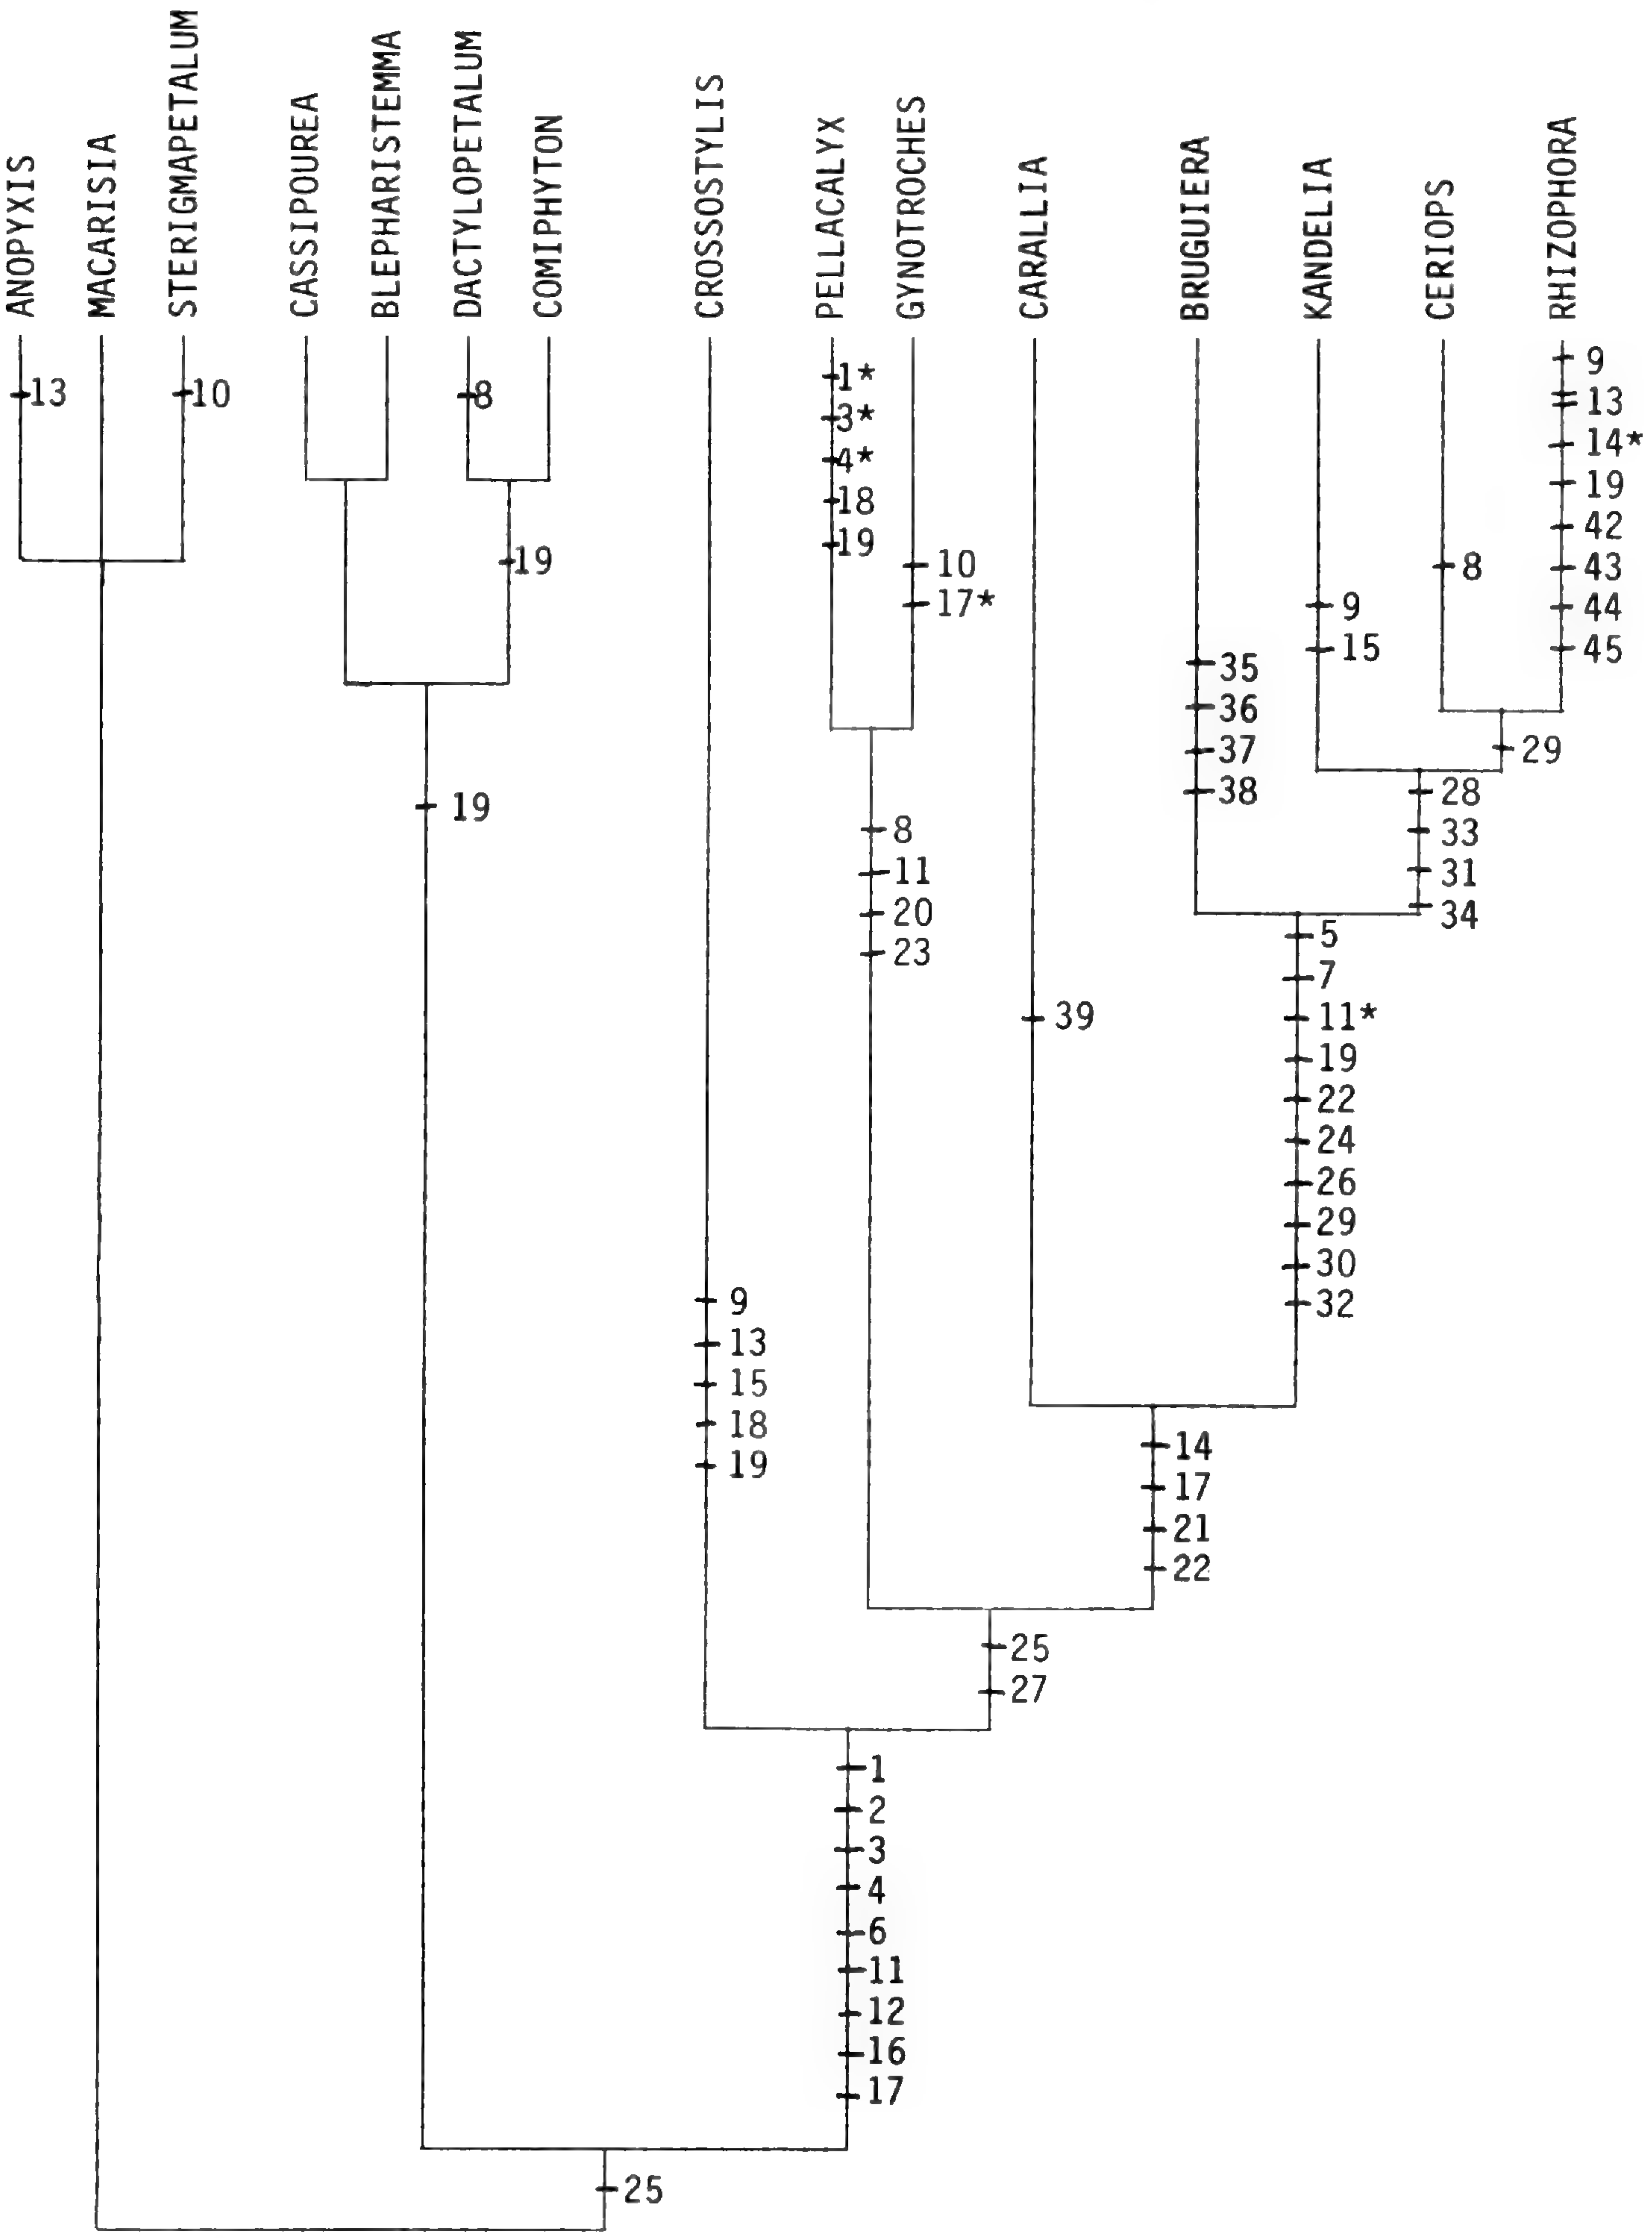

FIGURE 27. *Probable phylogenetic relationships of genera of Rhizophoraceae, a most-parsimonious cladogram resulting from analysis of the characters listed in Table 2 by PHYLIP (see text). Alternative equally parsimonious trees reverse the positions of the two basal clades and the genera that terminate them; all these nodes basically represent trichotomies. On the diagram, each mark indicates a one-step change in character state (thus two marks for the exappendiculate petals of* Rhizophora*); characters noted as changing in more than one place may be multistate or homoplastic or both. Asterisks indicate reversals.*

ECOLOGY AND BIOLOGY

The ecological status of mangroves is presented by Tomlinson (1986: 23) as that of species combining the attributes of pioneer species (e.g., early flowering, wide distribution, extended or even continuous flowering and fruiting, short period of dormancy) with attributes of mature-phase species (dense wood, slow growth, large seeds). It is suggested that this is because there is no real succession in the community (although zonation is pronounced) so that individuals have to be both pioneers and climax constituents at different stages in their life span within communities that are inherently unstable. The vegetation itself (mangal) largely shows the characteristics of a pioneer community.

Little is known about the ecology of terrestrial taxa in both families; this makes difficult the search for possible ancestral traits of mangrove taxa within extant rain forest plants.

The following paragraphs outline some of these morphological and biological features, with inevitable emphasis on mangrove taxa, which have been most extensively studied. These plants are unusual in the possibilities they offer, not only for systematic out-group comparison, but for *ecological* out-group comparison, since it is useful to establish those features that occur in unrelated mangrove taxa, i.e., in mangrove members of other families, and which may suggest themselves as features of direct functional significance, and therefore of limited systematic and phyletic value. Aerial roots are an obvious example. In contrast, some features occur in mangrove taxa but not in their terrestrial or ecological relatives.

AERIAL ROOTS

The aerial roots of *Rhizophora* are all initiated from above-ground parts and develop as a series of sympodial loops, which branch aerially only when they are damaged or when the root apex becomes anchored at the end of a loop (Fig. 28). Sympodial branching is adventitious and is of two contrasted kinds. After damage it is distal, i.e., immediately behind the damaged portion, but after anchoring it is proximal, i.e., some distance behind the point of anchorage. A remarkable anatomical transformation occurs in aerial roots as they become submerged distally. Aerial roots have extensive development of trichosclereids, lack aerenchyma, develop secondary xylem, and branch infrequently and adventitiously. Submerged roots lack trichosclereids and other mechanical tissues, develop a lacunose aerenchymatous cortex, have little secondary xylem, and branch abundantly and nonadventitiously. This kind of root system seems unique to *Rhizophora.* On old trees the trunk-borne roots develop as massive flying buttresses, the trunk base itself being obconical (Fig. 1).

As described in the previous section, *Ceriops tagal* and *Bruguiera sexangula* develop a fluted base formed by the coalescence of clusters of stilt roots that are initiated on the hypocotyl after the seedling has taken root (Fig. 2). This kind of development is also found in the quite unrelated New World mangrove *Pelliciera rhizophorae* (Pelliceraceae) (Tomlinson, 1986). Flutings of this kind seem also to be the maximum extent of aerial root development in *Kandelia.* However, in *Ceriops* and some species of *Bruguiera* an emergent portion of the subterranean root system further develops by the periodic looping of the major horizontal roots, each loop becoming the site of a woody pneumatophore from which branch roots subsequently arise (Fig. 29).

Aerial roots in tropical woody plants have a specific function in supplying oxygen to the submerged roots by the shortest possible pathway in anaerobic, waterlogged substrates. Consequently, such structural variations can be seen as convergences in which developmental modifications result in an identical suite of clearly nonhomologous functional components (Gill & Tomlinson, 1975; Tomlinson, 1986). The functional components always include anchoring and absorption, connecting the separate units horizontally (cable component), and providing for aeration. Consequently, we are provided with a clear picture of the limited value of aerial roots in phyletic analysis. At the same time, this aspect of functional morphology could be a necessary preadaptation in a hypothetical ancestor for the Rhizophoreae. *Kandelia,* which lacks pneumatophores, makes implausible any direct statement about the root system of ancestral mangrove Rhizophoraceae, since it could represent either an ancestral or a derived state. Troll & Dragendorff (1931) denied that aerial roots have a respiratory function and preferred to see them as allowing the trees to root in sediments whose level may fluctuate. The aerating and layering functions are, of course, not mutually exclusive.

WOOD ANATOMY

The relevance of wood anatomy to ecological as distinct from phyletic considerations is again well borne out by a comparison between the mangrove and nonmangrove Rhizophoraceae. The former are uniformly characterized by relatively narrow vessels with scalariform perforation plates, the latter by wider vessels with partly or exclusively simple perforation plates. One can ascribe the differences in vessel diameters to direct ecological causes because they render the wood of mangroves safer in environments where vessel embolisms are likely to be more frequent as tensions are increased because of the low water potential of sea water (Scholander et al., 1965). Safety is maximized by the production of large numbers of narrow elements (Tomlinson, 1986; Zimmerman, 1983). On the other hand, scalariform perforation plates, whose function is quite unknown, do not seem to have any necessary significance in relation to water stress as suggested by "ecological out-group comparison." Vessel elements in all other true mangroves have simple perforation plates (Janssonius, 1950; Panshin, 1932). Significantly, Sperry (1985) provided experimental evidence that scalariform perforation plates in the palm *Rhapis excelsa* restrict the size of bubbles in recently embolized vessels as they refill with water under positive pressures. Restricting bubble size may facilitate recovery of vessels after water columns are broken during exceptional water stress in any plant. Mangrove Rhizophoraceae could then have a functional advantage not found in their ecological associates from other families.

ARCHITECTURE

Phyllotactic differences between Rhizophoraceae and Anisophylleaceae, so far as they are understood, are but one of a suite of characters that lead to architectural differences of quite a fundamental nature. In the Rhizophoraceae there is a strong tendency toward continuous growth and the expression of Attims's model, whereas *Anisophyllea* suggests rhythmic growth and Massart's model. Continuous growth has been suggested as an adaptive feature in mangrove taxa simply because the tree must remain permanently active metabolically in order to maintain its salt balance (Scholander, 1968; Hallé et al., 1978; Tomlinson, 1986). Trunk axes are therefore monopodial, although they may branch continuously or diffusely. Branching seems always to be by syllepsis (Fig. 31; cf. Wheat, 1981). The branches themselves may then repeat the structure of the parent axis (Attims's model, as in *Rhizophora*) but progressively become plagiotropic by apposition (Fig. 30). Their incipient orthotropy is, however, demonstrated when they are released from apical control; reiteration in *Rhizophora* occurs chiefly by dedifferentiation of existing sylleptic branches.

Species of *Bruguiera*, notably *B. gymnorrhiza*, more nearly conform to Aubréville's model, since from inception the branches are plagiotropic by apposition. Dedifferentiation of axes is less common. Although distal branches in trees belonging to these contrasted models all become superficially similar, there is a strong underlying difference: *Bruguiera* tends to remain narrow-crowned, while *Rhizophora* is very plastic in its crown form, especially as lower branches are readily supported by aerial roots. Very likely part of the ecological success of *Rhizophora* as compared with *Bruguiera* lies in this greater plasticity of form. Little is known about the architecture of inland Rhizophoraceae, but superficial study suggests a limited range of crown form comparable to that in *Bruguiera*. *Carallia* and *Gynotroches* seem to conform to Attims's model.

Anisophyllea, in contrast, provides an extreme example of Massart's model (Vincent & Tomlinson, 1983), since the trunk grows episodically, producing pronounced tiers of branches, which are themselves strongly plagiotropic. The trunk axis supports only scale leaves. The differences in phyllotaxis that underlie this contrast have already been mentioned.

Multiple serial buds occur in *Anisophyllea* spp. and some other Anisophylleaceae. The extent to which these are committed at inception to become either reproductive or vegetative branches is unknown. Serial buds also occur in Rhizophoraceae but are more strictly committed at the inception of the first primordia on the axillary apex; the pair of bracteole primordia that form on a future inflorescence apex can be distinguished from leaf primordia that form on a future vegetative apex. It should be emphasized that in most Rhizophoraceae that we have studied, vegetative branching is by syllepsis, additional vegetative "reserve" buds may be formed as part of a primary branch complex, but their further development is very limited (Wheat, 1981). In both inland and mangrove genera, when the plant is in reproductive condition, an inflorescence develops in the axil of each leaf of a pair, and, at least on vigorously growing shoots, a single vegetative bud develops above this, although it is often not evident even with a hand lens. In adult *Rhizophora*, reiteration can occur from these residual buds, but more usually reiteration is the result of dedifferentiation of existing branches. Adventitious buds, however, do occur on the hypocotyl of damaged seedlings (Larue & Muzik, 1954; Gill & Tomlinson, 1969).

In summary, we recognize that Rhizophoraceae and Anisophylleaceae differ in architecture and reiterative ability in ways that support their seg-

regation as two families. If this discussion seems imperfectly formulated, it is simply because the problem of morphological plasticity in woody plants of the tropics itself is a subject that remains little understood, despite its considerable ecological importance.

FLORAL MECHANISMS

Understanding of floral structure and development stands in an interesting relationship to our knowledge of floral mechanism, which is fairly complete for the mangrove taxa, from the work of Tomlinson et al. (1979) and Kondo et al. (1987), but is scarcely investigated for either terrestrial Rhizophoraceae or Anisophylleaceae. In the Rhizophoreae there is an initial contrast between *Rhizophora*, which is wind-pollinated, and the other genera, which are animal-pollinated. Evidence for wind pollination comes from floral mechanism, pollen–ovule ratios, dispersibility of pollen, and infrequency of insect visitors, even though the flowers do not display a conspicuous wind-pollination syndrome as it is familiarly understood for temperate trees. Animal pollinators of other genera include birds, bees, moths, and butterflies, at least, with each species or group of species visited by a particular type of flower visitor. Floral specialization involves a very distinctive explosive mechanism that physically projects the light pollen onto the visitor but only when the mechanism is tripped by the visitor (cf. Figs. 32, 33). Differences in the biotic interaction relate to differences in flower size, orientation, and attractant (nectar and odor). *Ceriops decandra* and *Kandelia* lack any specialized mechanism and seem to be pollinated by rather generalized visitors. Of interest is that *Ceriops tagal* and *C. decandra* are strongly contrasted in their floral mechanism. The existence of light powdery pollen in the taxa with animal pollination is an example of the way in which pollen characteristics may be misleading about the method of pollination; most animal-pollinated plants have heavy, sticky pollen. In the Rhizophoreae one may speculate that this pollen type is a preadaptation for wind pollination in *Rhizophora*, which represents

a derived condition, and is itself an adaptation to animal pollination by the distinctive explosive projection of pollen. Flower orientation itself provides contrast with reference to classes of visitor. Small-flowered species of *Bruguiera* have erect flowers, suitable for the approach from above of small, delicate-winged visitors, such as butterflies; large-flowered species of *Bruguiera* have pendulous flowers on recurved pedicels and are approached from below by large visitors like birds. There is evidence that pollination can occur in conditions of autogamy, allogamy, and gectonogamy, but none for apomixis (Kondo et al., 1987).

The general ecological conclusion is that this group of related mangrove plants partitions the available pollinator resource by adopting either different mechanisms, or, where there is a common mechanism, by varying it to suit different types of pollinator.

CONCLUSIONS

The phyletic and systematic conclusions of the various contributors to this symposium are drawn from an examination of a remarkable diversity of characters, ranging from features of gross morphology to ultrastructural details of sieve-tube plastids. Consciously or unconsciously there is a good deal of weighting of these characters; consciously because there can be bias towards acceptance of a character state if it agrees with a pre-existing position, unconsciously because a single biological character (e.g., wind-dispersed seeds) may be reflected in several morphological characters (dehiscent fruits, winged seeds, thin seed coat). Rarely is a character sufficiently understood at a functional level for the bias to be rational. The taxonomist will emphasize that it is impractical to consider the possible biological significance of all attributes of a character in making systematic hypotheses, but the consequences of this restriction should at least be understood. The more information one has about a feature used in systematic analysis, the more likely that its systematic or phyletic significance can be correctly assessed. Subjectivity is an inevitable consequence of the empiricism of systematic methodology—the papers in this symposium are replete with examples—and any claim of objective neutrality is particularly inappropriate where the evolutionary polarity of character states is continually invoked. There should be some appreciation of what may be termed "biological" attributes of characters if they are to be manipulated successfully.

Within this broad spectrum of attributes, specific attention needs to be given to three classes of information: correlation among characters; functional aspects of characters; developmental history of characters, particularly at the primordial level.

An understanding of the way in which seemingly different characters are correlated is necessary since an apparent complex that may or may not be structurally connected may all be subsumed as a single character if the interdependence is appreciated. For example, phyllotaxis, stipular morphology and nodal anatomy are interlinked; thus, aspects of nodal vasculature may be a direct expression of phyllotaxis, as in the presence or absence of split laterals, distinguishing Rhizophoraceae from Anisophylleaceae. More subtle physiological connections need to be sought, as in the relation between leaf succulence and salt-excluding mechanisms in Rhizophoraceae.

The contrast between mangrove and terrestrial taxa in such features as root morphology, leaf anatomy, wood structure, and embryo development could well be cited as characters with little systematic weight because their functional attributes are at least perceived, if not totally understood—they are the "Anpassungsmerkmal" of Schimper. It is well established that the tribe Rhizophoreae is an advanced group, even though a diagnostic feature is the presence of scalariform perforation plates in its wood. An evolutionary scenario sees this simply as the retention of a putatively primitive character. If this is true, it is surely helpful to know why it has been retained. If the preferred explanation of the function of scalariform plates in restricted air-bubble size in embolized vessels is accepted, we can appreciate its occurrence in a more informed way.

Developmental information may simply add to the range of characters made available, an attribute that strongly justifies embryological study (cf. Tobe & Raven, 1987a, b), but it can also clarify structural, functional, and correlative attributes; for example, floral development suggests that pleiomery is derived in the Rhizophoraceae. The best example is provided by *Kandelia*. Here the feature is related to a rather unspecialized floral mechanism that may be derived, not an ancestral feature. Currently we have no evidence for a specialized pollinator group in this genus. Comparative study of embryo development shows a trend of modification leading from epigeal germination to vivipary, with *Bruguiera* the least specialized within the viviparous group. "Vivipary" becomes more useful as a systematic character when viewed developmentally, even though we do not understand its functional significance. Developmental study may also reveal the extent of convergence, in which superficially similar structures show contrasted developmental pathways; the diversity of root systems is a very gross example.

These examples relate to "primordial development" (Tomlinson, 1982); "ontogenetic development" provides an independent set of attributes. The distribution of axes with contrasted kinds of phyllotaxis in Anisophylleaceae clearly has an ontogenetic component that is still incompletely explored. Once it has been done and its correlation with stem vasculature worked out, we are likely to be in a position to make evolutionary statements, because some of the phyllotactic patterns in this species are clearly derived, as indicated by their uniqueness.

Inevitably these considerations of "character analysis" to which we have drawn attention may lie in the realm of "consummations devoutly to be wished" as far as practicing systematists are concerned. Nevertheless we hope that investigations of functional, developmental, and correlative attributes can be seen to play a central role in systematics.

SEED MORPHOLOGY AND ANATOMY OF RHIZOPHORACEAE, INTER- AND INFRAFAMILIAL RELATIONSHIPS[1]

Hiroshi Tobe[2] *and Peter H. Raven*[3]

ABSTRACT

We present an overall study of the seed morphology and anatomy of all Rhizophoraceae (10 inland and 4 mangrove genera). Morphologically seeds are arillate, winged or nonappendaged; both arillate and winged seeds are borne in capsular fruits, and nonappendaged seeds in baccate or indehiscent hard-walled capsules. Seed coat anatomy is diversified in correlation with the seed and fruit morphology, but a well-developed exotesta and a fibrous exotegmen are common to all inland genera. Despite certain minor divergences, the seed coat of different genera of Rhizophoraceae is defined as exotestal, exotestal-exotegmic, or undifferentiated. Different combinations of seed morphological and anatomical features characterize different genera or groups of genera. An overall comparison of seeds and other reproductive characters confirms that in Rhizophoraceae arillate seeds and the presence of a fibrous exotegmen are plesiomorphic features that can be used in searching for related families. Seed morphology and anatomy also support grouping Rhizophoraceae with Elaeocarpaceae and Celastraceae, and the exclusion of Elaeocarpaceae from Malvales. Our comparison further suggests that the seed morphology and anatomy of Rhizophoraceae have evolved as the result of adaptation to different methods of seed dispersal from ant dispersal to dispersal by wind, bird, mammal, or water. We carried out a cladistic analysis of the genera of Rhizophoraceae on the basis of 16 reproductive characters (including those of seed morphology and anatomy). Blepharistemma, Cassipourea, Comiphyton, Anopyxis, Macarisia, *and* Sterigmapetalum, *all inland genera that have been assigned to Macarisieae, are characterized by having many plesiomorphies (particularly a superior ovary). The last three genera have winged seeds and a thinner seed coat (apomorphies), whereas the first three have arillate seeds. Among the four remaining inland genera, which have been assigned to Gynotrocheae,* Crossostylis *(with arillate seeds) differs greatly from the others in having only one apomorphy (i.e., an inferior ovary); it retains many plesiomorphies. In contrast,* Carallia, Gynotroches, *and* Pellacalyx *share a nonappendaged seed and a persistent meso- and endotegmen, both clearly synapomorphies, and* Gynotroches *and* Pellacalyx *further share some distinct synapomorphies, suggesting their close affinities. The four mangrove genera—*Bruguiera, Ceriops, Kandelia, *and* Rhizophora*—which have been segregated as Rhizophoreae, share many synapomorphies (e.g., an undifferentiated seed coat and the complete lack of the tegmen), and therefore the coherence of Rhizophoreae is not in doubt. Cladistically the mangrove genera are more closely related to* Carallia, Gynotroches, *and* Pellacalyx *than to Macarisieae. Based on our cladistic analysis, the traditional infrafamilial classification is revised, and a new tribe Crossostylideae, which consists of* Crossostylis *only, is proposed.*

Traditionally, Rhizophoraceae have been broadly defined to contain one mangrove tribe Rhizophoreae (4 genera) and three inland tribes: Macarisieae (6 genera), Gynotrocheae (4 genera), and Anisophylleae (4 genera) (e.g., Melchior, 1964). The comparative study of wood anatomy (van Vliet, 1976) and leaf architecture and anatomy (Keating & Randrianasolo, this volume; Baas, pers. comm.) has supported this broad definition of the family. In contrast, embryological evidence (Tobe & Raven, 1983), as well as an overall comparison based on various systematic characters (Dahlgren & Thorne, 1984), strongly suggested that the overall group was heterogeneous and indicated the need for further embryological studies of the constituent genera and tribes as an important key to their

relationship. Earlier embryological studies were limited to 9 of 18 genera: *Bruguiera, Ceriops,* and *Rhizophora* of Rhizophoreae (Karsten, 1891; Cook, 1907; Carey, 1934; Mauritzon, 1939; Juncosa, 1982, 1984b); *Cassipourea* of Macarisieae (Juncosa, 1984a); *Carallia* and *Gynotroches* of Gynotrocheae (Karsten, 1891; Haberlandt, 1895; Mauritzon, 1939; Corner, 1976); and *Anisophyllea, Combretocarpus,* and *Poga* of Anisophylleae (Karsten, 1891; Hou, 1958; Vaughan, 1970; Geh & Keng, 1974). Most of these studies were concerned with relatively few embryological features.

Thus we recently presented an overall embryological study of "Anisophylleae" (Tobe & Raven, 1987b) and, with support of evidence from other sources, justified the separation of Anisophylleaceae as a distinct family from the rest of Rhizophoraceae, as proposed earlier by several authors (e.g., Ridley, 1922; Cronquist, 1981, 1983; Dahlgren, 1983). Subsequently, we presented the first comprehensive embryological study on two inland genera, *Cassipourea* and *Sterigmapetalum* of Macarisieae (Tobe & Raven, 1987a), which were recently separated from Macarisieae as constituting a new tribe Hypogyneae (Steyermark & Leisner, 1983), and we provided some discussion on infrafamilial relationships based on data available. Juncosa (pers. comm.) has surveyed the respective embryological features of the remaining tribes, Gynotrocheae and Rhizophoreae. Consequently, Rhizophoraceae are becoming one of the most well-known families with respect to their embryological characters.

Previous embryological studies of Rhizophoraceae have lacked comprehensive, comparative information on the seed morphology and anatomy of the whole family. Concerning the seed morphology, Schimper (1893), Hou (1958, 1968), Floret (1974, 1976), and Tobe & Raven (1987a) described some of the constituent genera and suggested that Rhizophoraceae are diverse in this feature. However, no overall studies, except for the preliminary discussions in our previous paper (Tobe & Raven, 1987a), have been made.

Carey (1934) provided fragmentary descriptions on the seed coat anatomy of *Rhizophora* and *Ceriops* of Rhizophoreae. Later, Corner (1976) described some details of the seed coat anatomy of *Carallia, Gynotroches,* and *Pellacalyx* (all Gynotrocheae); Tobe & Raven (1987a) described those of *Cassipourea* and *Sterigmapetalum* of Macarisieae; and Juncosa studied those of *Carallia* and *Gynotroches.* These works contained important suggestions inducing further studies. For example, Corner (1976, 1: 161) defined the seed coat of both *Gynotroches* and *Pellacalyx* as "exotegmic," with the exotegmen fibrous and, on the basis of seed coat anatomy, transferred the two genera into Legnotidaceae, a family first described by Endlicher (1840) as "Legnotidae" to comprise *Cassipourea* and *Gynotroches.* Tobe & Raven (1987a) showed that *Cassipourea* and *Sterigmapetalum* (Macarisieae) have a thick and a thin testa, respectively, and are clearly distinct from each other based on seed coat anatomy. Juncosa (pers. comm.) reports that the seed coat of *Carallia borneensis* differs from those of other inland genera in having no persistent tegmen and a vascularized testa. Thus, the works of Corner (1976), Tobe & Raven (1987a), and Juncosa strongly suggested the utility of seed coat anatomy in considering relationships of genera in Rhizophoraceae and indicated that an overall study of seed coat anatomy was needed for further understanding of infrafamilial relationships. The utility of the seed morphology and anatomy in such considerations has already been demonstrated in studies on several unrelated families (e.g., Cruciferae—Vaughan & Whitehouse, 1971; Polygalaceae—Verkerke, 1985), leading to a revision of conventional tribal classifications in each case.

This paper presents the features of seed morphology and anatomy for the whole family Rhizophoraceae, which consists of 14 genera (excluding the genera of Anisophylleaceae). These results, which have revealed a considerable degree of diversity in these features, are then used together with other evidence to clarify infrafamilial phylogenetic relationships. Dahlgren (this volume) has used these features extensively in searching for relatives, and this analysis is of fundamental importance for such comparisons.

Materials and Methods

Twenty-one species representing all 14 genera of Rhizophoraceae were investigated. Collection data are provided in Table 1. For microscopic observations mature and immature seeds were microtome sectioned following standard paraffin methods described elsewhere (Tobe & Raven, 1987b). Some hard specimens, like those of *Ceriops,* were embedded in glycol methacrylate, sectioned with glass knives, and stained with 0.1% Toluidine Blue (e.g., Figs. 28, 29). Scanning electron micrographs were also used in observing seeds of *Gynotroches* and *Pellacalyx,* and they were prepared following the standard method using a JEOL 25S instrument

TABLE 1. *Studied taxa, collections, and materials. Asterisk (*) indicates that dry herbarium materials were investigated. Tribal positions of genera follow Melchior (1964) and Floret (1976).*

(Tobe & Raven, 1987b). Comparisons among genera were made on the basis of mature seeds, and when materials were available, seed coat ontogeny was investigated to understand the mature structure more completely. The terminology on seeds and seed coat anatomy follows Corner (1976) and Schmid (1986); Schmid elaborated Corner's terminology.

OBSERVATIONS

The seeds of rhizophoraceous genera have either an aril or a wing, or they lack appendages. Arillate seeds occur in *Blepharistemma*, *Cassipourea*, and *Comiphyton* (all in Macarisieae), which have loculicidally (?) or septicidally dehiscent or indeshiscent capsular fruits (Floret, 1976), and in *Cros-*

sostylis (Gynotrocheae), which has capsular fruits of unknown dehiscence mode. Winged seeds occur in *Anopyxis*, *Macarisia*, and *Sterigmapetalum* (all in Macarisieae), which have septicidally dehiscent capsular fruits (Floret, 1976; contrary to Floret, Arênes (1954) described fruit dehiscence in *Macarisia* as loculicidal, but we confirmed septicidal dehiscence in *M. pyramidata*). Nonappendaged seeds occur in *Carallia*, *Gynotroches*, and *Pellacalyx* (all in Gynotrocheae), which have baccate fruits, and in *Bruguiera*, *Ceriops*, *Kandelia*, and *Rhizophora* (all in Rhizophoreae), which have indehiscent hard-walled fruits. Both the aril and the wing develop as an outgrowth of the exostome: compare the young arillate seed of *Cassipourea malosana* (Figs. 1, 2) with the young winged seed of *Anopyxis klaineana* (Figs. 3, 4). In the case of the aril, a raphal tissue, which continues from the outer integument, may also join the aril formation; however, a funicular or hilar tissue never joins there. Therefore, as discussed in a previous paper (Tobe & Raven, 1987a), the aril and the wing are homologous to each other, and the histogenetic origin of both structures are regarded substantially as exostomal.

We have also confirmed that the seed coat anatomy correlates with the external seed morphology type (i.e., arillate, winged, and nonappendaged) and, in addition, that within the nonappendaged seed category the seeds of *Gynotroches* and *Pellacalyx* are distinct from those of *Carallia*, as already described by Corner (1976) to some degree. The details are documented below.

ARILLATE SEEDS

Blepharistemma. It has been previously uncertain whether *Blepharistemma* has an aril, a wing, or neither, because fruits and seeds of this genus are undescribed. We found for the first time that *B. membranifolia*, the only species of the genus, has a fleshy aril (Fig. 5), which covers nearly the upper half of the seed. The mature seed is ellipsoid, with a somewhat conspicuous raphe, and very slightly depressed toward the lateral side; it is 4.3–4.5 mm long and 2.4–2.5 mm thick, as measured from the raphe to antiraphe (R–A), and 2.2–2.3 mm thick from side to side (L–L) (see Tobe & Raven, 1987a, fig. 14, for directions of width measurement).

The oldest seed coat available is 0.20–0.22 mm thick in total, comprising the testa 135–142 μm thick and the tegmen about 50 μm thick. When the embryo sac is mature, the outer and inner integuments are 3–4 cells and 4–5 cells thick, respectively. The outer integument increases its thickness in postfertilization stages and eventually differentiates into a 1-cell-layered exotesta, a 3–6-cell-layered mesotesta, and a 1-cell-layered endotesta (Fig. 6). There is no clear histological difference between the mesotesta and the endotesta. Exotestal cells are radially enlarged, thick-walled, and tanniferous, forming a palisade (Fig. 6). Meso- and endotestal cells are much smaller than the exotestal cells, but also somewhat thick-walled and tanniferous. The endotestal cells often contain crystals. On the other hand, the inner integument develops into a 1-cell-layered fibrous exotegmen and 2 or 3 underlying unspecialized cell layers, the latter of which apparently disintegrates further. (The seeds investigated in this study seem still somewhat immature, and we believe that the underlying cell layers below the exotegmen eventually disappear completely.) Of the constituent cell layers, the exotesta is the most conspicuously developed as a mechanical structure; therefore, the seed coat of *Blepharistemma* is exotestal.

Cassipourea. Cassipourea is a large and variable genus (4 subgenera and 80 species (Alston, 1925; Airy Shaw, 1973)), which shows a range of variation in seed size and anatomical structure. We described some details of seed size and seed anatomy earlier (Tobe & Raven, 1987a), and therefore these are only briefly summarized here. Only data on the total thickness of the mature seed coat were added.

The mature seed is ellipsoid (*Cassipourea guianensis* and *C. gummiflua* var. *verticillata*) to broad ellipsoid (*C. malosana*) and slightly depressed to the raphe. In *C. guianensis*, the seed is 8.9–9.2 mm long and 2.6–2.8 mm thick (R–A) to 3.3–3.6 mm thick (L–L); in *C. gummiflua* var. *verticillata* it is 4.2–4.4 mm long and 1.6–1.8 mm thick (R–A) to 2.2–2.4 mm thick (L–L); in *C. malosana* it is 5.0–5.2 mm long and 2.8–3.1 mm thick (R–A) to 4.5–4.8 mm thick (L–L). The aril is fleshy and wholly covers the seed except on the chalazal and antiraphe side.

In the three examined species, the mature seed coat is 0.16–0.22 mm thick in total and is composed of a 1-cell-layered exotesta, a 2–6-cell-layered mesotesta, a 1-cell-layered endotesta, and a 1-cell-layered exotegmen; all other cell layers of the tegmen are crushed and disappear, although both the outer and the inner integuments are multiple cell-layered at the mature embryo sac stage. The exotesta comprises enlarged cuboid, thick-walled cells; the meso- and endotesta are composed of much smaller cells, and endotestal cells may

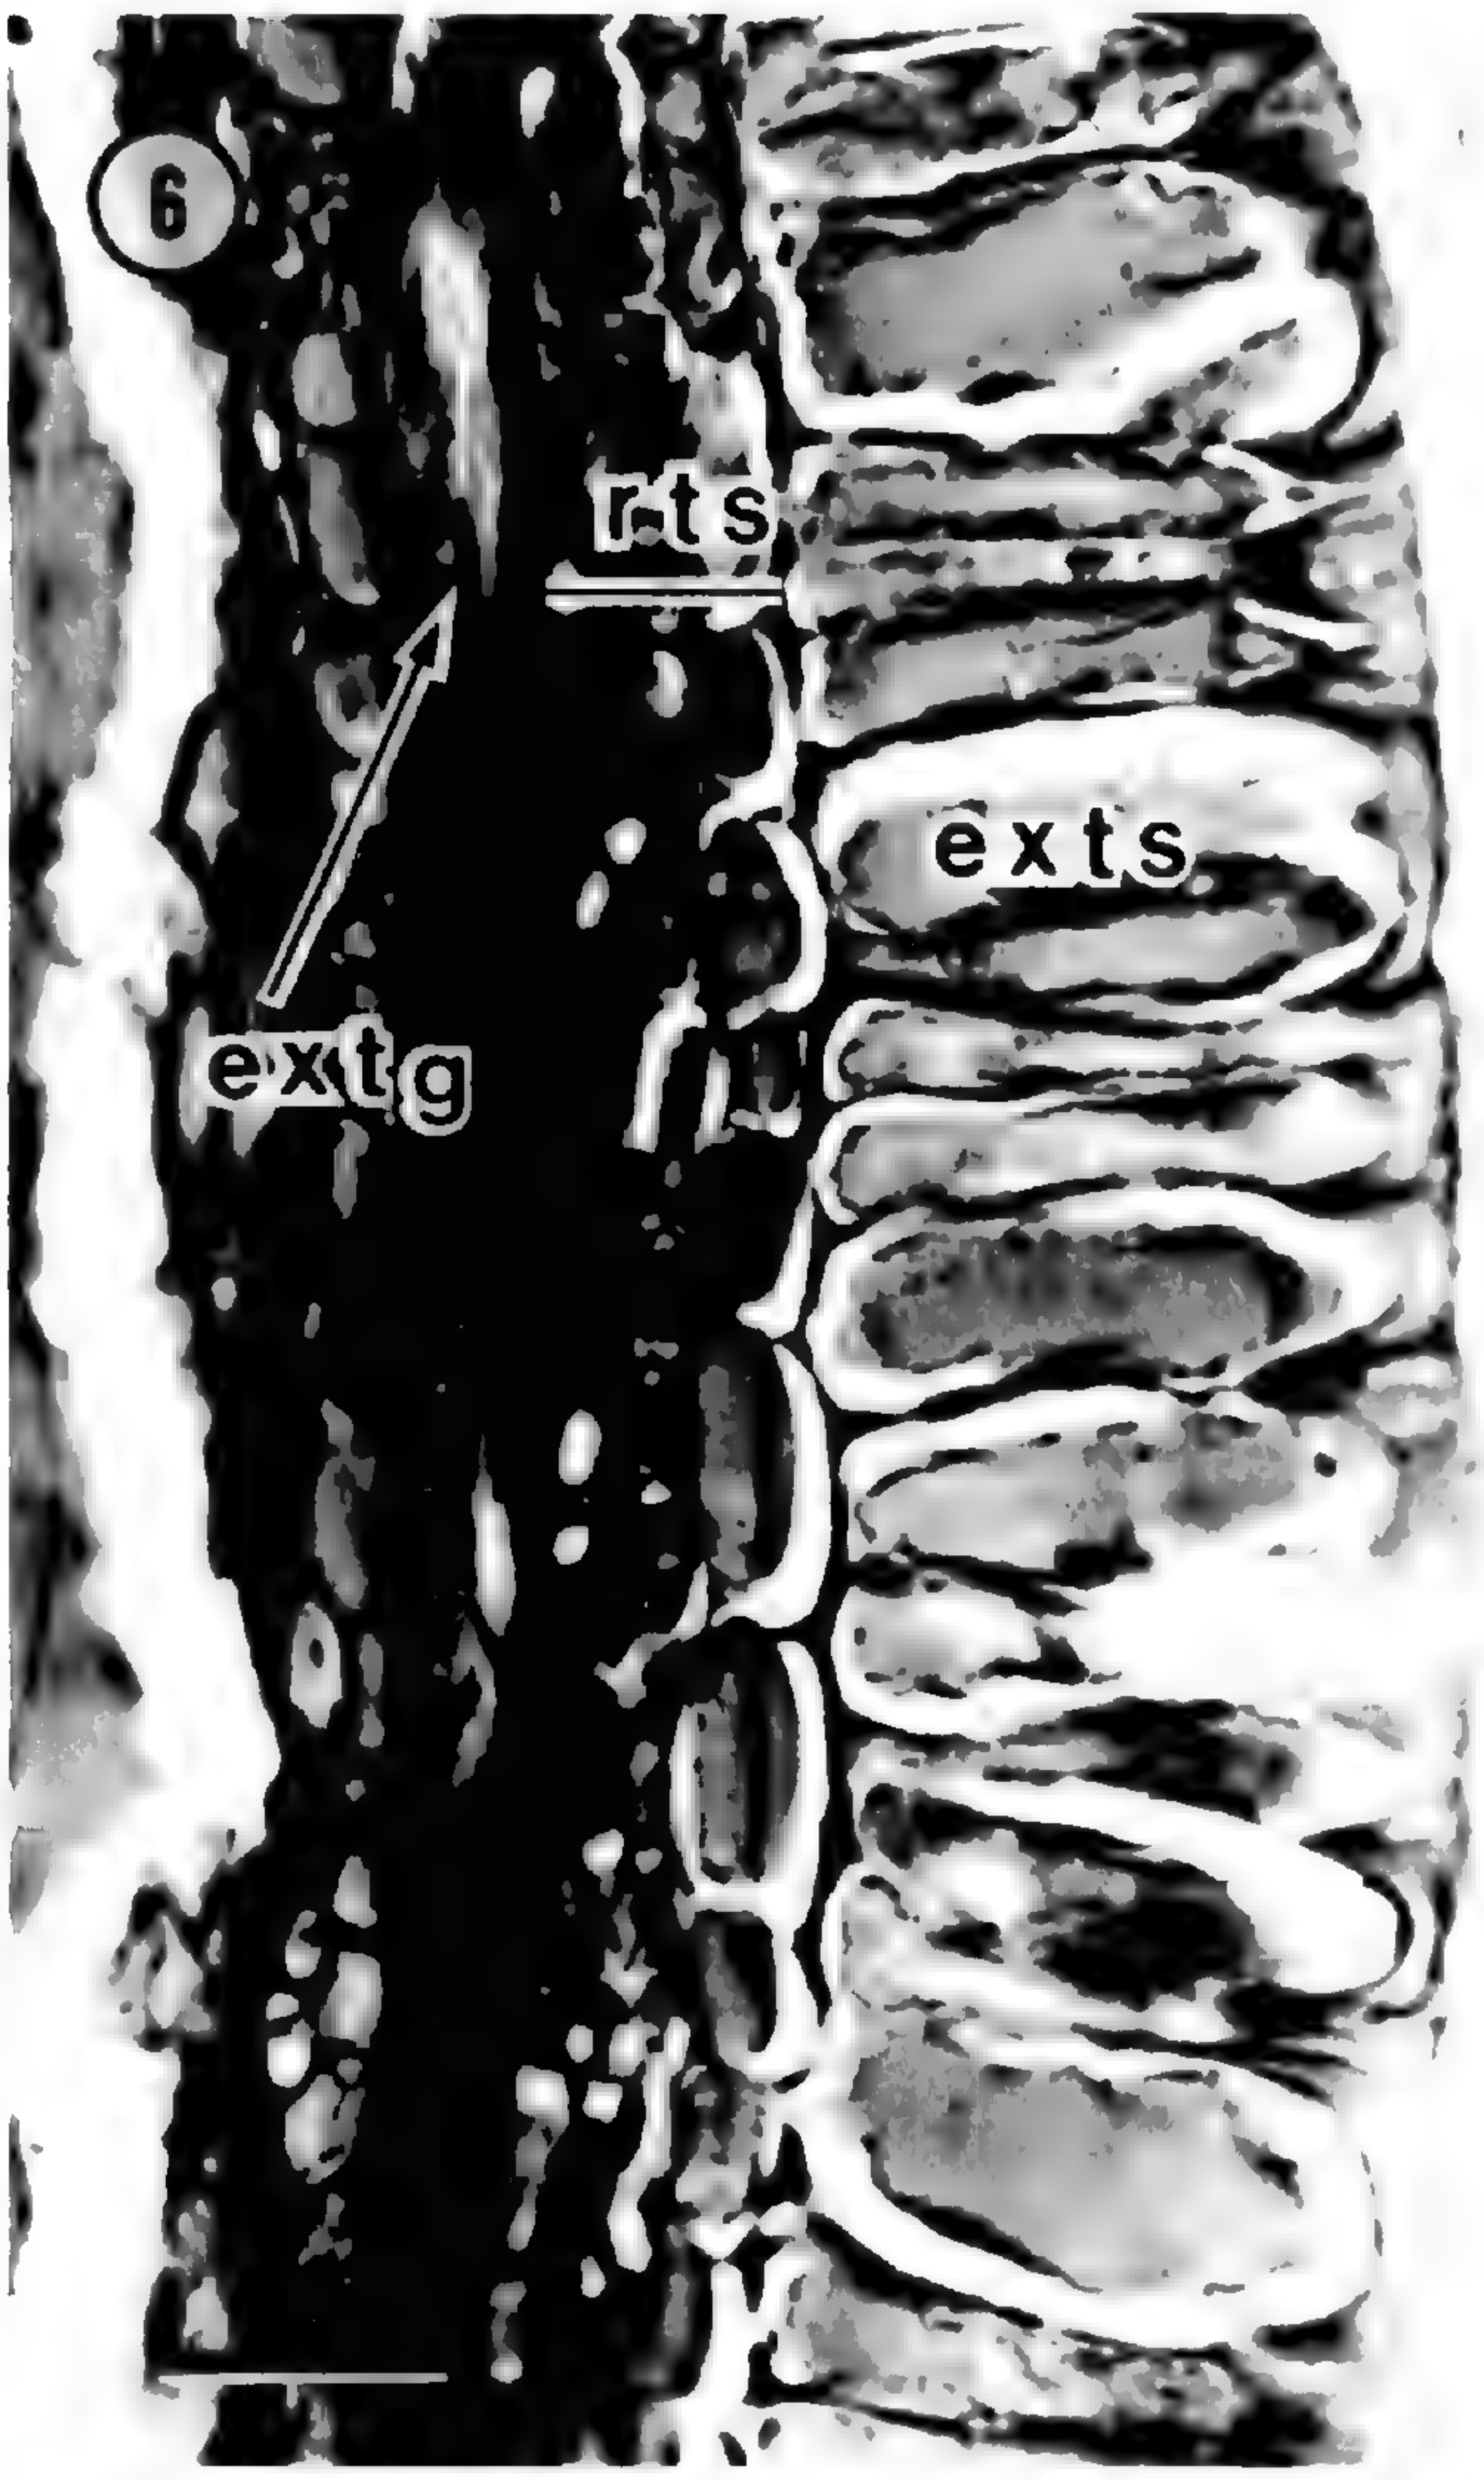
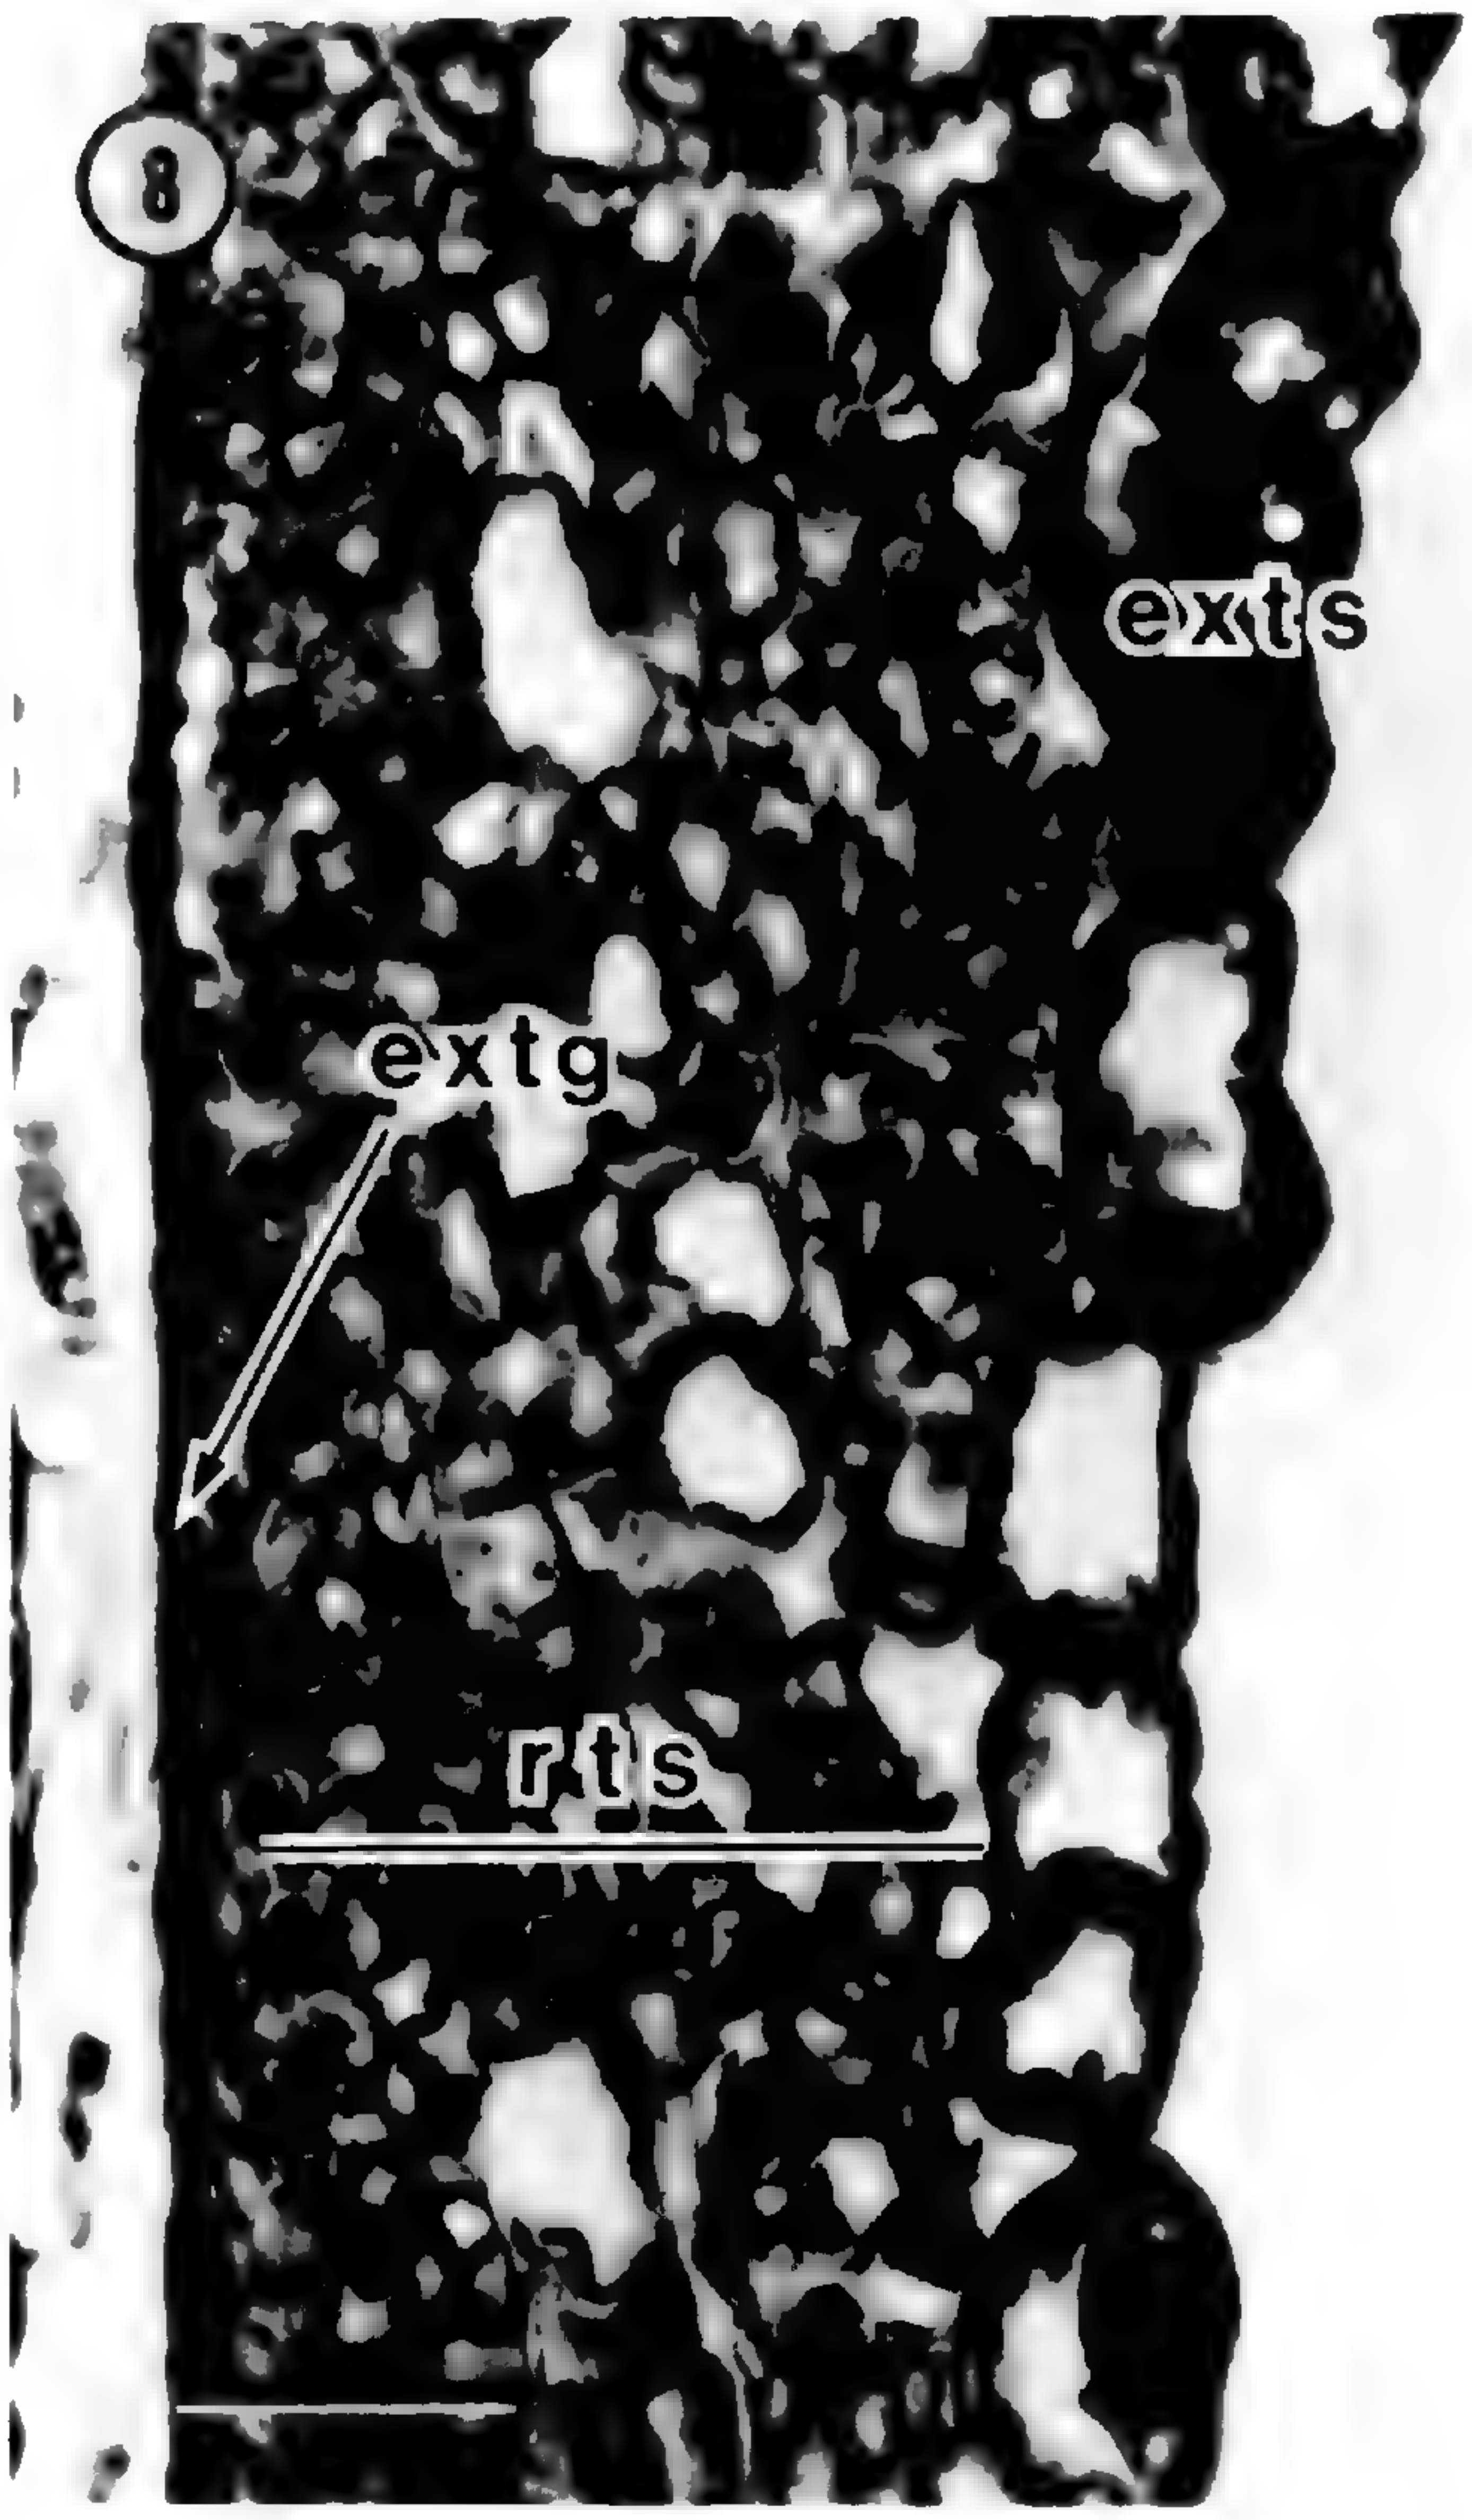
6



7

8



contain crystals; the exotegmen is composed of longitudinally elongate, thick-walled fibrous cells. Testal cells are mostly tanniferous. In all three species, the exotesta is most conspicuously developed as a mechanical structure, and therefore the seed coat of *Cassipourea* is exotestal.

Comiphyton. The mature seed of the only species of the genus, *C. gabonense*, is narrowly ellipsoid (Fig. 7) and nearly circular in cross section; it is 7.0–7.5 mm long and 2.0–2.8 mm in diameter. The aril is restricted to a micropylar top, and its tissue is apparently irregularly folded (Fig. 7). Compared with those of the species examined of *Cassipourea*, the seed coat surface of *Comiphyton* is more undulated, although it is uncertain whether this difference distinguishes *Comiphyton* from all species of *Cassipourea.*

The mature seed coat is 0.14–0.18 mm thick in total and is composed of a 1-cell-layered exotesta, an 8–10-cell-layered mesotesta, a 1-cell-layered endotesta, and a 1-cell-layered exotegmen (Fig. 8). There is no clear difference between the mesotesta and the endotesta. The exotesta is composed of somewhat enlarged, thick-walled tanniferous cells; the meso- and endotesta comprise much smaller cells, and they do not contain crystals; the exotegmen is composed of longitudinally very narrow, fibrous cells. No other cell layers of the tegmen persist. Considering the structure of the entire seed coat, only the exotesta is relatively well developed as a mechanical structure. Therefore, the seed coat of *Comiphyton* is exotestal.

Crossostylis. The mature seeds of the three examined species, *C. biflora*, *C. grandiflora* (Fig. 9), and *C. multiflora*, are ellipsoid, bearing a raphe as a very narrow longitudinal ridge. The mature seed is 2.1–2.3 mm long and 1.4–1.6 mm in diameter in *C. biflora*; 3.6–3.8 mm long and 1.8–2.0 mm in diameter in *C. grandiflora*; and 1.8–1.9 mm long and 1.0–1.2 mm in diameter in *C. multiflora*. The aril is membranous, and its tissue is irregularly folded. The aril spreads over the micropylar top and does not tightly cover the seed proper.

The mature seed coat structure differs from species to species. In *Crossostylis grandiflora*, the mature seed coat is relatively thick—0.19–0.20 mm in total—and is composed of a 1-cell-layered exotesta, a 2–3-cell-layered mesotesta, a 1-cell-layered endotesta, and a 1-cell-layered exotegmen (Fig. 10). There is no histological difference between the mesotesta and the endotesta. At the mature embryo sac stage, the outer and the inner integuments are 4–5 cells thick and 9–11 cells thick, respectively. As the seed matures, therefore, the inner integument completely disappears except for the outer epidermis—i.e., exotegmen—while the outer integument remains nearly persistent. The exotesta comprises enlarged, extremely thick-walled, tanniferous cuboidal cells; the meso- and endotesta are formed by unspecialized smaller cells; and the exotegmen is composed of longitudinally elongate, thick-walled, fibrous cells. Since the exotesta is most conspicuous as a mechanical structure, the seed coat of *C. grandiflora* is exotestal.

The mature seed coat structures of *Crossostylis biflora* (Fig. 13) and *C. multiflora* (Figs. 11, 12) are very similar. The total thickness is about 0.09 mm (*C. biflora*) or 0.06–0.07 mm (*C. multiflora*). The mature seed coat is basically composed of a 1-cell-layered exotesta, a 1-cell-layered mesotesta, a 1-cell-layered endotesta, and a 1-cell-layered exotegmen; however, the mesotesta and even the endotesta may be lacking in *C. multiflora* (Figs. 11, 12). Although we did not confirm the thickness of the integuments, they seem to be multiplicative, as we saw more clearly in our sample of *C. grandiflora*. The exotesta is covered with a thick cuticle; its cells are longitudinally elongate and contain tanninlike pigments. The meso- and endotestal cells are much smaller than those of the exotesta and contain crystals. The exotegmen is composed of extremely sclerotic, longitudinally elongate, fibrous cells. Compared with that of *C. grandiflora*, the exotegmen of these species is much more conspicuously developed as a mechanical structure. Therefore, the seed coat of *C. biflora* and *C. multiflora* is exotestal-exotegmic.

WINGED SEEDS

Anopyxis. The species examined, *A. klaineana*, has a large mature seed; it comprises the seed proper and a membranous wing (Fig. 14). The seed proper is oblanceoloid but extremely depressed laterally, and it is 13.4–13.7 mm long and 5.2–5.7 mm thick (R–A) to 1.6–2.1 mm thick (L–L). The

---

wing is always larger than the seed proper and is 23.9–25.0 mm long and 10.6–11.4 mm wide.

The mature seed coat is thin and 0.09–0.11 mm thick; for the most part it is apparently composed largely of a 1-cell-layered exotesta and a 1-cell-layered exotegmen (Fig. 15). In the mature embryo sac stage, however, the outer and the inner integuments are 4–5 cells thick and 6–7 cells thick, respectively. As the seed matures, therefore, all integumentary cell layers except for the outer epidermis of both integuments seem to degenerate or collapse. The exotesta is composed of enlarged, thick-walled, tanniferous cells, and the exotegmen of longitudinally elongate, thick-walled, fibrous cells. Both the exotesta and exotegmen are conspicuous as mechanical layers, and therefore the seed coat of *Anopyxis* is exotestal-exotegmic.

Macarisia. The mature seed of this genus, like that of *Anopyxis,* comprises a seed proper and a membranous wing (Fig. 16). The size of seed varies within the genus; the species examined, *M. pyramidata,* is known to have the largest seeds in the genus (Arènes, 1954), which, however, are much smaller than those of *Anopyxis.* In *M. pyramidata,* the seed proper is ellipsoid but extremely depressed laterally as in other species of the genus; it is 3.5–3.9 mm long and 2.1–2.5 mm thick (R–A) to 0.4 mm thick (L–L). The wing is always larger than the seed proper and is 8.5–9.1 mm long and 3.6–4.2 mm wide.

The mature seed coat of *Macarisia pyramidata* is 0.05–0.07 mm thick in total, and it comprises mainly a 1-cell-layered exotesta and a 1-cell-layered exotegmen (Fig. 17). Crystalliferous (endotestal) cells may remain at places between the exotesta and the exotegmen (Fig. 17). We did not examine the thickness of integuments because we lacked material. The exotesta is composed of enlarged, thick-walled, and tanniferous cells; the exotegmen comprises longitudinally elongate, thick-walled, fibrous cells. Based on *M. pyramidata,* the seed coat of *Macarisia* is exotestal-exotegmic.

Sterigmapetalum. Although the seed structure of this genus (consisting of seven species according to Steyermark & Liesner, 1983) has not been emphasized as a systematic character, it agrees with those of *Anopyxis* and *Macarisia* in having a seed proper and a membranous wing on the micropylar top. The morphology and anatomy of the mature seed of *S. heterodoxum* were discussed by Tobe & Raven (1987a). In this paper, only characteristic features of the species are briefly summarized, and data on the total thickness are added.

The seed proper is oblanceoloid and extremely depressed laterally; it is 5.0–6.0 mm long and 1.6–2.0 mm thick (R–A) to 0.8–1.0 mm thick (L–L). The wing is 7.4–10.2 mm long and 3.9–5.0 mm wide. (For other species of the genus, Steyermark & Liesner (1983) described the seeds of *S. obovatum* as oblong, plano-convex, 8 mm long and 3.5–4 mm wide.)

The mature seed coat is 0.08–0.10 mm thick in total and is composed only of a 1-cell-layered exotesta and a 1-cell-layered exotegmen, although the outer and the inner integuments were originally 2–4 cells thick and 8–10 cells thick, respectively. The exotesta comprises enlarged, somewhat radially elongate, thick-walled, tanniferous cells; the exotegmen is composed of longitudinally elongate, thick-walled, fibrous cells. The seed coat of *Sterigmapetalum* is exotestal-exotegmic.

NONAPPENDAGED SEEDS

Gynotroches. The mature seeds of the only species of the genus, *G. axillaris,* are ellipsoid and small with an areolate surface (Fig. 18). They are

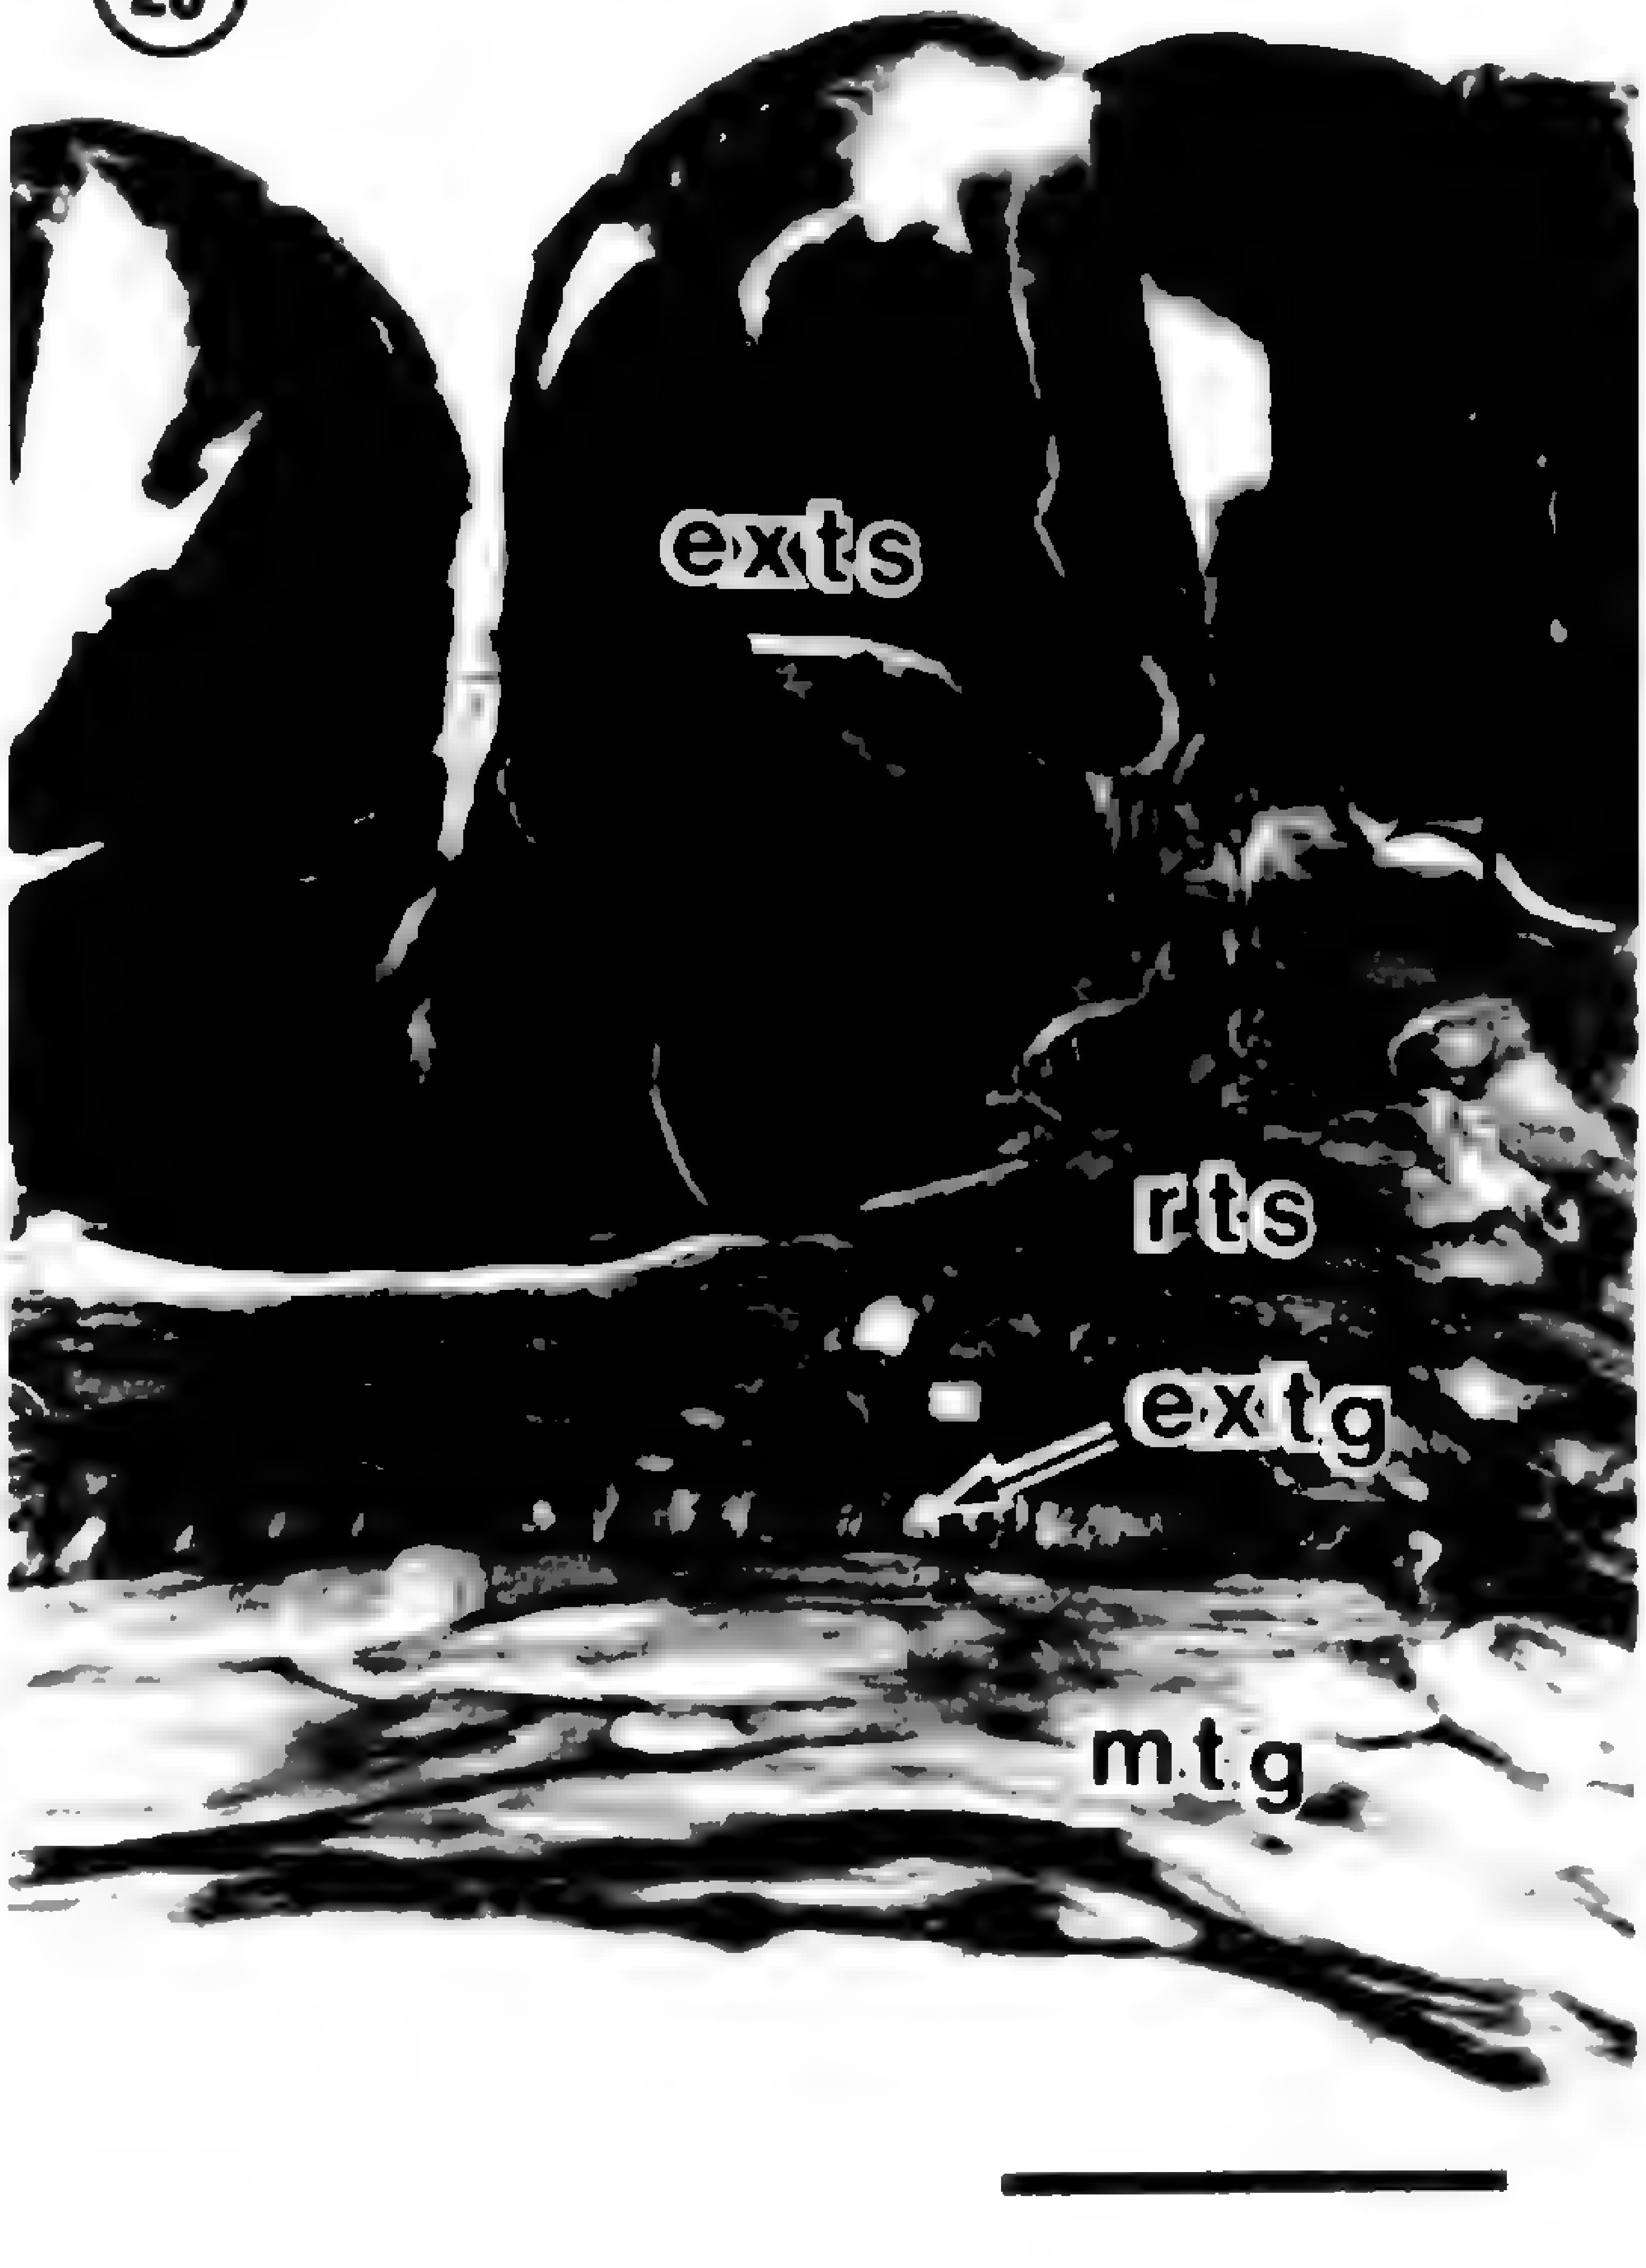
㉕



about 1.5 mm long and 0.5 mm thick (R–A) to 0.3 mm thick (L–L). A raphe is relatively conspicuous.

The mature seed coat is 0.12–0.14 mm thick and comprises a thick testa and a thick tegmen (Fig. 19). At the mature embryo sac stage, the outer and the inner integuments are 2 cells thick and 6–8 cells thick, respectively; a nonmultiplicative outer integument is characteristic of the genus. Even in the mature seed coat, all integumentary cell layers persist and form a 1-cell-layered exotesta, a 1-cell-layered endotesta, a 1-cell-layered exotegmen, a 4–6-cell-layered mesotegmen, and a 1-cell-layered endotegmen (Fig. 19). The exotesta is composed of remarkably enlarged, thick-walled, and tanniferous cells; the endotesta of much smaller and unspecialized cells; the exotegmen of radially elongate, thick-walled, fibrous cells; the underlying meso- and endotegmen of nonspecialized but somewhat thick-walled cells. Because of the very conspicuous development of the exotesta, the seed coat of *Gynotroches* is exotestal.

Corner (1976, 1: 161; 2: 260, fig. 315) reported that the mesotegmen (= "mesophyll") is eventually crushed, and interpreted the cell layers below the exotegmen as the "nucellus." However, since the nucellus disintegrates earlier, even in ovular stages (Juncosa, unpubl.), Corner seems to have misunderstood the persistent meso- and endotegmen as the "nucellus."

Pellacalyx. The mature seeds of the genus are elliptic-oblong and small, often with an areolate surface. The shape and size of the mature seeds differ somewhat from species to species (Hou, 1958). The mature seed of *P. lobbii* and *P.* cf. *saccardianus* (Fig. 20) that were investigated in this study are both ellipsoid. Their size is 1.7–1.8 mm long and 0.7–1.1 mm in diameter in *P. lobbii* and 1.2–1.4 mm long and 0.7–0.8 mm in diameter in *P.* cf. *saccardianus.*

The mature seed coat of *Pellacalyx lobbii* and *P.* cf. *saccardianus* is nearly the same, 0.26–0.28 mm thick in total. The seed coat, like that of *Gynotroches,* is composed of a thick testa and a thick tegmen (Fig. 21). The outer and the inner integument are 2 cells thick and 6–8 cells thick, respectively; all cell layers persist up to the mature seed coat stage, although the tegmen may further increase its thickness. Thus the mature seed coat comprises a 1-cell-layered exotesta, a 1-cell-layered endotesta, a 1-cell-layered exotegmen, a 6–9-cell-layered mesotegmen, and a 1-cell-layered endotegmen (Fig. 21). Exotestal cells are enlarged, thick-walled, and tanniferous; endotestal cells are much smaller and not specialized; cells of the exotegmen are longitudinally elongate, thick-walled, and fibrous; and those of the underlying meso- and endotegmen somewhat thick-walled. An undulation or "ribbon-like" structure (Corner, 1976) of the endotesta and the exotegmen is characteristic of the genus. As in the case of *Gynotroches,* Corner (1976, 1: 161, 2: 261, fig. 316) erroneously described the "nucellus" as persistent. But the nucellus that he considered is evidently the persistent meso- and endotegmen, because the nucellus completely disappears at a much earlier stage (Juncosa, unpubl.).

Carallia. The shape of the mature seed differs from species to species: oblong, oblong-ellipsoid, oblong-ovoid, ovoid, or reniform; the seed surface is areolate or corrugate; the size varies between 3 × 1.5 mm and 11 × 4 mm (Hou, 1958). The mature seeds examined of *C. brachiata* and *C. calophylloidea* are reniform, with the micropylar end close to the chalazal end and curved linear embryos (Fig. 22). The size is 5.5–6.0 mm long and 5.0–5.2 mm in diameter (when measured along the longest direction and the thickest middle part of the seed body). The mature seed of *C. eugenioidea,* another species investigated, is oblong-ovoid, and, probably like those of most other species, has a straight linear embryo; it is 3.0 mm long and 1.5 mm in diameter.

The mature seed coat of *Carallia brachiata* is 0.33–0.40 mm thick and is apparently composed only of a thick testa with exotestal cells extremely enlarged, thick-walled, and tanniferous (Fig. 24). Unlike the seed coat of *C. eugenioidea,* there is no tegmen, as Corner (1976) indicated. At the mature embryo sac stage, however, the outer and the inner integuments are 3–4 cells thick and 6–7 cells thick, respectively. Later, the young seed coat is evidently composed of a thicker testa and a thicker tegmen, where the differentiation of a

[1] Tribal positions of genera follow Melchior (1964) and Floret (1976).

[2] Data from Alston (1925), Arènes (1954), Floret (1974, 1976), Geh & Keng (1974), Hou (1958, 1968), Sprague & Boodle (1909), Steyermark & Liesner (1983), Tomlinson et al. (1979), and our observations.

1-cell-layered exotegmen apparently occurs (Fig. 23). The structure of the exotegmen in the young seed coat in *C. brachiata* looks the same as those of other genera that have the persistent exotegmen. In *C. brachiata* the whole tegmen seems to degenerate as the seed develops. The meso- and endotesta, 10–20 cells thick in total, comprise much smaller cells than those of the exotesta.

The mature seed coat of *Carallia eugenioidea*, like that of *C. brachiata*, has a thick exotesta that comprises extremely enlarged, thick-walled, tanniferous cells (Fig. 25); the total thickness of the seed coat is 0.21–0.39 mm. The meso- and endotesta are histologically very similar and about 4–8 cell layers thick in total. Their cells may contain crystals. *Carallia eugenioidea*, unlike *C. brachiata* but like *Gynotroches* and *Pellacalyx*, has a persistent tegmen, which comprises a 1-cell-layered fibrous exotegmen and a 4–5-cell-layered underlying mesotesta. The endotegmen appears to have nearly collapsed at maturity. At the mature embryo sac stage, the outer and the inner integument are only 3 cells thick and 5–6 cells thick, respectively. Therefore, even in postfertilization stages, nearly all cell layers of the inner integument appear to remain uncrushed.

Both *Carallia brachiata* and *C. eugenioidea* have no vascular bundles in the integuments or seed coats (except where a raphal vascular bundle is continued from a funicle). Because of the very

[1] Tribal positions of genera follow Melchior (1964) and Floret (1976).

[2] In *Cassipourea* and *Sterigmapetalum*, inner and outer integuments are both initially two cells thick and later increase their thickness (Tobe & Raven, 1987a); this multiplicative nature of the integuments was further confirmed in *Blepharistemma*, *Ceriops*, and *Kandelia* in the present study and therefore is probably true of all other genera of Rhizophoraceae when they have thick integuments. Measurements of the thickness of the integuments were made on mature ovules with organized embryo sacs.

[3] Data from *Crossostylis grandiflora*.

[4] Data from *Crossostylis biflora* and *C. multiflora*.

conspicuous development of the exotesta as a mechanical structure, the seed coat of *Carallia* is exotestal.

NONAPPENDAGED VIVIPAROUS SEEDS

Bruguiera, *Ceriops*, *Kandelia*, and *Rhizophora*. The mature seed taken from the indehiscent hard-walled fruit is cylindrical, 6.0–8.0 mm long, and 3.0–3.5 mm in diameter (*C. tagal*; Figs. 26, 27). The mature seed contains ample endosperm, as do those of the inland genera, but the endosperm of all the mangrove genera except *Bruguiera* characteristically extrudes from the micropyle and overflows the seed to fill up the space between the fruit wall and the seed (Haberlandt, 1895; Cook, 1907; Carey, 1934; Juncosa, 1982, 1984b). Such an endosperm structure is most conspicuous in *Ceriops* (Figs. 26, 27), least so in *Kandelia*.

The mature seed coat anatomy does not show any diversity and is nearly the same in all four mangrove genera (Cook, 1907; Carey, 1934; Tobe, unpubl.). The mature seed coat is 0.6–1.3 mm thick in total and comprises only a thick testa; it completely lacks the tegmen. Although the massive inner integument is present at ovular stages (Fig. 28), it completely disintegrates in pre- and post-fertilization stages (Fig. 29; see also Cook, 1907; Carey, 1934). The testa is 20–60 cells thick but it is apparently undifferentiated and merely com-

prises many tanniferous or nontanniferous cells and vascular tissues. According to Carey (1934), in *Rhizophora mucronata* "the outer integument [= testa] is differentiated into two zones, an outer which contains the extensive vascular supply, and an inner in which the cells are regularly arranged and meristematic," but in *Ceriops candolleana* the inner one "is not sharply defined as it is in *Rhizophora*." On the basis of our observations, the vascular strands, which are profusely branched in the testa, are distributed in the middle part of the testa in all the species examined, but they certainly do not always demarcate the inner zone. Since the seed coat anatomy of mangrove genera is not directly comparable with those of inland genera, it can be designated for our discussion as an "undifferentiated" seed coat.

DISCUSSION

As described above, the seeds of Rhizophoraceae show certain fundamental differences in their morphology and anatomy. These features are summarized in Tables 2 and 3. In Table 2, the methods of seed dispersal are also indicated as a basis for subsequent discussions. Despite the diversity of these characters, there are several major character coincidences in certain groups of genera. All Macarisieae with a superior ovary (i.e., unspecialized ovary position), and *Crossostylis* (Gynotrocheae), with an inferior ovary (i.e., derived ovary position), always have either an aril or a wing on the seed; in contrast, the remaining genera, which have an inferior or semi-inferior ovary, lack any sort of seed appendage. Anatomically, all Macarisieae and Gynotrocheae (all inland groups) basically have a similar mature seed coat structure and consistently have a well-developed exotesta and (fibrous) exotegmen; their seed coat is either exotestal or exotestal-exotegmic. In contrast, all Rhizophoreae (the mangrove group) do not have a histologically differentiated seed coat, and they entirely lack a tegmen.

AFFINITIES OF RHIZOPHORAEAE

The accumulating data strongly confirm that Rhizophoraceae are monophyletic. In particular, the combination of subdermally initiated laticifers[4] in the gynoecial wall (and sometimes even in other floral parts) with colletors[5] is unique to Rhizophoraceae (see also Juncosa & Tomlinson, this volume b). Dahlgren (this volume), on the basis of a cladistic approach incorporating various vegetative, reproductive (including embryological), and chemical characters, suggests that Rhizophoraceae are closely related to Elaeocarpaceae of Malvales and Celastraceae of Celastrales and possibly with Erythroxylaceae of Geraniales. We agree with this suggestion. In searching for closely related families, Dahlgren selected as plesiomorphies of Rhizopho-

---

[4] Juncosa & Tomlinson (1987) reported the presence of the subdermally initiated laticifers in mangrove genera; Floret (1974: 502, pl. 2, figs. a–c) figured this particular cell layer in the ovary wall of *Comiphyton gabonense*, although he did not specify it in the text. We confirmed the presence of laticifers in the ovary wall or calyx wall of *Gynotroches* (Gynotrocheae), *Anopyxis*, *Blepharistemma*, *Cassipourea*, and *Sterigmapetalum* (Macarisieae) but not in *Pellacalyx*. Material of *Macarisia* was not available to check this character.

[5] The occurrence of colleters has been recorded in *Cassipourea* (Alston, 1925), *Rhizophora* (Gill & Tomlinson, 1969; Lersten & Curtis, 1974), *Bruguiera* and *Kandelia* (Tomlinson et al., 1979; Metcalfe & Chalk, 1950, 1: 602; Hou, 1958). We confirmed the presence of colleters in all other genera available: *Carallia* (Gynotrocheae), *Blepharistemma*, *Macarisia*, and *Sterigmapetalum* (Macarisieae).

raceae the presence of an endothelium, the presence of an aril, the exotegmic seed coat, a chlorophyllous embryo, a Pvc-type sieve-element plastid, the presence of certain types of alkaloids, and the occurrence of a combination of some embryological features. We add the possession of deeply incised petals, because such petals are also undoubtedly plesiomorphic in Rhizophoraceae and Elaeocarpaceae. In addition, the occurrence of multiplicative inner and outer integuments may be more strongly emphasized as another symplesiomorphy shared by all of the families mentioned above.

From the viewpoint of seed morphology and anatomy, *Blepharistemma*, *Cassipourea*, and *Comiphyton* of Macarisieae best agree with Elaeocarpaceae and Celastraceae in having arillate seeds and a fibrous exotegmen (and albuminous seeds and linear embryos; Weibel, 1968; Corner, 1976). The only conspicuous difference between these three genera of Macarisieae and Elaeocarpaceae–Celastraceae is the absence of a persistent meso- and/or endotegmen in the latter. In Rhizophoraceae, a persistent meso- and endotegmen occurs only in *Gynotroches*, *Pellacalyx*, and certain species of *Carallia*, all of which are undoubtedly specialized genera in the family as discussed later. Seed morphology and anatomy have not been investigated fully in Elaeocarpaceae and Celastraceae, and therefore it cannot be determined with certainty that this difference will hold up when more information is available. Critical, however, is the fact that the arillate seeds occur in the genera of Macarisieae that have a superior ovary (a plesiomorphy), and that a fibrous exotegmen is common to all inland genera, which are less advanced in general than the mangrove genera. These features support Dahlgren's suggestion that the presence of an aril and a fibrous exotegmen is plesiomorphic in Rhizophoraceae and justify the use of those seed features in searching for related families.

Comparisons with Anisophylleaceae may also be needed. Even though embryological evidence as well as various other lines of evidence suggest that this family is distinct (Tobe & Raven, 1987b), wood anatomy (Keating & Randrianasolo, this volume; Baas, pers. comm.), and floral morphology (Tobe Baas, pers. comm.), and flora morphology (Tobe & Raven, in press) link it with Rhizophoraceae. Wood and leaf anatomy particularly suggest that Anisophylleaceae and Gynotrocheae may be closely related. Our observations, however, indicate that Anisophylleaceae lack subdermally initiated laticifers and colleters, both of which are characteristic of Rhizophoraceae and support their interpretation as a closely linked monophyletic evolutionary unit not directly related to Anisophylleaceae. The present study further shows that, even apart from the presence or absence of an aril, the seed morphology and anatomy of Anisophylleaceae differ greatly from those of Rhizophoraceae in completely lacking a tegmen (see Tobe & Raven, 1987b, for data on Anisophylleaceae). Therefore, Anisophylleaceae seem clearly to be much more distantly related to Rhizophoraceae than to Elaeocarpaceae and Celastraceae; Rhizophoraceae and Anisophylleaceae are evidently more distantly related than we have suggested elsewhere (Tobe & Raven, in press).

Dahlgren (this volume) has suggested that Elaeocarpaceae have probably been misplaced in Malvales and ought to be transferred near Celastraceae of Celastrales sensu Dahlgren, along with Rhizophoraceae. In terms of seed coat anatomy, most Malvales other than Elaeocarpaceae (e.g., Bombacaceae, Malvaceae, Sterculiaceae, and Tiliaceae) are characterized by a palisadal structure of exotegmen, which is unknown in Elaeocarpaceae (see Corner, 1976). Thus the seed coat anatomy also supports the exclusion of Elaeocarpaceae from Malvales and, as already discussed above, their close relationships with Rhizophoraceae and Celastraceae.

EVOLUTION OF SEEDS IN RHIZOPHORACEAE

As discussed above, the arillate seeds of *Blepharistemma*, *Cassipourea*, and *Comiphyton* (Macarisieae) and *Crossostylis* (Gynotrocheae) apparently represent an archaic, ancestral state in Rhizophoraceae. Judged from the distribution of seed characters in Rhizophoraceae (Tables 2, 3), some of the specialized seed types seem clearly to have evolved more than once.

In Macarisieae, arillate seeds (in *Blepharistemma*, *Cassipourea*, and *Comiphyton*) and winged seeds (in *Anopyxis*, *Macarisia*, and *Sterigmapetalum*), both types borne in capsular fruits, are probably dispersed by ants and wind, respectively; arillate seeds might also be dispersed by birds (see Ridley, 1930; van der Pijl, 1969, for general discussions of seed dispersal). What may have induced an evolutionary change from ant dispersal to wind dispersal is uncertain. Anatomically, in contrast with a relatively thick seed coat of arillate seeds (ca. 0.2 mm thick), the seed coat of winged seeds is thinner (less than 0.1 mm thick). The thinner seed coat might be adaptive in lightening the seeds for wind dispersal. Despite this innovation in seed dispersal, however, the area of distribution of the genera with winged seeds is at present restricted. *Anopyxis* is restricted to West Africa, *Macarisia* to Madagascar, and *Sterigmapetalum* to the Amazon (see Juncosa & Tomlinson, this volume b, for a distribution map). In contrast, *Cassipourea*, which has arillate seeds, is widely distributed in Africa, India, and South America. *Blepharistemma* and *Comiphyton*, also with arillate seeds, are confined to the Kerela district of southwestern India and West Africa, respectively.

The seeds of *Crossostylis*, which traditionally has been assigned to Gynotrocheae, resemble those of *Blepharistemma*, *Cassipourea*, and *Comiphyton* in having an aril and in being produced in capsular fruits. The distribution of *Crossostylis* (comprising 13 species) at present is restricted to and scattered in Polynesian islands, considerably separated from that of Macarisieae; it partly overlaps with the distribution area of the rest of Gynotrocheae and of Rhizophoreae. These facts may suggest that the arillate, small–medium-sized seeds of *Crossostylis* are now or formerly were dispersed by birds from one island to another. Ridley (1930: 423–424) discussed bird-dispersed arillate seeds. Van der Pijl (1969: 30) gives an example: in Indonesia, the fruit-pigeons (*Carpophaga*) eat nutmeg with its aril ("arillode") and disseminate it outside the region. Variation in seed size and seed coat anatomy within the genus may reflect complex methods of seed dispersal.

The nonappendaged seeds of *Carallia*, *Gynotroches*, and *Pellacalyx* (Gynotrocheae), which are borne in baccate fruits, are much smaller than the arillate seeds of Macarisieae in general. The number of seeds per fruit is either 1(–5) (*Carallia*) or ca. 20–40 (*Gynotroches* and *Pellacalyx*). Those seeds are very hard and were difficult to section with a microtome. Fruit and seed structure of these genera seem to indicate that the seeds are endozoochorous and dispersed by birds or mammals. Bird or bat dispersal seems to provide a likely explanation of the wide distribution of these genera throughout the islands of southeastern Asia, west to India and Madagascar (*Carallia*).

Seeds of the four mangrove genera—*Bruguiera*, *Ceriops*, *Kandelia*, and *Rhizophora* of Rhizophoreae—produce viviparous seedlings in indehiscent hard-walled fruits. They do not exhibit histological differentiation in their seed coats, probably because the seeds are protected by the fruit wall and therefore are not specialized against external environments. When they fall from the parent plant, the dropped fruits or seedlings are undoubtedly dispersed by sea water, as discussed by many workers (e.g., Ridley, 1930; Hou, 1958). The mangrove genera are at present best represented from the western Pacific to the Indian Ocean; *Rhizophora* is pantropical (Graham, 1964). *Rhizophora*, the most widely distributed genus of the family, is also the only one that is wind pollinated (Tomlinson et al., 1979), a system that might be well suited to newly colonized habitats.

To sum up, the seeds of Rhizophoraceae seem to have evolved as the result of adaptation to changes in seed dispersal methods, that is, from ant dispersal to dispersal by wind, bird, mammal or water. The diversity in the seed morphology and anatomy, in conjunction with the diversity of fruit structure, is well explained by such changes in the methods of seed dispersal, and vice versa. However, the actual methods of dispersal of the seeds of the nonmangrove genera are very poorly known and should be studied in the field.

PHYLOGENETIC RELATIONSHIPS WITHIN RHIZOPHORACEAE

The accepted infrafamilial classification of Rhizophoraceae is based primarily on androecial position (i.e., perigynous or epigynous), the number of carpels or ovarian locules, and the number of ovules per carpel (e.g., Melchior, 1964). Data from seed morphology and anatomy and fruit structure generally support the traditional classification in separating Macarisieae, Gynotrocheae, and Rhizophoraceae as distinct units.

For the cladistic analysis, we chose 16 characters whose character-state evaluations were possible; these include characters of embryology, seed morphology and anatomy, and floral morphology (Table 4). The character-state evaluation in Rhizophoraceae was made on the basis of outgroup comparison with Elaeocarpaceae and/or Celastraceae. Data on Rhizophoraceae, Elaeocarpaceae, and Celastraceae were obtained from the following references: Rhizophoraceae—Schimper (1893), Haberlandt (1895), Cook (1907), Carey (1934), Melchior (1964), Floret (1974, 1976), Corner (1976), Tomlinson et al. (1979), Juncosa (1982, 1984a, b), Tobe & Raven (1987a), and present study; Elaeocarpaceae—Mauritzon (1934), Venkata Rao (1953), Corner (1976), Cronquist (1981), and Hyland & Coode (1982); Celastraceae—Mauritzon (1936), Berkeley (1953), Adatia & Gavde (1962), Copeland (1966), Corner (1976), and Cronquist (1981). Results of character-state evaluation within the Rhizophoraceae are provided in Table 4, their distribution in the family in Table 5, and a cladogram based on these features in Fig. 30.

The cladogram (Fig. 30) indicates that, except for six genera of Macarisieae, the eight remaining

TABLE 4. *Character-state evaluation of some selected reproductive characters in Rhizophoraceae.*

Character	Plesiomorphy[1]	Apomorphy
1. Ovary position	superior	inferior or semi-inferior
2. Numbers of ovules per carpel	2	many
3. Structure of nucellus	crassinucellate	tenuinucellate
4. Number of archesporial cells in ovule	many	1
5. Formation of endothelium	occurs	absent
6. Nature of outer integument	multiplicative	not multiplicative
7. Integumentary (or seed coat) vasculature	absent	present
8. Development of endosperm	not overflow from embryo sac	overflow
9. Seedling	not viviparous	viviparous
10. Fruit morphology	capsular	baccate or indehiscent
11. Type of seed appendage	aril	wing
12. Presence or absence of seed appendage	present	absent
13. Total thickness of mature seed coat	> 0.1 mm	< 0.1 mm
14. Histological differentiation of seed coat	occurs	does not occur
15. Development of exotegmen	persistent, fibrous	early disintegration
16. Development of meso- and endotegmen	early disintegration	persistent

[1] All plesiomorphies occur not only in some or all inland genera of Rhizophoraceae but also are common to the outgroups, e.g., Elaeocarpaceae and Celastraceae. References for data on each family are presented in the text.

genera of the family share an inferior or semi-inferior ovary (a synapomorphy). The genera of Macarisieae retain many plesiomorphic features, including a superior ovary. Within Macarisieae, Floret (1976) recognized three subgroups on the basis of floral and seed characters: 1) *Anopyxis*, *Macarisia*, and *Sterigmapetalum*; 2) *Blepharistemma*, *Comiphyton*, and *Cassipourea* subg. *Dactylopetalum*; and 3) the three remaining subgenera of *Cassipourea* (see Tobe & Raven, 1987a, for revision). Later, emphasizing probable coincidences in the seed morphology and anatomy, but on the basis of meager data, we suggested closer affinities among *Anopyxis*, *Macarisia*, and *Sterigmapetalum* on the one hand, and among *Blepharistemma*, *Cassipourea*, and *Comiphyton*

TABLE 5. *Distribution of character states of some selected reproductive characters in Rhizophoraceae. Plesiomorphy (−); Apomorphy (+). Character numbers correspond to those given in Table 4.*

	Character

[1] Three-letter abbreviations given in parentheses are used in a cladogram (Fig. 30).

[2] Data from personal observations on *Crossostylis grandiflora*.

[3] The number of archesporial cells in an ovule in the mangrove genera is not well documented; Karsten (1891) described two megaspore mother cells in *Ceriops candolleana*. This character must be confirmed in this and other mangrove genera.

on the other (Tobe & Raven, 1987a). The present study confirms the relationships that we suggested then. Character-state comparisons indicate that *Anopyxis, Macarisia,* and *Sterigmapetalum* share the synapormorphies winged seeds and a thinner seed coat, and thus constitute a single clade. On the basis of seed morphology and anatomy, therefore, we propose the division of Macarisieae into two subtribes: 1) Cassipourinae, comprising *Blepharistemma, Cassipourea,* and *Comiphyton*; and 2) Macarisinae, comprising *Anopyxis, Macarisia,* and *Sterigmapetalum.* Wood anatomy (van Vliet, 1976) and leaf architecture (Keating & Randrianasolo, this volume) do not provide a clear distinction between the two subtribes; wood anatomical comparison rather suggests that *Comiphyton* is intermediate between *Macarisia* (Macarisinae) and *Cassipourea* (Cassipourinae) (van Vliet, 1976). An overall comparison of their vegetative morphology (Sprague & Boodle, 1909), however, suggests close affinities between *Anopyxis* and *Macarisia.* Leaf anatomy strongly supports our suggested subtribal classification (Baas, pers. comm.): *Anopyxis–Macarisia(–Sterigmapetalum)* have a nonpluriseriate epidermis and a differential hypodermis, whereas *Blepharistemma–Cassipourea(–Comiphyton)* have a pluriseriate epidermis but lack a discernible hypodermis. For further elucidation of the relationships in this group, a comprehensive study of the largest and most widely distributed genus, *Cassipourea,* seems essential.

Crossostylis, which has been placed in Gynotrocheae, shares only one apomorphy (an inferior ovary) with any group other than the six genera of Macarisieae. Apart from the ovary position, in contrast, *Crossostylis* agrees nearly completely with Macarisieae in many plesiomorphic features. Juncosa & Tomlinson (this volume b) summarize that *Crossostylis* shares stilt roots, roots having no hairs, bijugate phyllotaxy, imbricate stipules, flat floral apices, and several-layered laticifers with other Gynotrocheae (sometimes excepting *Pellacalyx*), and shares most of these features also with Rhizophoreae. It is uncertain whether those shared structures represent apomorphic character states or not, but at least some of them are probably synapomorphies, suggesting phylogenetic affinities of *Crossostylis* with the rest of Gynotrocheae and all Rhizophoreae.

Crossostylis, however, is clearly distinguished from other Gynotrocheae and all Rhizophoreae in not sharing the apomorphies noncapsular fruit and the nonappendaged seed. The cladistic analysis thus indicates mutual closer affinities between the rest of Gynotrocheae and all Rhizophoreae, and leaves *Crossostylis* in a distinct evolutionary line. Juncosa (unpubl.) suggests an intermediate position for *Crossostylis* between Macarisieae and Gynotrocheae, and we agree with this interpretation. *Crossostylis* seems to be more appropriately assigned to its own tribe, Crossostylideae, as also suggested by Juncosa (pers. comm.).

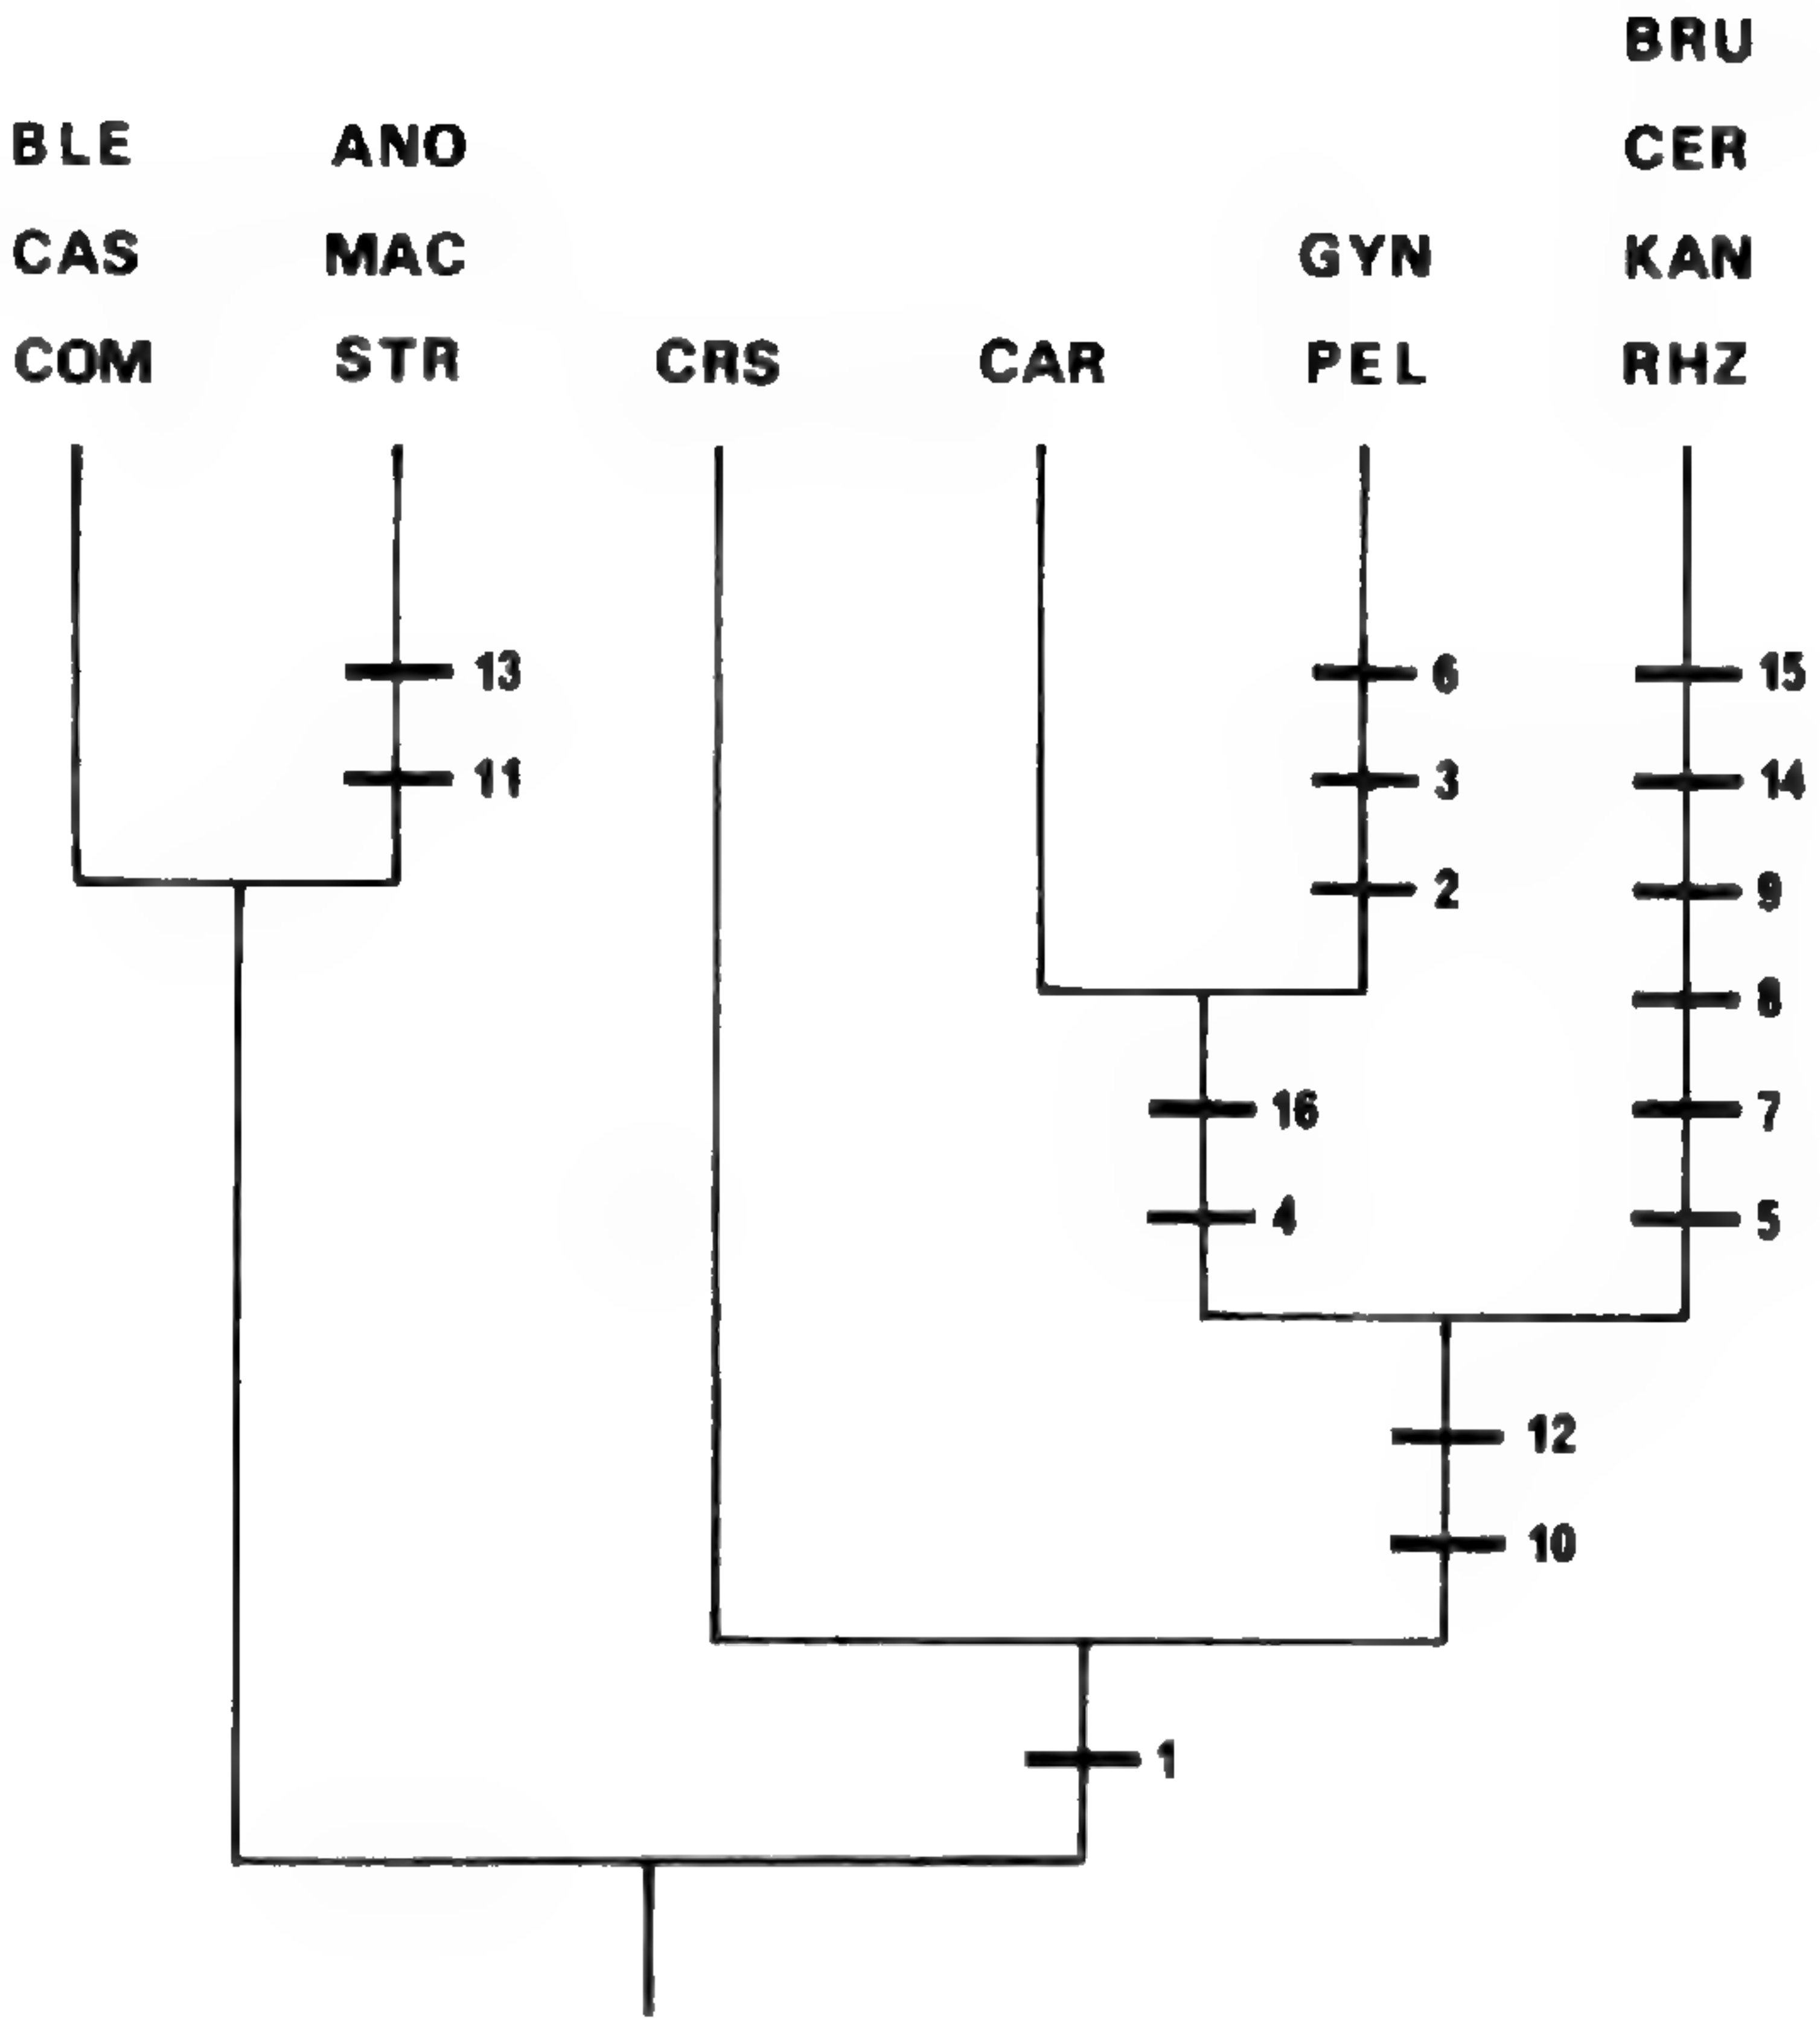

FIGURE 30. *A cladogram illustrating evolutionary interrelationships of the genera of Rhizophoraceae. Character numbers 1–16 and three-letter abbreviations of genera are shown in Tables 4 and 5, respectively.*

Carallia, Gynotroches, and *Pellacalyx* have been grouped in Gynotrocheae; this treatment seems reasonable because as a group they have no synapomorphies with Rhizophoreae. The three genera share two synapomorphies: a one-celled ovuled archesporium and a persistent meso- and endotegmen (although the latter feature may be inconsistent in *Carallia*). *Gynotroches* and *Pellacalyx* closely resemble each other in sharing the following additional apomorphies: a multiovulate carpel, a tenuinucellate ovule, and a nonmultiplicative outer integument; in contrast, *Carallia* is characterized by retaining the plesiomorphic states of those characters. Thus, we suggest that *Gynotroches* and *Pellacalyx* should be segregated as a subtribe Gynotrochinae, and *Carallia* should be treated as the monogeneric subtribe Carallinae.

In considering the phylogenetic relationships of *Carallia,* the diversity within the genus must be taken into account. For example, with respect to the mature seed coat structure, Corner (1976) described "tegmen without trace" in *Carallia* *brachiata*; likewise, Juncosa (unpubl.) did not see a tegmen in *C. borneensis*. We did not observe a tegmen in the mature seed coat of *C. brachiata*, either (Fig. 24). In contrast, in the mature seed coat of *C. eugenioidea* (Fig. 25) and in the younger seed coat of *C. brachiata* (Fig. 23), we observed thick, distinct tegmic cell layers, the outermost of which even assumed the fibrous, exotegmenlike structure that is characteristic of all other inland genera. In its lack of a tegmen in the mature seed coat, *Carallia* might be compared to Rhizophoreae; however, when they are compared throughout their ontogeny, they appear to be quite distinct. Thus, in Rhizophoreae, the inner integument or young tegmen soon disintegrates because of the enlargement of the embryo sac in postfertilization stages, but in *Carallia* it does not disintegrate until much later, and it may even persist, as in *C. eugenioidea*. Furthermore, in *Carallia* the outermost cell layer of the inner integument differentiates into the fibrous exotegmen, but in Rhizophoreae such a histological differentiation has not been observed.

The thickness and vasculature of the outer integument in *Carallia* seems to be diverse. According to Juncosa (unpubl.), *C. borneensis* has a 7–15-cell-layered outer integument at anthesis, which is vascularized as it is in Rhizophoreae. However, in the samples of *C. brachiata* and *C. eugenioidea* we observed, there were only 3–4-cell-layered outer integuments at the mature embryo sac stage; the outer integument of those two species has not space for vascularization at that stage, and no vascular bundles were observed in testae even in later stages, although the raphe always contained some vascular tissues.

To sum up, we suggest that in *Carallia*, as well as in *Gynotroches* and *Pellacalyx*, the tegmen was originally persistent, but that a tegmenless seed coat (as in *C. brachiata* and *C. borneensis*) apparently evolved, almost certainly independently from Rhizophoreae. Likewise, the vasculature of the testa in *Carallia* seems to have been acquired only in certain species of the genus with an extremely thickened outer integument or testa, but probably independently of the evolutionary line leading to Rhizophoreae.

Although *Carallia* is diverse, it apparently should continue to be placed in Gynotrocheae, along with *Gynotroches* and *Pallacalyx*.

The four mangrove genera—*Bruguiera*, *Ceriops*, *Kandelia*, and *Rhizophora*—share the following synapomorphies: endothelium not formed, outer integument vascularized, endosperm overflowing, viviparous seedlings, testa not differentiated histologically, and tegmen lacking. Thus, the mangrove genera undoubtedly form a coherent group, Rhizophoreae. Wood anatomy (van Vliet, 1976), leaf architecture (Keating & Randrianasolo, this volume), leaf anatomy (particularly stomatal type; Baas, pers. comm.), and consistent distinct chromosome number ($2n = 36$; Yoshioka et al., 1984) also support the coherence of Rhizophoreae. The cladistic analysis indicates that Rhizophoreae have direct relationships with Gynotrocheae (not including *Crossostylis*), rather than with Macarisieae.

On the basis of our cladistic analysis, we suggest the following revised classification:

Family Rhizophoraceae (not including Anisophylleaceae)
- Tribe Macarisieae
  - Subtribe Cassipourinae
    - *Blepharistemma*
    - *Cassipourea*
    - *Comiphyton*
  - Subtribe Macarisinae
    - *Anopyxis*
    - *Macarisia*
    - *Sterigmapetalum*
- Tribe Crossostylideae
    - *Crossostylis*
- Tribe Gynotrocheae
  - Subtribe Carallinae
    - *Carallia*
  - Subtribe Gynotrochinae
    - *Gynotroches*
    - *Pellacalyx*
- Tribe Rhizophoreae
    - *Bruguiera*
    - *Ceriops*
    - *Kandelia*
    - *Rhizophora*

THE CONTRIBUTION OF LEAF ARCHITECTURE AND WOOD ANATOMY TO CLASSIFICATION OF THE RHIZOPHORACEAE AND ANISOPHYLLEACEAE[1]

Richard C. Keating[2]
and Voara Randrianasolo[3]

ABSTRACT

Leaf-architectural and wood-anatomical data on the 18 genera traditionally considered to comprise the Rhizophoraceae were analyzed for insight on the intergeneric affinities. The four genera of the tribe Anisophylleae, considered on other lines of evidence to comprise the family Anisophylleaceae, are not readily separated using new data from leaf structure, or from a new look at the wood-anatomical literature. Leaves of both families are elliptic, and few features distinguish the two families or help separate the tribes of Rhizophoraceae s. str. or help separate the tribes. Anisophylleaceae have no marginal teeth or glands; they differ mainly from the Rhizophoraceae in having alternate leaves and no stipules. Leaves of the tribes Macarisieae, Gynotrocheae, and Rhizophoreae show some tribal-level variations in secondary venation, crystal type and distribution, and a few other features. The Rhizophoraceae leaves have an apiculate glandular tooth known as the Macarisioid type. Wood features, analyzed from the literature, do not readily distinguish the two families. Possible affinities of the Anisophylleaceae are not easily established using vegetative data. The Rhizophoraceae share a number of features with Celastraceae, Eleaocarpaceae, Hugoniaceae, Lepidobotryaceae, and Oxalidaceae.

The Rhizophoraceae are a family of tropical-forest and mangrove trees variously considered as comprising either 14 or 18 genera, a disparity coming from inclusion of the genera *Anisophyllea*, *Combretocarpus*, *Poga*, and *Polygonanthus* as a tribe Anisophylleae vs. their exclusion as the family Anisophylleaceae. Tobe & Raven (1987a) discussed the taxonomic history of the Anisophylleaceae, while van Vliet (1976) and Juncosa & Tomlinson (this volume) provided a detailed taxonomic background on the Rhizophoraceae (sensu lato). However, to place this contribution in perspective, a brief review follows.

Among modern systems, the genera of Anisophylleae have been included as a tribe in the Rhizophoraceae by Melchior (1964) and Takhtajan (1980), and by Thorne (1983) as a subfamily. Dahlgren (1983) and Cronquist (1983) recognized the separate family Ansiophylleaceae. In a review of the taxonomy and ecology of the Asian Rhizophoraceae, Hou (1958) included the genera of Anisophylleae. Prance et al. (1975) also followed this approach in a revision of Amazonian Rhizophoraceae. Van Vliet (1976), in a detailed analysis of the wood anatomy, concluded that the Rhizophoraceae comprise 18 genera arranged in four tribes (see Table 1), including the four genera assigned to the tribe Anisophylleae. Van Vliet (1976) concluded that wood-anatomical data provide no convincing case for excluding the Anisophylleae. This is no doubt partly due to the unusual amount of variation in the three tribes of the Rhizophoraceae s. str. In Table 1, we recognized a fifth tribe, Hypogyneae, which was separated from the tribe Macarisieae by Steyermark & Liesner (1983) on the basis of several morphological features (but cf. Juncosa and Tomlinson, this volume). Tobe & Raven (1987a) found that floral, seed, and embryo-

Trichomes (simple): C = common, F = few, – = absent.

logical characters do not support segregation of this tribe.

The ordinal position of the 18 genera is even less agreed upon than the family composition. Melchior (1964) and Takhtajan (1980) assigned the Rhizophoraceae, including Anisophylleae, to the Myrtales. However, the consensus of the symposium on Myrtales at Sydney in 1981 (see Dahlgren & Thorne, 1984) was that the family should be excluded from that order. Cronquist (1983) retained the two families apart in his Rosidae with Anisophylleaceae in Rosales and Rhizophoraceae in the Rhizophorales. Dahlgren (1983) placed the Anisophylleaceae in the Corniflorae (Cornales) and the Rhizophoraceae in the Myrtiflorae (Rhizophorales). Thorne (1983) placed his Rhizophoraceae s. l. in the Corniflorae (Cornales). While a large literature has developed on various aspects of mangrove biology and management (see Rollet, 1981), the evolutionary relationships of the mangrove genera and their relatives remain much less studied.

Leaf architecture of samples of all genera of Rhizophoraceae and Anisophylleaceae is examined in this study to assess the contribution of foliar

characters to several taxonomic problems. Histological features detectable from cleared whole leaves are included in the observations. The leaf-architecture scheme developed by Hickey (1973, 1979), and later applied by Doyle & Hickey (1976), Hickey & Wolfe (1975), and Hickey & Doyle (1977) has supplied a practical basis for gathering and interpreting these data in an evolutionary context. In addition, we have reviewed the wood-anatomical data from the comprehensive studies of Marco (1935) and van Vliet (1976). Using these data we will assess the intergeneric variability, the degree to which tribal groupings can be supported, and whether the exclusion of Anisophylleaceae from Rhizophoraceae can be sustained. These are the easier tasks. More complex is an assessment of the position of the Ansiophylleaceae among the angiosperms.

MATERIALS AND METHODS

The leaf sample, including 53 specimens representing all 18 genera, was obtained from the herbaria of the Missouri Botanical Garden (MO), Paris (P), and some individual collectors. In addition, descriptions were amplified after inspecting all Rhizophoraceae slides deposited in the National Cleared Leaf Collection currently deposited at the Peabody Museum of Yale University. All specimens are cited following generic descriptions.

All of the leaves were studied as safranin-stained clearings. The permanent specimens prepared for this study were cleared in 5% NaOH followed when necessary by 5.25% $NaHCO_3$ (commercial laundry bleach). Chloral hydrate was avoided, as it tends to destroy the differential stainability of venation. The clearings were dehydrated to 95% ethanol, stained in 0.5% safranin-O in 95% ethanol, dehydrated to toluene, and mounted between glass plates in cover glass resin. Hickey's (1979) descriptive protocol was followed. Leaf rank on a scale of 1–4 with three subdivisions within each rank, as presented by Hickey (1977 and pers. comm.), was scored for each specimen. The term "domain" is used to denote the area bounded by veins of a given rank, except that intercostal area is used instead of "secondary domain." The shape of intercostal areas and higher-order domains is a useful measure of the regularity of architectural organization (Hickey, pers. comm.).

Except where descriptions from other literature are specifically noted, all of the descriptions given here and used for discussions and conclusions are restricted to the specimens cited. No claim is made that the sample observed encompasses all of the variation, particularly in the larger genera.

OBSERVATIONS

Anisophyllea R. Br. ex Sabine (Figs. 32–39)

Leaves are chartaceous to membranaceous, entire, markedly asymmetrical in most species, ovate on one side, elliptic to obovate on the other. Those of *A. pomifera* are symmetrical and suborbiculate. Vincent & Tomlinson (1983) described the marked dimorphy in *A. disticha*. Venation is acrodromous, basal or suprabasal; the primary vein is slightly curved and is the same size as or larger than the acrodromous secondaries. Secondaries are perfect, extending more than ⅔ the distance toward the apex. Simple intersecondaries are present or absent. The uniformly curved secondaries originate from the primary at a narrow or wide acute angle, the upper more obtuse or acute than the lower. Tertiaries are percurrent and forked or unforked and may be acute or perpendicular to the primary vein; angle of origin is acute or right, exmedially or admedially to the secondaries. Quaternary veins may be percurrent or not and are random orthogonal to the tertiaries. Stomata appear to have 2 large paracytic guard cells surrounded by 8–10 smaller epidermal cells with radiating anticlinal walls. The margin in *A. meniandii* has shallow convex glands that are not approached by any larger veins. Minor veins in the area often have tracheoidal endings but do not closely approach the gland. Other species have no detectable glands.

Specimens examined. *Anisophyllea apetala* King: SARAWAK. *Clemans & Clemans 21596* (MO). *A. boehmii* Engl.: Burundi, *Reekmans 2686* (MO). *A. cinnamomoides* (Gardner & Champ.) Alston: Sri Lanka, *Meijer 1709* (MO), *Macnae s. n.* (1968) (US; LJH 1855). *A. disticha* (Jack) Baillon: Sumatra, *Toroes 2610* (US; LJH 1856); Borneo, *Elmer 20409* (MO). *A. griffithii* (Jack) Baillon: North Borneo, *Anderson 4290* (MO). *A. meniandii* Aubrév. & Pellagrin: Liberia, *Jacques-Georges 25941* (MO). *A. poggei* Engl. ex De Wild & T. Durand: Congo, *Makany 1054* (MO). *A. pomifera* Engl., Malawi, *Pawek 7414* (MO).

Anopyxis (Pierre) Engl. (Figs. 1, 2)

Leaves are symmetrical, oblanceolate, with an attenuate apex and cuneate base. The texture is membranaceous and the margin entire. The eucamptodromous pattern tends toward brochidodromy distally. The primary vein is moderately thick and straight. Secondary veins have a widely acute divergence, are uniform base to apex, and curve uniformly toward the margin. Long sinuous intersecondaries are common. Tertiary veins are acute exmedially and right or obtuse admedially. They are often percurrent with intersecondaries and, distally, with secondaries. Tertiary veins are generally oblique to the primary vein. Quaternary and quinternary veins produce orthogonal domains of irregular shape. The polygonal islets are often formed in interquinternary domains. Occasional marginal glands are vascularized by short straight veins that originate on a secondary arch. The gland is a shallow mound on the edge of the entire margin.

Specimen examined. *Anopyxis calaensis* Sprague: Nigeria, *Kennedy 1561* (MO).

Blepharistemma Wall. ex Benth. (Figs. 3–6)

The leaf is symmetrical and elliptic, obovate, or lanceolate with an acute apex and an acute or obtuse base. Texture is chartaceous or membranaceous. The margin is shallowly toothed in *B. corymbosum* or entire in *B. membranifolia*. Eucamptodromous secondaries originate from the straight primary vein at a uniform wide acute or acute angle. In the distal half of *B. membranifolia* the secondaries are brochidodromous. Occasional simple intersecondaries are present and may be exmedially forked. Tertiary veins are sinuously percurrent, often forked, forming polygonal domains with intersecondaries. Tertiary angles of origin are variable, but the tertiaries tend to be oblique to the primary vein. They originate mostly orthogonal to the secondaries but may be exmedially acute. Quaternaries and quinternaries form irregular orthogonal domains. Teeth are shallow, strongly asymmetric, and curved inward to a small concave sinus. An asymmetrical turbinate gland having a superficial columnar epidermis protrudes from the apex parallel to the margin or incurved toward the sinus. A single vein the diameter of a secondary originates from a secondary arch and curves apically to the sinus, ending in the tooth apex, just below the gland. Just inside the margin, tertiary and quaternary veins branch off from the tooth vein and become part of the looped marginal venation.

Specimens examined. *Blepharistemma corymbosum* Wall. & Benth.: India, *Metz 713* (P). *B. membranifolia* (Miq.) Ding Hou: India (CAZ).

Bruguiera Lam. (Fig. 27)

Leaves are coriaceous or chartaceous, entire, symmetrical, elliptic or oblong, with an acute apex and base. Venation, not easily seen, is brochidodromous with tertiary and quaternary arches or with a tendency toward a strong (sub)marginal secondary collector vein. Secondaries diverge from the stout, straight primary vein at a wide-acute to acute-decurrent angle and meet the superadjacent secondaries at an obtuse or right angle. The upper secondaries may be more obtuse than the lower. Intersecondaries are simple or composite and are often admedially ramified or "perfect admedially." Tertiary arches may enclose the secondaries and form an intramarginal vein. Tertiaries originate from either side of the secondaries at acute, right, or obtuse angles. Tertiaries may be randomly forked and may form large polygonal domains elongated parallel to the secondaries. Quaternary veins have a random polygonal relationship to the tertiaries. The margin has occasional shallow glands, obscurely vascularized in the existing preparations.

Specimens examined. Bruguiera gymnorrhiza (L.) Lam.: cultivated (FTG) [RCK 1443]; Ryukyu Islands, *Kokuhara & Sunagawa 83* (US; LJH 1851). *B. parviflora* (Roxb.) Wright & Arn.: Australia, *Blake 16995* (US; LJH 1852).

Carallia Roxb. (Fig. 21)

Leaves are chartaceous to membranaceous, symmetrical, entire or toothed, elliptic, obovate or ovate, mucronate or acute at the apex and acute to decurrent at the base. Venation is brochidodromous or eucamptodromous basally and brochidodromous distally. Secondary veins diverge at a narrow or wide acute angle from the straight primary, at a uniform angle, or more widely acute angle approaching the apex. Secondaries in brochidodromous segments join the superadjacent secondaries acutely and may be enclosed by tertiary and higher-order arches. Tertiaries may diverge at right angles or be acute exmedially and obtuse admedially. Tertiaries ramify randomly and may be retroflexed; the branches are sometimes aligned with the secondaries and intersecondaries. Intersecondaries are basally simple, distally composite, or forked. In *C. brachiata,* intersecondaries evenly divide the intercostal areas and join the superadjacent secondary high in the intercostal area. Teeth in *C. fascicularis* are acuminate, closely spaced, and are basally and distally concave. Veins originate from eucamptodromous arches (tertiary and higher sized) and enter the teeth symmetrically. They pass off higher-order loops and veinlets obtusely, forming garland connections below the teeth. *Carallia brachiata* had no expressed teeth but regular, papillate, nonstaining glands. Vascularization is often by an approaching marginal loop or several small anastomosing veins that often flare just below the gland. Hou (1958) reported the teeth to be dense in juvenile leaves and quite variable for the genus in general.

Specimens examined. Carallia brachiata (Lour.) Merr.: Hainan, China, *Lau 488* (MO); Indochina, *Pierre 683* (A, MO). *C. fascicularis* Guillaumin: Cochinchina, *Poilane 116* (US; LJH 1848). *C. integerrima* DC.: India, *Saldana 15267* (US; LJH 1850). *C. lucida* Roxb.: Burma, *Gallatly 783* (US; LJH 1849).

Cassipourea Aubl.
(Figs. 13–16, 19, 20)

The leaf is symmetrical and elliptic to wide ovate (to orbiculate in *C. rotundifolia*). Texture is chartaceous to coriaceous, and the margins are entire or shallowly toothed. The straight primary vein is attached to brochidodromous secondaries, which in turn pass off tertiary and quaternary loops. Secondary arches attach to superadjacent secondaries at acute, right, or obtuse angles. In *C. rotundifolia,* the venation pattern is reverse eucamptodromous with retroflexed secondaries. Secondary veins have a wide-acute, uniform angle of origin from the primary vein. They form regular intercostal areas. Intersecondaries are simple, short, and forked, or long, then extending to the secondary arches. There may be several per intercostal area. Tertiary veins are obtuse or random admedial to the secondaries, and acute or random exmedially. Tertiaries are forked and not often percurrent. Tertiary domains are irregularly polygonal, with several extending across an intercostal area. Quaternary veins originate randomly, forming irregular, well- or poorly defined domains. Teeth are very shallow with a slightly convex glandular surface that may have a tuft of simple trichomes. No sinus is distinguished distal to the apex. Teeth are vascularized by a single arching vein originating from a secondary arch. As the vein curves apically toward the tooth, it passes off tertiary and quaternary loops. No marginal glands were detected in *C. ceylanica.*

Specimens examined. Cassipourea brittoniana Fawcett & Rendle: Jamaica, *Award & Proctor 14422* (GH, US: LJH 1198). *C. barteri* (Hook. f.) N. E. Br.: Cote d'Ivoire, *Chevalier 19981* (P); *C. ceylanica* (Gardn.) Alston: Sri Lanka, *Mueller et al. 69042737* (MO); Sri Lanka, *Cooray 70040204R* (US: LJH 1854). *C. elliptica* Poir.: British Honduras, *Schipp 254* (GH; LJH 1302). *C. guianensis* Aublet: Puerto Rico, *Liogier 10575* (GH; LJH 1199); Brazil, *Dahlgren & Sella 86* (US: LJH 1853). *C. gummiflora* Tul. var. *gummiflora*: Madagascar, *Boivin s.n.* (1851) (P). *C. peruviana* Alston: Peru, *Croat 20518* (MO); Peru, *Klug 2235* (GH: LJH 1301). *C. rotundifolia* (Engl.) Alston, Tanganyika, *Schlieben 3552* (GH; LJH 1303).

Ceriops Arn. (Figs. 28, 29)

Leaves are coriaceous, entire, symmetrical, oblong, with a rounded apex and an acute, decurrent base. Venation is obscure, brochidodromous. Secondaries diverge from the straight primary moderately acutely, the upper ones somewhat more obtuse than the lower. Secondary arches join the superadjacent secondaries obtusely. Intersecondaries are simple, equally dividing the intercostal areas. Tertiary veins originate at obtuse or right angles admedially and exmedially and may be admedially ramified. Quaternary veins branch from transverse tertiaries and run parallel to the secondaries. Occasional convexities in the margins do not look glandular and are not obviously vascularized.

Specimens examined. Ceriops boiviniana Tul.: Madagascar, *Gentry 11901* (MO: LJH 4512); Comoro Isl., *Lorence 2872* (MO).

Combretocarpus Hook. f. (Fig. 40)

Leaves are membranaceous, entire, symmetrical, elliptic, with an obtuse apex and acute base. Secondaries arising from the straight primary vein are brochidodromous distally and eucamptodromous basally. Secondaries arise at a uniform, narrowly acute angle and are uniformly concave. The brochidodromous secondaries join superadjacent secondaries at right angles. Simple intersecondaries are present. Tertiary veins are percurrent and arise from both sides of secondaries at right angles. Tertiaries are oblique to the midvein at a uniform angle. Quaternary veins are orthogonal to tertiaries. Looped venation is typical at the margin but a straight collector vein may be present. No teeth or marginal glands were detected.

Specimen examined. Combretocarpus rotundatus (Miq.) Danser: North Borneo, *van Niel 4271* (MO).

Comiphyton Floret (Figs. 7, 8)

Leaves are symmetrical, narrowly oblong, with an acuminate apex and obtuse base. Texture is membranaceous, and margins are entire. Eucamptodromous secondaries arise from a straight primary vein at a moderately acute divergence angle with the upper veins more obtuse than the lower ones. The secondaries are uniformly curved with lower secondaries being longer and more strongly ascending. The few short intersecondaries are exmedially forked. Tertiary veins are sinuously percurrent and oriented at approximately right angles to the primary vein, especially the outer ones. They are acute exmedially and obtuse admedially. Quaternary and quinternary veins arise orthogonally and form irregular polygonal domains. No teeth are expressed, but shallow, marginal, domelike glands are present. Short, single veins arise from secondary or tertiary loops and end directly below a gland. The leaf venation drawings of Floret (1974) agree with my observations.

Specimen examined. Comiphyton gabonensis J. J. Floret: Gabon, *Le Testu 5918* (P).

Crossostylis Forster & G. Forster (Fig. 23)

Leaves are chartaceous, entire or toothed, symmetrical, wide oblong to narrow obovate, with an acute or obtuse apex and an acute to subdecurrent base. Venation is brochidodromous or sometimes basally eucamptodromous. Secondaries arise with a narrow- or wide-acute divergence from the straight primary vein. Secondaries are uniformly curved, join the superadjacent secondaries at right angles, and are enclosed by tertiary and quaternary arches. Tertiary veins are usually forked, originating at random angles. Quaternary and quinternary veins form irregularly polygonal domains and are often retroflexed. Teeth are shallowly crenate with a fine glandular apiculum. A single, conspicuous tooth vein originates at a secondary or higher-order arch, which becomes smaller in diameter distally. Smaller veins of the marginal reticulum attach decurrently to the tooth vein.

Specimens examined. Crossostylis biflora Forster: Samoa, *Veupel 493* (US: LJH 2256); Tahiti, *Balgooy 1715* (MO); *C. multiflora* Brongn. & Gris.: New Caledonia, *McPherson 2344* (MO).

Gynotroches Blume (Fig. 24)

Leaves are chartaceous, entire, elliptic with an acuminate apex and an acute base. Venation is eucamptodromous with secondaries uniformly curved after diverging at a wide acute angle from the straight primary. Intersecondaries are admedially simple and exmedially composite. Tertiary veins are acute exmedially, obtuse admedially, and admedially and transversely ramified. Quaternaries and quinternaries are polygonal to irregular. Uncommon marginal, glandlike, shallow protuberances are not consistently vascularized. An enlarged vein may end in the vicinity, but it may not originate as deeply as a secondary or tertiary arch.

Specimens examined. Gynotroches axillaris Blume: Philippines, *Wenzel 1323* (MO); MO 2227076 (MO).

Kandelia Wight & Arn. (Figs. 30, 31)

Leaves are chartaceous, entire, symmetrical, obovate, with an obtuse apex and an acute base.

Venation is obscure, brochidodromous, with secondaries arising at a moderately acute angle from the straight primary vein. Upper secondaries are more obtuse than lower secondaries. Secondary arches join the superadjacent secondaries at right or obtuse angles. Simple or composite intersecondaries are present. Tertiary veins diverge from secondaries at right angles from both sides and may be transversely ramified. No marginal glands were detected.

Specimens examined. *Kandelia candel* (L.) Druce: Taiwan, *Murata & Nishimura 31214* (MO); Taiwan, *Peng 6042* (MO).

Macarisia Thouars

Leaves are symmetrical or asymmetrical, elliptic to suborbiculate. The apex is emarginate, or rounded, or acute or acuminate, and the base is acute to decurrent. The texture is chartaceous or coriaceous and the margin entire or shallowly toothed. Eucamptodromous secondary veins diverge moderately acutely and uniformly from the straight primary vein. They are gradually apically curved and unbranched. Secondaries in the distal half of the leaf may be brochidodromous. The few intersecondaries are short and ramify into tertiaries. Tertiary veins may be sinuously percurrent, and connections to secondaries are at right angles or variable. In *M. lanceolata* the tertiaries are admedially obtuse and exmedially acute. Tertiaries are oriented relatively uniformly at right angles to the primary vein. Quaternary veins are orthogonal to tertiaries, forming irregular polygonal domains. Higher-order veins are indistinguishable in a reticulum. Areole veinlets often anastomose to form smaller suspended islets within an areole. Teeth are shallow, and strongly asymmetric; they have rounded convex bases leading to shallow, rounded, concave sinuses above the glandular apex. The turbinate gland points apically and is surrounded by a tuft of simple trichomes. A single vein originates from a secondary arch and curves toward the tooth apex where it flares slightly. It does not supply the sinus. Tertiary and smaller veins that form marginal loops or the submarginal reticulum merge decurrently or randomly with the tooth vein.

Specimens examined. *Macarisia lanceolata* Baillon: Madagascar, *Capuron 11.339SF* (MO). *M. pyramidata* Thouars: Madagascar, *Serv. Forestier 11R460* (MO); Madagascar, *Dorr 4495* (MO).

Pellacalyx Korth. (Fig. 22)

Leaves are chartaceous, entire, symmetrical, oblong, with an acuminate apex and an obtuse base. Venation is eucamptodromous basally and looped brochidodromous distally. Uniformly curved secondary veins diverge from the straight primary at a uniform, widely acute angle. Secondaries are enclosed by tertiary and higher-order arches. Intersecondaries are short, admedially simple, and exmedially composite. Tertiary veins are transversely ramified and originate from secondaries acutely, both admedially and exmedially. Quaternary and quinternary veins are random. Depressions in the leaf margin contain round, flat-topped glands. A single strong vein arises from a tertiary eucamptodromous loop and ends just at the margin below each gland.

Specimen examined. *Pellacalyx frustulata* Merr.: Philippines, *Wenzel s.n.* (1915) (MO).

Poga Pierre (Figs. 42, 43)

Leaves are chartaceous or membranaceous, entire, symmetrical, elliptic, oblong or lorate, with an acuminate or emarginate apex and an acute base. Venation is brochidodromous with tertiary and higher-order arches, or eucamptodromous at the base becoming brochidodromous distally. The straight or curving primary vein, often distally forked, produces secondaries at a wide acute angle, with upper secondaries often more obtuse than the lower. Secondary arches join the superadjacent secondaries at acute angles. Intersecondaries are simple at the primary vein, becoming composite exmedially. Tertiary veins are sinuous and obliquely percurrent, joining secondaries or intersecondaries. Tertiaries arise at acute angles admedially from secondaries and at right angles exmedially, or their course may be irregular. Quaternary veins are random, often retroflexed, forming incomplete domains. Quinternary veins may be retroflexed in any orientation. No marginal glands were detected.

Specimens examined. *Pogo oleosa* Pierre: Cameroon, *Zenker s.n.*, (1909) (US: LJH 1858); Nigeria, *Ariwaodo s.n.* (1983) (FHI).

Polygonanthus Ducke (Fig. 41)

Leaves are membranaceous, entire, elliptic, with an acuminate apex and an asymmetric, acute base. Eucamptodromous secondaries arise at a wide acute angle from the straight primary vein. A few of the ascending secondaries connect brochidodromously. Some dominant secondaries show an incipient suprabasal acrodromy. Simple intersecondaries are long, robust and common. Tertiary veins are straight, percurrent, and oblique to the midvein at a constant angle. Tertiaries diverge at right angles from both sides of secondaries. Quaternary veins form regular polygonal domains, often elongated parallel to the secondaries. Quinternary veins arise randomly from lower-order veins. No marginal glands were detected. At the leaf tip, the midvein ends at the margin similarly to tooth vasculature in the Macarisieae.

Specimen examined. Polygonanthus amazonicus Ducke: Brazil, *daSilva 4486* (MO).

Rhizophora L. (Figs. 25, 26)

Leaves are coriaceous, entire, symmetrical, oblong or elliptic with an obtuse apex and an acute base. Venation is brochidodromous, and the secondary arches may form a strong composite collector vein. Secondaries diverge from the straight primary at a right or acute (decurrent) angle. The divergence angle is uniform, or the upper and lower secondaries may be more acute than the middle sets. Secondary arches join superadjacent secondaries at acute, right, or obtuse angles. Intersecondaries are absent or simple and arising from primary veins or from secondary loops; they are obmedially ramified parallel to the secondaries. Tertiaries arise at a right angle from both sides of secondaries, are not percurrent, are often orthogonal with intersecondaries, and often are admedially ramified forming a random reticulum with no directional orientation to the primary vein. No marginal glands were detected.

Specimens examined. Rhizophora mangle L.: Florida, *Curtiss 5438* (US: LJH 1846); Hawaii, *Degener & Wielbese 3363* (MO). *R. mucronata* Lam.: Caroline Isl., *Anderson 1049* (US: LJH 1847). *R. stylosa* Griffith: Australia, *Gill 220-4* (MO).

Sterigmapetalum Kuhlm. (Figs. 17, 18)

The leaves are symmetrical, oblanceolate or elliptic, with an acute or emarginate apex and a rounded to acute decurrent base. The leaves are entire-margined and chartaceous. Venation is looped brochidodromous, and secondaries have an acute to wide acute divergence from the straight primary vein. Secondaries are uniformly spaced with the arches fusing with the superadjacent secondaries at obtuse or right angles. Composite intersecondaries may be present. Tertiary veins originate mostly at right angles exmedially and admedially, and are oblique to the primary vein at a constant angle. Tertiaries are forked percurrent, producing irregular but evenly sized domains. Quaternary veins are orthogonal to tertiaries. Quaternary and higher-order loops festoon the secondary arches. Veinlets in the areoles often anastomose to form small suspended islets. Rarely a flattened marginal gland is found that may be directly vascularized by a single vein arising from a tertiary loop. The illustration of leaf architecture by Steyermark & Liesner (1983) agrees with these observations.

Specimens examined. Sterigmapetalum guianense Steyerm. subsp. *ichunense* Steyerm. & Liesner: Venezuela, *Liesner 7314* (MO); Venezuela, *Clark 7275* (MO).

DISCUSSION

VENATION PATTERNS

Brochidodromy and eucamptodromy appear to be quite closely related since intermediate forms are often found. In intermediate leaves, the distal secondary veins are always brochidodromous and the proximal secondary veins always eucamptodromous. The ontogeny of lamina tissue in many dicot leaves begins with the blocking out of the distal portion of the lamina, while the proximal portion is produced later following intercalary growth of the midrib. In early developmental stages of *Fuchsia* and *Hauya* (Onagraceae; Keating, unpubl.), brochidodromous leaves appear to have more or less simultaneous lamina inception with unified marginal growth. The cross attachment of secondary arches to the superadjacent secondaries occurs as the marginal expansion is slowing down. In eucamptodromous leaves, the later basipetal inception of secondaries on the midrib is followed by an acropetal marginal expansion of the lower lamina. This produces apically arching secondaries that eventually dissipate in submarginal loops parallel to the margin.

Transitions between distal brochidodromy and basal eucamptodromy are commonly found in *Anopyxis*, *Carallia*, *Crossostylis*, and *Pellacalyx* of the Rhizophoraceae, as well as *Combretocarpus*, *Poga*, and *Polygonanthus* of the Anisophylleaceae.

The developmental transition from brochidodromy to eucamptodromy suggests a phylogenetic recapitulation, but further, it is certainly clear that the two venation patterns are closely related with eucamptodromy always appearing later in development. The data of Hickey & Wolfe (1975) show that brochidodromy is stratigraphically earliest, and it tends to have the lowest rank order (organizational complexity and regularity) of any type of angiosperm venation pattern.

Rhizophoreae, having the most coriaceous leaves, are exclusively brochidodromous with well-developed secondary arches meeting the superadjacent secondaries at an obtuse angle. These arches have tended to become straightened, forming a submarginal collector vein, a tendency shown by no other tribe. This implies a leaf ontogeny with little if any basal acropetal expansion. Instead, it can be hypothesized that the leaves have a uniform marginal expansion, followed by a more abrupt cessation of expansion and a more synchronized final marginal differentiation.

Tertiary veins in the Rhizophoraceae generally do not show predictable patterns in most genera. They are generally forked, not percurrent, and have irregular domains. Branching from secondaries is acute to obtuse and seldom sufficiently well developed to be called orthogonal, or regularly polygonal.

Areolation is most commonly imperfect, although it may be well developed in *Blepharistemma*, *Comiphyton*, and *Macarisia* of the Macarisieae, and in *Combretocarpus* of the Anisophylleaceae. Free vein endings are variable within each tribe but generally fewer than seven. The highest number, to greater than 20 in *Anisophyllea*, is large for both families.

The most distinctive pattern of secondary architecture is found in *Anisophyllea*, most species of which show basal and suprabasal acrodromy (Fig. 32). Some species (*A. griffithii*, Fig. 33, and a specimen of *A. pomifera*) are not acrodromous but rather eucamptodromous with irregular spacing of the pinnate secondaries on the midvein. All specimens of the other three genera of Anisophylleaceae are eucamptodromous, often with distal brochidodromy. *Polygonanthus* has some secondaries that show the tendency toward strong ascending curvature parallel to the margin as seen in *Anisophyllea*.

MARGINAL TEETH AND GLANDS

As leaf teeth in the Rhizophoraceae are best developed in the Macarisieae, we will refer to them as the Macarisioid type. The teeth are best developed and largest in *Blepharistemma* (Figs. 3–5), although conspicuous expression can also be found in the genera *Macarisia* (Figs. 10–12), *Cassipourea* (Figs. 13, 14), and in *Carallia* of the Gynotrocheae. In Macarisieae, the teeth are markedly asymmetric, having a gently convex margin proximal (basal) to the tooth apex. The apex is incurved facing directly onto an abruptly or gradually concave sinus.

Tooth vascularization is always by a single vein usually originating from an ascending secondary vein or tertiary loop. It may begin below the tooth and curve gradually toward the apex, entering the tooth symmetrically (Figs. 11, 12). In other cases, the vein originates directly opposite the tooth apex and follows a straight course toward the distal margin of the tooth, supplying the sinus as well as the apex (*Blepharistemma*, Fig. 5). The tooth vein is usually more strongly developed than the neighboring veins, which often join it oriented randomly or decurrently. The tooth vein ends slightly flared at the margin, which is surmounted by a turbinate, rounded or flattened gland. On expressed teeth, glands are often incurved toward the sinus. They often show no stainability and often have a surface of columnar cells. No visible epithem appears within the lamina distal to the vein. On leaf margins with glands but no expressed teeth, the relationship between veins and glands is not basically different from those leaves with expressed teeth.

Carallia fascicularis shows an unusual tooth for the family. It is concave on both sides, very frequent and conspicuous, and is vascularized by one vein with tertiary garland connections to the neighboring tooth veins.

Lersten & Curtis (1974) reported on the structure of colleters as found at the base of stipules in *Rhizophora mangle*. They are not regularly associated with vascularization, and they appear from the evidence presented to have no obvious relationship to glandular teeth in other genera of the family.

Within the available data, there are no strong correlations between the degree of expression of glands and teeth with the habit or habitat. It can be noted in general that the four specialized mangrove genera have more coriaceous leaves than the inland genera. Givnish (1979) reviewed the statistical data showing a correlation between toothed (nonentire) leaves and a thin, noncoriaceous lamina. He also noted that deciduous leaves are toothed more frequently than evergreen leaves. If the ancestors of Rhizophoraceae were thin-leaved and possibly from seasonal habitats, the nontoothed leaves are clearly derived. On the other hand, the best-developed teeth are found only on plants with eucamptodromous venation, while brochidodromous leaves have very reduced teeth/glands or no marginal features at all. Hickey & Wolfe (1975) presented stratigraphic evidence that the brochidodromous pattern is primitive in angiosperms. While it is tempting to regard teeth in Rhizophoraceae as a reduction series, this cannot be taken as proven.

EPIDERMIS AND STOMATA

The paradermal outline of the anticlinal walls of epidermal cells is not particularly useful systematically in these genera. In nearly all specimens, cells are polygonal (isodiametric or elongated up to 2:1 length/width ratios) and are the same on both surfaces. *Blepharistemma* has sinuous abaxial epidermal cells, *Macarisia* and *Poga* have papillate abaxial epidermal surfaces. *Anisophyllea* species vary in cell outline from polygonal to undulate to interlocking shapes with the two surfaces matching or not. In some genera, occasional larger rounded cells occur that have more radiating neighbors than most of the smaller cells. Such large cells were found in *Carallia* and *Pellacalyx* of the Gynotrocheae, and in *Anisophyllea* and *Polygonanthus* of the Anisophylleaceae.

Observations on stomatal types are difficult in some cases, as they may be quite obscure in clearings. Nevertheless, a few conclusions seem valid. The Rhizophoreae are quite distinct with their apparently cyclocytic patterns (Figs. 27, 29, 31). The subsidiary cells appear narrow and differentiated from other epidermal cells. They vary in number from 5 to 8–10 cells surrounding the guard cells. Stomata are exclusively abaxial in all genera observed. While the brachyparacytic pattern is most common in all other genera of both families, anomocytic and anisocytic types were noted as well.

IDIOBLASTIC CELLS

The Macarisieae and Hypogyneae are distinguished by having prismatic crystals with small druses rarely present (*Blepharistemma*). All other genera studied have only druses, no prismatics. Occasional specimens have no crystals. Druses in the Rhizophoreae are normally birefringent but have centers that appear dark or extinct under polarized light. This phenomenon was also noted in *Pellacalyx*, a genus otherwise clearly belonging to Gynotrocheae.

In the Gynotrocheae, druses tend strongly to cluster along veins with only a few scattered randomly in the mesophyll. In other tribes, the distribution of crystals varies among the genera. Crystals may cluster nonexclusively at the veins, and many are scattered randomly. In this respect, the Anisophylleaceae are unexceptional.

Foliar sclereids of several types were noted in this study in both families. A series of studies by Rao & Bhattacharya (1978), Rao et al. (1978), and Rao & Das (1979) have also called attention to these cell types, particularly in the tribe Rhizophoreae. "Diffuse polymorphic sclereids" (Rao et al., 1978), here called astrosclereids, are found in *Bruguiera*, *Ceriops*, and *Rhizophora* (Figs. 25, 26) of the Rhizophoreae and in *Pellacalyx* of the Gynotrocheae. A second type, the terminal tracheoid, is characteristic of *Macarisia*, *Cassipourea*, *Crossostylis*, *Bruguiera*, and *Kandelia* (Fig. 30) of the Rhizophoraceae, as well as in *Anisophyllea*, *Combretocarpus*, and *Poga* (Fig. 43) of the Anisophylleaceae. Only in Rhizophoreae are astrosclereids and terminal tracheoids commonly found together.

FAMILY AND TRIBAL DELIMITATION: RHIZOPHORACEAE

A review of the available leaf-architectural and histological data (Table 2) demonstrates much overlap in most features and an apparent relatedness among all of the genera. Yet a few characters readily distinguish the tribes. The Macarisieae and Hypogyneae have prismatic crystals in the leaves, and the Hypogyneae are further differentiated by having mostly looped brochidodromous leaf venation instead of mostly eucamptodromous as found in the Macarisieae.

In several genera of the Macarisieae (*Anopyxis*, *Blepharistemma*, *Comiphyton*, *Macarisia*), the leaf-rank organization is unusual: the tertiary veins and areolation show a high level of organization while the secondaries are less well organized. Normally, rank order increases proceed in ascending order from secondaries through tertiaries to the organization of areoles (Hickey, 1977). Following current practice (Levin, 1986; Hickey, pers. comm.) we have ranked the leaves according to the highest level obtained so that the maximum evolutionary advancement is reflected in the classification. In his study of the leaf architecture of Euphorbiaceae: Phyllanthoideae, Levin (1986) hypothesized that venation where secondaries are less well organized than tertiaries represents a regression of rank order. He found this type among leaves from arid, arctic, and alpine habitats. What its significance is in the Macarisieae remains obscure, as these genera do not face such environmental stresses.

The Gynotrocheae and Rhizophoreae are distinguished from the Macarisieae by having druses in the leaves. The Rhizophoreae have coriaceous leaves with brochidodromous venation and a cyclocytic stomatal pattern unique in the family. Also, three of the four genera in this tribe have astrosclereids in the leaves. The Gynotrocheae have chartaceous leaves and brachyparacytic or other noncyclocytic stomata. In many respects the Rhizophoreae are the most unified and specialized group of genera due to their mangrove habit, vivipary, chromosome morphology (Yoshioka et al., 1984), bijugate phyllotaxy (Tomlinson & Wheat, 1979), and the leaf

TABLE 2. *Summary of leaf characters of the Anisophylleaceae and tribes of Rhizophoraceae.*

	Macarisieae	Hypogyneae	Gynotrocheae	Rhizophoreae	Anisophylleaceae
Shape	elliptic, obovate, oblanceolate, suborbiculate, symmetrical, or asymmetrical	elliptic, oblanceolate, ovate (wide or narrow) orbiculate	elliptic, obovate, ovate (often narrow)	elliptic, occasionally obovate	elliptic, suborbiculate, symmetrical or asymmetrical
Apex	acuminate to emarginate or rounded	acuminate to emarginate or rounded	acuminate to obtuse	acute to obtuse	acuminate to rounded or emarginate
Base	decurrent, acute to obtuse	decurrent, acute to rounded	decurrent, acute to occasionally obtuse	decurrent to acute	decurrent to acute or rounded
Margin	toothed or entire	toothed or entire	toothed or entire	entire	entire
Texture	membranous or coriaceous	chartaceous or coriaceous	chartaceous	chartaceous or coriaceous	chartaceous
Primary vein	straight; normal to enlarged	straight; normal	straight; normal to enlarged	straight; normal to enlarged	straight; normal; one to several
Secondary type	eucamptodromous to distally brochidodromous	looped brochidodromous to brochidodromous; one reverse eucamptodromous	brochidodromous, eucamptodromous to distally brochidodromous	brochidodromous	brochidodromous, eucamptodromous, acrodromous
Secondary vein origin	wide to narrow acute	wide to medium acute	wide to narrow acute	wide to narrow acute	basal to suprabasal and strongly ascending to wide acute
Intercostal areas	regular or irregular	regular, occasionally irregular	regular or irregular	mostly regular	regular or irregular
Rank order	2r0–3r1	1r3–4r0	1r0–3r0	2r0–3r2	2r0, 4r1
Intersecondaries	short, forked to long, sinuous	simple or composite long or forked	simple or composite often forked	simple or composite often obmedially ramified	none, few, or common; short, long; simple to distally composite
Tertiary veins	random angle; sinuous percurrent or forked	acute to obtuse angle; forked or percurrent; occasionally parallel to secondaries	right to obtuse admedially; right to acute exmedially transverse or parallel to secondaries; ramified or forked	usually right admedially & exmedially; occasionally obtuse or acute	right or acute; sinuous or forked percurrent; mostly alternate

TABLE 2. *Continued.*

	Macarisieae	Hypogyneae	Gynotrocheae	Rhizophoreae	Anisophylleaceae
Tertiary domains	irregularly polygonal	irregular or regular polygonal	irregular	irregularly polygonal; occasionally parallel to secondaries	irregular polygonal
Highest order	5–7	5–7	5–7	5–8	5–10
Areole development	mostly imperfect, few well developed	imperfect to well developed	incomplete to imperfect	incomplete, imperfect to well developed	incomplete, imperfect to well developed
Areole shape	irregular, polygonal	irregular to polygonal to rectangular	irregular; occasionally polygonal	irregular to polygonal	irregular to polygonal
Free endings	0–2, 1–7, 1–5	0–2, 0–8, mostly < 0–4	1–3, 0–6, 2–9, 3–10	0–4, 0–8	0–2, 3–9, 10–18, 15–> 20
Tracheoidal endings	none	to 70% only in *Cassipourea ceylanica*	none	none or common	none to few to > 50%
Marginal venation	looped; occasionally incompletely looped	looped or incompletely looped	looped or incompletely looped	looped or incompletely looped	looped to incompletely looped; often intramarginal vein
Crystal type	prismatics, rare druses	prismatics	druses, small to medium	druses, sand and small prismatics	druses
Distribution	along veins or random in mesophyll	along veins or random in mesophyll; occasional in epidermis	along veins; random mesophyll or epidermis	along veins, random mesophyll	along veins, random mesophyll
Adaxial epidermis shape	polygonal	polygonal	polygonal; occasionally larger rounded cells	polygonal	polygonal to undulate to interlocking; occasionally large centered cells
Length/width ratio	1–1.5:1	1–2:1	1–2:1	1–2:1	1:1, 1–2:1
Abaxial epidermis shape	polygonal	polygonal	polygonal	polygonal	polygonal to interlocking (same as adaxial epidermis)

TABLE 2. *Continued.*

	Macarisieae	Hypogyneae	Gynotrocheae	Rhizophoreae	Anisophylleaceae
Relative size	same or smaller than adaxial	same or usually smaller than adaxial	same or smaller than adaxial	same as adaxial	same or smaller than adaxial
Stomate type	brachyparacytic, anisocytic, few diacytic, anomocytic	brachyparacytic, anomocytic, paracytic (few diacytic, anisocytic)	brachyparacytic, few anomocytic, anisocytic	obscure but probably all cyclocytic with 5–10 subsidiary cells	brachyparacytic, anisocytic, diacytic, paracytic, anomocytic
Position	abaxial	abaxial	abaxial	abaxial	abaxial
Sclereids	absent	absent	absent	astrosclereids in 3 of 4 genera	absent
Trichomes	absent to very common simple; near veins or random	absent to occasional, simple, long; near veins and lamina	absent	absent	absent to occasional, simple, short to long
Hypoderm	occasional, 2 layered	occasional, 2 layered	absent	usually present, 2 layered	absent

features mentioned above. Juncosa (1984b) found that *Rhizophora* has the most specialized shoot apical morphology and hypocotylar anatomy, with *Bruguiera* more transitional to inland genera of Rhizophoraceae. Leaf samples of *Bruguiera* showed the lowest rank order and the highest number of free vein endings for the tribe, but they are not otherwise distinctive architecturally.

The principal morphological diagnostic features of the Anisophylleaceae are the alternate leaves and the absence of stipules. No microscopic features absolutely distinguish its four genera from the Rhizophoraceae. Features not shared by Rhizophoraceae are asymmetrical leaves, teeth and marginal glands almost entirely absent, acrodromous venation, highest vein order to ten, and free vein endings per areole to greater than 20. But within the Anisophylleaceae these features characterize fewer than all of the species of one genus. All remaining recorded features are also found within the range of the variable tribes of Rhizophoraceae and supply no basis for separating the Anisophylleaceae from the Rhizophoraceae. A good case can be made that the Rhizophoreae are the most distinctive group based on their various specializations, including cyclocytic stomata, unusual druse crystals, high-ranking brochidodromous venation, vivipary, and mangrove habit. Yet much other available evidence argues for the obvious relatedness of the 14 genera of Rhizophoraceae s. str. and for their general similarity to the Anisophylleaceae. The only "teeth" in the Anisophylleaceae, the shallow marginal glands in *Anisophyllea meniandii*, are too simple structurally to allow an opinion on their origin or homologies.

COMPARISONS WITH LEAVES OF OTHER FAMILIES

The leaf architecture of the Rhizophoraceae is sufficiently generalized that comparisons with this aspect of other families is usually not particularly useful in affirming relationships. However, several of the families mentioned below are distinctly unlike the Rhizophoraceae. Each of the families was chosen by Dahlgren (this volume) for closer scrutiny after extensive comparisons using a broad data base. We compared all of the available cleared specimens in the National Cleared Leaf Collection, singling out those genera and species in particular that had the most elaborate, character-rich architecture.

The most useful characters appear to be of complex genetic origin, including secondary architecture, leaf shape, marginal configuration (tooth shape, gland type, and orientation of the related venation). The marginal configuration of the Cunonioid/rosoid leaf, with the internal epithem and the strongly converging marginal veins producing a hydathodal tooth, appears complex and monophyletic. It appears nowhere else than in the rosoid alliance as understood in all of the major current phylogenetic systems. However, there is insufficient information on the Macarisioid tooth type. The apiculate, deciduous gland serviced by a usually small single vein seems widespread and is probably not monophyletic, at least as the structure is detected in clearings.

Celastraceae

The ovate or elliptic leaves of this family are brochidodromous or eucamptodromous and of generally low rank order; the margins are faintly toothed and structurally Macarisioid. *Elaeodendron aethiopicum* and *Celastrus pringlei* have a single dominant vein that arises from a secondary or tertiary loop. It ends just below an apicular gland that is oriented adjacent to or points toward a sinus. All associated minor veins are decurrent on the dominant veinlet and do not participate in vascularizing the gland. In *Celastrus racemosus*, the tooth shape is Macarisioid but no dominant vein approaches the substantial gland. Two or three smaller marginal veins approach the gland but not closely.

A number of leaf characters of this family, particularly the secondary and higher order vasculature and the tooth type, are quite compatible with the Rhizophoraceae.

Cunoniaceae

The leaves have prominent teeth with three converging veins leading to an internal epithem. The converging veins have perpendicular cross braces, giving the Cunonioid tooth a unique appearance but not hiding an obvious similarity to the slightly simpler rosoid tooth. This type of tooth was held by Hickey & Wolfe (1975) to be ancestral to the rosoid tooth, an idea compatible with modern ideas concerning relationships between Cunoniales and Rosales. There is no similarity to the Rhizophoraceae at all.

Cyrillaceae

The two specimens available here, representing *Purdiaea nipensis* and *Cyrilla nipensis*, have elliptic to obovate leaves with entire margins. The brochidodromous secondaries are straightened into a collector vein or are looped, respectively. While *Purdiaea* is unexceptional in its higher-order venation and other features, the *Cyrilla* specimen does have incomplete venation with 15–20 vein endings per undefined aerole. It has stellate hairs of a type not seen in the Rhizophoraceae. The absence of teeth makes it impossible to compare marginal features productively, but the trend toward development of a strong submarginal collector vein in *Purdiaea* is not noted in the Rhizophoraceae.

Elaeocarpaceae

Leaves of this family show broad variation in the level of specialization (rank order), ranging from the 1r1 brochidodromous arrangement of *Elaeocarpus arnhemicus* to the 4r leaves of the genus *Sloanea*. Margins are toothed in all specimens seen, and the secondary architecture ranges from brochidodromous to forked craspedodromous. None of the observed patterns of higher-order venation or areolation can negate relationships with the Rhizophoraceae, nor does the tooth type. The teeth are typically Macarisioid with the strong medial vein servicing a prominent apiculate gland that often points to the sinus. The decurrent branching veins attached to the median vein diverge, often in a falcate curve, and they show no tendency to be involved in tooth venation. This family shows the closest resemblance to Rhizophoraceae on the basis of the leaf architecture.

Erythroxylaceae

The leaves examined have a secondary architecture of looped brochidodromous veins with irregular higher-order domains with a few unique or specialized features. Their level of organization is low first rank. Since the margins are entire, no tooth data are available. In most *Erythroxylon* species examined there is a rounded projecting apical gland vascularized by the midrib. They look the most macarisioid-like in a species from Java. Most of the glandular tips do not resemble the marginal features in the Rhizophoraceae. The family has trends of secondary and tertiary architecture unlike the Rhizophoraceae, including helicoid and admedially dendritic fourth- and fifth-order veins (*E. obtusifolium* from Sri Lanka) and secondaries closely spaced with higher-order veins parallel within the intercostal areas (*E. urbanii* from Puerto Rico).

Flacourtiaceae

Leaves of this large family vary greatly in size, shape, and secondary-venation patterns. Among the toothed leaves, two patterns are found, neither resembling the Rhizophoraceae. One of these has a Cunonioid vascular pattern with a strong median bundle that merges with two strongly converging lateral veins just below an apiculate tooth. The three converging veins are perpendicularly cross-braced with three or four minor veins. The other tooth type has one strong medial vein ending at the tooth apex, which may or may not have once had an apicular gland. Only one branch on the distal side passes through the sinus margin, providing it with conspicuous vascularization. No flacourtiaceous leaves seemed to approach the Rhizophoraceae architecturally.

Geraniaceae

Leaves of this family are often toothed and broadly elliptic. A principal characteristic of the family is parallelodromous secondary venation. Higher-order venation is not distinctive, and the low rank order (2r1) reflects the paucity of distinctive comparative architectural characters. The teeth are typically rosoid throughout all samples examined and therefore quite different from the Rhizophoraceae. *Viviana crenata* (Vivianaceae or Geraniaceae) is typically geranioid, including the presence of the rosoid tooth.

Hugoniaceae

The four *Hugonia* leaf specimens examined are generally compatible with Rhizophoraceae. The secondary architecture is eucamptodromous or looped brochidodromous, and the rank order ranges from 2r to 4r. The crenate margins have teeth very similar to the Macarisioid type. The tooth is generally incurved with the deciduous glandular apiculum pointing toward or located in the sinus. A single large vein, apically curved, arises from the secondary arch or loop and ends below the apiculum. It is associated with branching loops and minor veins that recurve or otherwise show no tendency to converge on the tooth. No features negate relationship with the Rhizophoraceae.

Ixonanthaceae

The three genera (five species) sampled here generally resemble the Rhizophoraceae, although the secondary architecture includes semicraspedodromous as well as brochidodromous types. Teeth are not universal but are found in *Octhocosmus*, and in a reduced form in *Ixonanthes*. Best-developed toothed margins are crenate with the glandular apiculae so "distal" on the tooth as to be on the proximal side of the sinus. A prominent vein arises from a secondary loop, sometimes in an organized semicraspedodromous pattern, and ends just below the gland. Some of the minor veins branching from this trace tend to converge toward the pad below the gland. This represents a significant difference from the Macarisioid tooth. Convergence of several veins toward the gland is a major characteristic of the Cunonioid/Rosoid/Fuchsioid type, although it appears to be an independent trend in the Ixonanthaceae. Other distinctive trends in this family include development of an entire leaf with a fibrous marginal vein in *Klainedoxa* and in *Irvingia*, and semicraspedodromous venation in *Octhocosmus*.

Lepidobotryaceae

The materials examined here are ovate leaves with entire margins and eucamptodromous secondary architecture. Intercostal areas are irregular, as are most of the tertiary domains and areoles. Some percurrent tertiaries are present. These unspecialized examples, *Papania scandens* and *Sarcotheca ferruginea*, are generally compatible with the Rhizophoraceae.

Oxalidaceae

Oxalis acuminata and the other species examined are trifoliate with entire ovate leaflets, which may be ciliate, looped brochidodromous, and with percurrent or irregular tertiaries. The reduced number of vein orders, five or six, and generally reduced appearance are compatible with the Rhizophoraceae.

Linaceae

The samples representing seven species are all more specialized than any Rhizophoraceae described. The secondary architecture is brochidodromous or eucamptodromous, but this ends the similarities. Tertiary and quaternary venation is virtually parallel, being perpendicular to the axis of the intercostal areas (*Roucheria griffithiana*) or parallel to them (*Roucheria calophylla*). *Linum* shows tendencies toward acrodromy and has fine, papillate/serrate, unicellular teeth. No multicellular teeth are present. Tooth glands in *Roucheria* are somewhat Macarisioid in appearance, as a median vein arises from a submarginal loop, ending just below the gland. However, there is also a definite tendency for lateral veins to converge toward the gland, a condition not seen in Rhizophoraceae. In *Linum* and *Reinwartia*, the small marginal projections are multicellular but not glandular or vascularized. It seems doubtful that the Rhizophoraceae leaf type has any close relationship with leaves of this family.

Rosaceae

This family is quite variable, and several types of secondary venation and teeth are found that bear much closer examination. *Fragaria* species generally have rosoid teeth, as does *Holodiscus discolor*, although the latter's medial vein is dominant, with the lateral ones being nearly absent. The marginal teeth of *Cotoneaster pyricantha* and *Kageneckia lanceolata* have deciduous apiculae and prominent medial tooth veins. Convergent lateral veins are present at most teeth or may not be obvious. The incurved appearance of the *Cotoneaster* tooth form is remarkably similar to the Macarisioid tooth.

Saxifragaceae

All leaves examined show a typical Rosoid hydathodal tooth with converging marginal veins that end in a flaring submarginal vascular plexus. They show no relationship to structures of the Rhizophoraceae.

Zygophyllaceae

The ovate leaves of this family are generally not toothed, and they have brochidodromous venation with a different appearance of areolation than Rhizophoraceae. One specimen, representing *Guaiacum sanctum* L., is craspedodromous with two or three small pointed teeth. A tooth is vascularized by a craspedodromous secondary vein that ends below its tip. There is apparently no apiculum or epithem at the tooth. Some minor veins form a converging buttress on the tooth vein. Overall, the tooth does not resemble Macarisioid architecture nor do the leaves resemble those of Rhizophoraceae in other respects.

WOOD ANATOMY

In the comparative wood anatomical literature, only two studies were found that were based on a comprehensive generic sample, those by Marco (1935) and by van Vliet (1976).

It should be noted that neither author developed a major operating hypothesis that the genera of Anisophylleae should be segregated as a separate family nor did their data and analyses support that view. Among the wood features they listed, only those mentioned below may have value in distinguishing the families. Table 3 provides a list of features we believe to have promise in differentiating the tribes and families.

Vessel tangential diameters of Anisophylleaceae overlap the high end of the range of Rhizophoraceae values, but they have the highest average and absolute values for this feature. Average vessel element length of the two families overlaps entirely, but Anisophylleaceae are at the short end of the range. Pores per square millimeter are the lowest for Anisophylleaceae with almost no overlap in the ranges for Rhizophoraceae. This correlates well with the high vessel tangential diameters. A computation of relative parabolic flow rates per mm^2 (Zimmermann, 1983) shows equivalent ranges with the Anisophylleaceae producing their flow rates with fewer pores and larger diameters on the average. The calculations were made using pooled data from the literature and are only indicative.

Macarisieae and Gynotrocheae have simple and scalariform perforations, while these in the Rhizophoreae are exclusively scalariform. Rhizophoreae also have the shortest vessel element lengths for the family, a character normally correlated with simple perforations (Dickison, 1975). It may be that efficiency of conduction (high flow rates) is not selected for in the mangroves. The generally small statures, coriaceous leaves, and restriction to saltwater habitats suggest the need to conserve water rather than to maximize its flow.

No other features—including fiber-tracheids, parenchyma or rays—seem to provide distinctive or mutually exclusive characters for the two families. Many of the characters are quite diagnostic for the genera, but differentiation of the tribes and of the two families is less readily accomplished. This is mostly due to very wide variation among the genera of Rhizophoraceae. The obvious distinctiveness of the Rhizophoreae is paralleled by the leaf data and can no doubt be explained by habitat specialization.

In other characters studied, the Anisophylleaceae show no similarity to the Rhizophoraceae. Chenery (1948) and Kukachka & Miller (1980) noted a positive aluminum test for the family, which is not shared by the Rhizophoraceae. Behnke (1981, 1984) noted S-type sieve element plastids in Anisophylleaceae and Myrtales but P-type in the Rhizophoraceae. In their embryological paper, Tobe & Raven (1987a) pointed out strong similarities of the Anisophylleaceae to the Myrtales and distinct differences with the Rhizophoraceae. However, they (1987b) later concluded that Anisophylleaceae and Rhizophoraceae do share enough developmental homologies to hypothesize common ancestry. The

TABLE 3. *Summary of selected wood features of the Anisophylleaceae and tribes of Rhizophoraceae.*

Character	Macarisieae; Hypogyneae	Gynotrocheae	Rhizophoreae	Anisophylleaceae
Vessel frequency (mm^2)	4-41 (138)	3-29	6-68	1-12
Vessel tangential diameter (μm)	21-340	71-300	34-130	84-430
Vessel element length (μm)	520-2,340	420-1,790	220-1,660	220-1,320
Perforations	simple/scalariform	simple/scalariform	scalariform	simple
IV pitting	alternate, opposite, transitional	alternate, opposite, transitional, scalariform	scalariform, transitional	alternate, with frequent coalescent apertures
Vessel-ray pitting	opposite, transitional, scalariform circular to elongate	alternate, opposite, reticulate circular to elongate	opposite to reticulate half-bordered to simple	rare, alternate to reticulate round to elongate
Fiber-tracheid length (μm)	960-3,390	1,210 3,480	libriform only 710-2,400	840-3,220
Ray type, seriation	heterocellular I, II; 1-5 seriate	heterocellular II, 2 distinct sizes; 1-32 seriate	heterocellular II, III, occasionally homocellular; 1-7 seriate	heterocellular II, 2 distinct sizes; 1-20 seriate
Ray tails, sheaths	1-36 square or erect cells	no tails, occasionally sheath cells	infrequent sheath cells	broad multiseriate, occasional sheath cells
Crystals	ray/axial parenchyma solitary, frequent or infrequent	ray/axial parenchyma solitary or clustered, frequent	ray parenchyma solitary	ray/axial parenchyma solitary, usually chambered to absent

perspective of vegetative anatomy alone is insufficient at present to resolve substantially this problem.

On the basis of their lack of vestured pits and intraxylary phloem and because of their possession of the Macarisioid tooth, the Rhizophoraceae s. str. appear to have no relationship to the Myrtales. Leaf teeth as known in all of the Rosales and Myrtales thus far examined are "rosoid," symmetrically vascularized by two to several converging veins surmounted by a secretory epithem, a submarginal foramen, and a connection to the surface through stomatelike pores. The tooth sinus is never reported to be included in the tooth vascularization. As described earlier here, the Macarisioid tooth is different in all respects. Thus far, the closest similarities to the Macarisioid tooth structure, and the general leaf architecture, can be found in the Dilleniid line. The Celastraceae (Celastrales), Elaeocarpaceae (Malvales), and Cyrillaceae (Ericales or Theales) are commonly classified in that lineage. Similarities seem more distant with the Hugoniaceae (Linales of Cronquist), Lepidobotryaceae (Geraniales of Dahlgren), and Oxalidaceae (Geraniales).

Considering that the field of comparative wood anatomy has a long established tradition, the results of comparisons among the families mentioned in this study are uncomfortably ambiguous. The newer field of leaf architecture has an equally well-drawn glossary and some organized preliminary synthesis regarding the character syndromes and their evolution. Here, too, we are left with equally large ambiguities. While the treatments of leaf architecture of families are far fewer than those based on comparative wood anatomy, existing comprehensive collections of cleared leaves should at least partially compensate. Some of these ambiguities may vanish in the future when the developmental bases of architectural forms becomes better understood and when the homologies of features of some of the larger phylads have been studied.

MORPHOLOGY AND PHENETICS OF RHIZOPHORACEAE POLLEN[1]

Edward L. Vezey,[2] Varsha P. Shah,[2] John J. Skvarla,[2,3] and Peter H. Raven[4]

ABSTRACT

Pollen morphologic data from light, scanning, and transmission electron microscopy were used in a phenetic analysis to assess variation within and among the four tribes traditionally included in Rhizophoraceae: Anisophylleeae, Gynotrocheae, Macarisieae, and Rhizophoreae. Principal components analysis revealed that pollen of Anisophylleeae is phenetically divergent from that of Gynotrocheae, Macarisieae, and Rhizophoreae, and therefore we recognize this taxon at the family level, Anisophylleaceae. In contrast Rhizophoraceae sensu stricto forms a phenetic continuum, with pollen of Macarisieae intermediate between Gynotrocheae and Rhizophoreae. Endoapertures of Anisophylleaceae pollen, when present, are circular and poorly defined, whereas all species of Rhizophoraceae possess endoapertures with some degree of fusion. Pollen of both families has a generalized angiosperm morphology, thereby providing no palynological basis for assessing relationships to Myrtales or other groups.

Comparative palynology in Rhizophoraceae has focused on the mangrove genus *Rhizophora*, primarily in connection with the recognition and study of paleo-shorelines (Kuprianova, 1959; Langenheim et al., 1967; Assemien, 1969; Rakosi, 1978; Sowunmi, 1981). Consequently, several species of *Rhizophora* have been well documented. Langenheim et al. (1967) used light microscope data (pollen shape and a unique endoaperture system) to characterize *R. mangle*, *R. samoensis*, *R. racemosa*, and *R. harrisonii*. Muller & Caratini (1977) expanded the study of modern Rhizophoraceae by employing transmission electron microscopy (TEM) in addition to light microscopy (LM) and scanning electron microscopy (SEM). Their analysis included three species studied by Langenheim et al. (1967), *R. mangle*, *R. racemosa*, and *R. harrisonii*, as well as *R. mucronata*, *R. stylosa*, *R. apiculata*, *R. lamarckii*, and *R. brevistyla*. Muller & Caratini (1977) essentially confirmed the findings of Langenheim et al. (1967), but underscored that most LM characters exhibit too much overlap to separate species. Although their study lacked the benefit of comparison with other Rhizophoreae (*Bruguiera*, *Ceriops*, and *Kandelia*), as well as other members of the family, they subdivided the *Rhizophora* pollen type into four groups by combining LM data with an SEM analysis of sculpture patterns.

Typically, other pollen studies of the family were accomplished as part of floristic or general morphologic surveys (Erdtman, 1952; Kubitzki, 1965; Huang, 1968; Guers, 1974; Geh & Keng, 1974; Sowunmi, 1974; Straka & Friedrich, 1984; Thanikaimoni, 1986a, 1987). SEM studies have been centered on the tribe Rhizophoreae (Tissot, 1979; Bertrand, 1983; Ludlow-Wiechers & Alvarado, 1983). For complete references to pollen studies in the family, see Thanikaimoni (1972, 1973, 1976, 1980, 1986b).

Little palynologic attention has been directed specifically to the taxonomic integrity within and among the four tribes traditionally included in Rhizophoraceae sensu lato: Anisophylleeae, Gynotrocheae, Macarisieae, and Rhizophoreae. Using LM, SEM, and TEM, we investigated the pollen morphology of all genera in these taxa. Of particular interest is Anisophylleeae, which on the basis of a broad array of characters has been considered to constitute a distinct family, Anisophylleaceae (see other symposium papers). With this in mind, we

conducted a phenetic analysis to assess overall morphologic variation within and among these groups and to test the hypothesis of separate familial status for Anisophylleaceae.

MATERIALS AND METHODS

POLLEN MORPHOLOGY

In our investigation, pollen from 51 collections (representing 39 species of Anisophylleaceae and Rhizophoraceae) was examined by light and electron microscopy (Table 1). Hereinafter, Rhizophoraceae is referred to in the strict sense (i.e., only the tribes Gynotrocheae, Macarisieae, and Rhizophoreae). All pollen were initially treated with the acetic anhydride/sulfuric acid acetolysis mixture of Erdtman (1960). For LM, whole grains were mounted in glycerine jelly and observed with a Leitz Ortholux microscope using transmitted light. Measurements (μm) were based on 10–50 undistorted grains when possible. Pollen for SEM was either air dried from 95% ethanol or critical-point dried, sputter coated with gold, and examined with either an ISI Super II SEM or ETEC Autoscan SEM. Pollen for TEM was processed as reported earlier (Skvarla, 1966) and examined with either a Philips model 200 TEM or Zeiss 10 TEM.

PHENETIC ANALYSIS

Operational Taxonomic Units (OTUs). Data from 27 collections (Table 1) were subjected to a numerical phenetic analysis as Operational Taxonomic Units (OTUs; Sneath & Sokal, 1973). These 27 OTUs represent 26 species (*Rhizophora mucronata* has two OTUs) and were selected if data were obtained for all 33 characters (Table 2).

Characters. The 33 characters (Table 2) used in the phenetic analysis are based on standard palynological data (Erdtman, 1952; Faegri & Iversen, 1975), and include 10 LM (1–10), 13 SEM (11–23), and 10 TEM (24–33) characters. Although most are self-explanatory, several merit elaboration. The variability in polar axis (P) and breadth (E) is often expressed in terms of range or minimum and maximum measurements. We used standard deviation (characters 2 and 4) in-

* TET = total exine thickness.

stead, because it is based on all grains measured and is less affected by sample size or aberrant grains. Character 6, endoaperture fusion, expresses information usually included for Rhizophoraceae pollen (e.g., Muller & Caratini, 1977). It is an ordered multistate character based on increasing percentage of endoaperture fusion and was processed in the same way as quantitative characters (Sneath & Sokal, 1973). Character 8, endoapertural index (EI), is the ratio of polar length of the endoaperture (PL) to polar axis (P). It is a ratio we have constructed to express the relative width of the endoaperture.

The 13 SEM characters describe the sculpture of three parts of the pollen surface: mesocolpia (11–14), poles (15–18), and mesocolpial margins (19–23). Although this information can be condensed into three unordered multistate characters, only ordered multistate characters are acceptable with principal components analysis (Gower, 1966). Therefore, as Gower (1966) recommended, we used binary (0, 1) characters to indicate absence (0) or presence (1) of a particular sculpture pattern.

TEM characters 24–28 were recorded as means of measurements (μm) taken from an average of six negatives. All measurements were mid-mesocolpial on equatorial sections perpendicular to the polar axis. Character 33 is an ordered multistate character based on increasing percentage of intercolumellar granulation. The remaining characters (29–32) are expressions of exine shape, that is, the relative contribution of tectum, columellae, foot layer, and endexine to the total exine thickness. In five cases it was necessary to take TEM data from a different collection of the same species (Table 3). This procedure was followed to insure adequate representation of all taxa.

Numerical Analysis. Phenetic variation was analyzed using NT-SYS (Rohlf et al., 1982), a package of multivariate computer programs designed for use in systematics. The data (Table 3) were standardized (i.e., each character being transformed to have a mean of zero and standard deviation of one), followed by calculation of a Pearson product-moment correlation matrix and principal components analysis (Sneath & Sokal, 1973). A minimum spanning tree (Dunn & Everitt, 1982) was calculated using an average taxonomic distance matrix (Sneath & Sokal, 1973) produced from the standardized data set.

Principal components analysis also produces a matrix of eigenvectors showing character loadings on each component (Table 5). If a character has a loading of 0.9 on component I, then $(0.9)^2$ or 0.81 (81%) of that character is expressed or statistically "explained" on component I and the remaining 19% on other components. Table 5 lists all characters with loadings greater than 0.5. If a character has a positive (+) loading, then OTUs with higher values for that character tend to be found toward the positive end of that component. Higher values include larger quantitative measurements, higher-numbered multistate character states, and binary (0, 1) characters with character state 1.

RESULTS

POLLEN MORPHOLOGY

Detailed LM, SEM, and TEM measurements and observations for 27 collections (Table 1) are given in Table 3, and summarized for Anisophylleaceae and each tribe of Rhizophoraceae in Table 4. The supplemental descriptions below include characters not considered in the numerical analysis, as well as unique morphological features in need of emphasis. Morphological delineation is based on all 51 collections (Table 1).

Anisophylleaceae

LM. Pollen is mainly tricolporoidate (occasionally tricolporate), rarely with two apertures, radially symmetrical, and isopolar. Syncolpate grains are common. Endoapertures, when present, are circular but poorly defined.

SEM (Figs. 1–9). Of special note is *Anisophyllea disticha,* which differs markedly from all other species in this study by having a striate surface.

TEM (Figs. 36–43). In *A. disticha* and *A. obtusifolia,* a narrow and highly undulating columellae layer is present in sectional planes near the equator (Figs. 36, 38). In a different sectional plane of *A. obtusifolia,* and in *A. laurina,* the columellae layer is straight, and the foot layer is thinner than the tectum (Figs. 39, 41).

Gynotrocheae

LM. Pollen is tricolporate, radially symmetrical, and isopolar. Endoapertures in all grains are fused laterally, the only tribe so distinguished.

SEM (Figs. 30–35). A psilate–punctate surface is dominant in this tribe.

TEM (Figs. 44–49). In *Crossostylis grandiflora* a trace of granular matrix similar to that described for Macarisieae (see below) is present at the lower tectum margin (Fig. 46). *Pellacalyx* differs from other Gynotrocheae by having a thin tectum and tall, branched columellae that become shorter at the poles (Figs. 48, 49); granules are suggested beneath the lower tectum margin and the distal parts of the columellae.

Macarisieae

LM. Pollen is tricolporate, rarely dicolporate and tetracolporate, radially symmetrical, and isopolar. Shape has the greatest range of the tribes, from suboblate to prolate (character 5, Table 3).

SEM (Figs. 10–23). This tribe processes variable pollen sculpture (Table 4).

TEM (Figs. 50–63). Intercolumellar spaces are either partially or completely filled with a matrix of granules (Figs. 50, 52, 54, 55, 57, 59). Some columellae also are granular distally. In taxa with prominent fused (zonorate) endoapertures (character 6, Table 2), the endexine is granular in the mesocolpia in the vicinity of the endoaperture.

Rhizophoreae

LM. Pollen is tricolporate, radially symmetrical, and isopolar (except some grains in *Rhizophora mucronata*).

SEM (Figs. 24–29). Pollen of *R. mucronata* has a basically punctate–rugulate surface. However, this pattern varies among the five collections examined (Table 1), as well as within collections. In the collection *A. Torre & J. Pavia 11483* rugulate elements are distinct; some grains in this collection showed a punctate–rugulate surface on one hemisphere and a psilate–punctate surface on the other. Dicolporate grains were common. In the collection *J. Bossier 9947* the surface has a faint rugulate–punctate sculpture, while in the collection *Greve 290* it is psilate–punctate. In the collection *Hervien s.n.,* made in 1964, the pollen grains are psilate–punctate, faintly rugulate–punctate, or distinctly rugulate–punctate. Some dicolporate grains are also present in this collection. In the collection *P. Marot 2602* the grains are rugulate–punctate; some also have spinules. Note that spinules were present on the mesocolpial margins of *Carallia brachiata* (Fig. 35), *C. eugenioides* (Figs. 33, 34), and *Gynotroches axillaris* (Fig. 30).

TEM (Figs. 64–69). Tectum thickness is the most variable of the four groups (character 24, Table 3).

PHENETIC ANALYSIS

Principal components analysis reveals two phenetically distinct groups of OTUs (Fig. 70). One group, consisting of all Anisophylleaceae OTUs, is located toward the positive end of component I and the negative end of component II. The first two components account for 25.5 and 20.7% of the total variation. The other group is an elongated continuum formed by the three tribes of Rhizophoraceae, with Macarisieae OTUs distributed across phenetic space between Rhizophoreae and Gynotrocheae. The minimum spanning tree indicates

R7	23	1.2	23	1.4	100	1	4	.17	5	.22	0	1	1	0	0	1

[1] OTU symbols from Table 1 (column 1), characters as in Table 2.

[2] The TEM data for A4, A5, G3, and M2 were taken from the other collection of the same species (Table 1). The TEM data for A6 were taken from the *Pires 1281* collection.

considerable distortion within Gynotrocheae (Fig. 70). Relationships within this tribe are clarified by including component III, which accounts for an additional 13.0% of the total variation (Fig. 71). Component III also reveals marked divergence between *Anisophyllea disticha* (A1) and the other Anisophylleaceae OTUs.

OTUs are distributed across component I based on overall size, tectum thickness, collumellae height, and other characters (Table 5). Thus the larger grains of Anisophylleaceae and Rhizophoreae are to the right (Fig. 70), and the smaller Gynotrocheae pollen is to the left. Anisophylleaceae and Rhizophorea OTUs separate along component II because of differences in sculpture, shape, and other characteristics (Table 5).

TABLE 4. *Summary of data in Table 3 for Anisophylleaceae and each tribe of Rhizophoraceae.*[1]

OTU	Characters															
	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16

The minimum spanning tree interconnects Gynotrocheae OTUs with two short and two long links (Fig. 71). The short connections are *Carallia eugenioides* (G2) to *C. brachiata* (G1) and *Gynotroches axillaris* (G4) at distances of 0.630 and 0.636, respectively. *Pellacalyx* cf. *saccardianus* (G5) joins *C. brachiata* (G1) and *Crossostylis grandiflora* (G3) at distances of 1.035 and 1.023.

Connections within Macarisieae average 0.793, but only one OTU (*Dactylopetalum sessiliflorum*, M5) links with more than two other OTUs within the tribe. The congeneric OTUs *Sterigmapetalum heterodoxum* (M8) and *S. obovatum* (M9) are separated by a distance of 1.377. *Sterigmapetalum obovatum* (M9) is actually more similar (0.603) to *Bruguiera gymnorrhiza* (R1) than to any OTU of its own tribe.

Most Rhizophoreae are directly linked to *Bru-*

TABLE 5. *Character loadings from principal components analysis.*[1]

Direction	Loadings	I	II	III
+	.80–.89		13	
	.70–.79	1, 3, 26	10, 17, 21	16
	.60–.69	9, 20, 24, 25	6, 31	12
	.50–.59		9	22, 28, 32
−	.80–.89	11, 15		
	.70–.79		5	
	.60–.69	8, 32		
	.50–.59	6	25, 28	14, 18, 23, 33

[1] Numbers under each component refer to characters outlined in Table 2. Only characters with loadings greater than 0.5 are shown.

guiera gymnorrhiza (R1), with two exceptions (R5 and R7) which are two links away. The links within Rhizophoreae are the shortest of any tribe, averaging 0.639. In a similar manner, all Anisophylleaceae OTUs are joined to *Anisophyllea obtusifolia* (A3) but at much longer distances (lower similarity) than those within Rhizophoreae. Even discounting *A. disticha* (A1), links within Anisophylleaceae average 0.923, higher than any tribe of Rhizophoraceae. A1 joins A3 from a distance of 1.796, the longest link on the minimum spanning tree. *Anisophyllea disticha* is actually more similar to three Macarisieae OTUs than to *Combretocarpus rotundatus* (A4), the next closest OTU within Anisophylleaceae. The closer Macarisieae OTUs are *Cassipourea elliptica* (M3), *Comiphyton gabonense* (M4), and *Dactylopetalum sessiliflorum* (M5).

Intertribal links are shorter than many intratribal connections. *Blepharistemma membranifolia* (M2), for example, is more similar to R1 (0.702) than to either M3 (0.833) or M9 (0.718). Likewise, *Macarisia ellipticifolia* (M6) is more similar to G5 (0.819) than to either M1 (0.906) or M4 (0.850).

The phenetic gap between Anisophylleaceae and Rhizophoraceae is spanned by a link between *Combretocarpus rotundatus* (A4) and *Dactylopetalum sessiliflorum* (M5) at a distance of 0.913. Although this is greater than intertribal connections within Rhizophoraceae, it is shorter than several links within Anisophylleaceae.

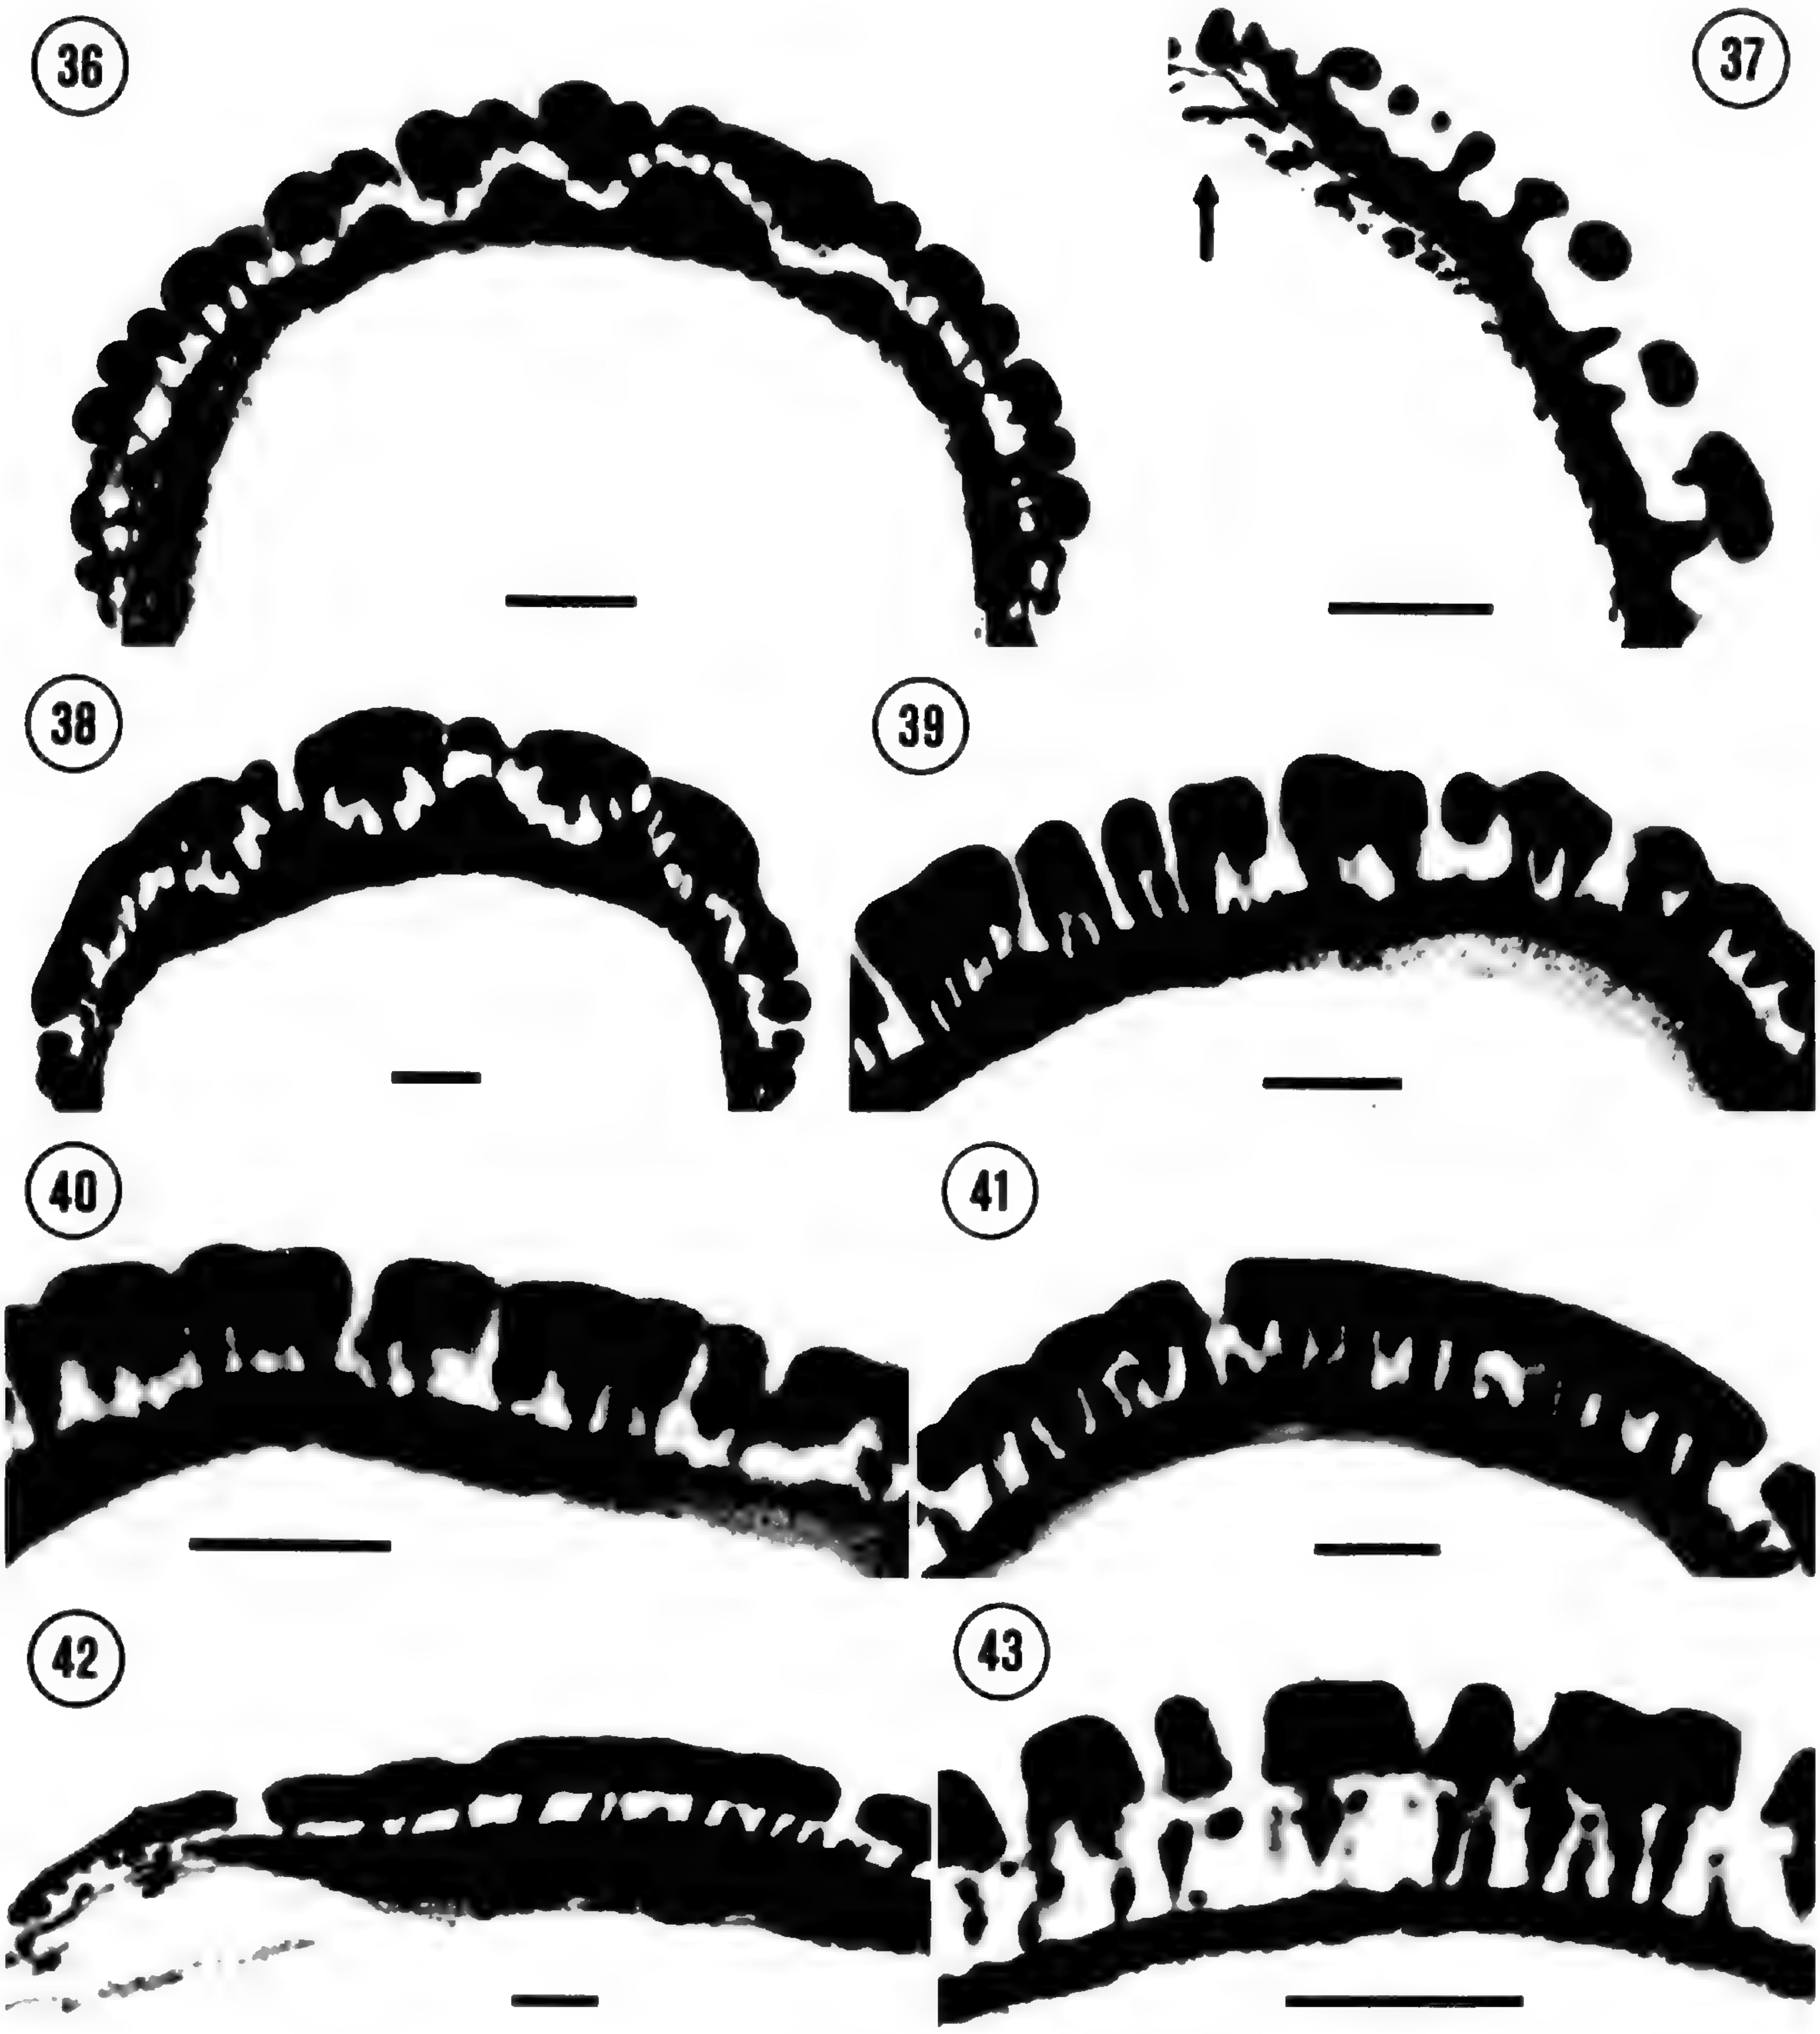
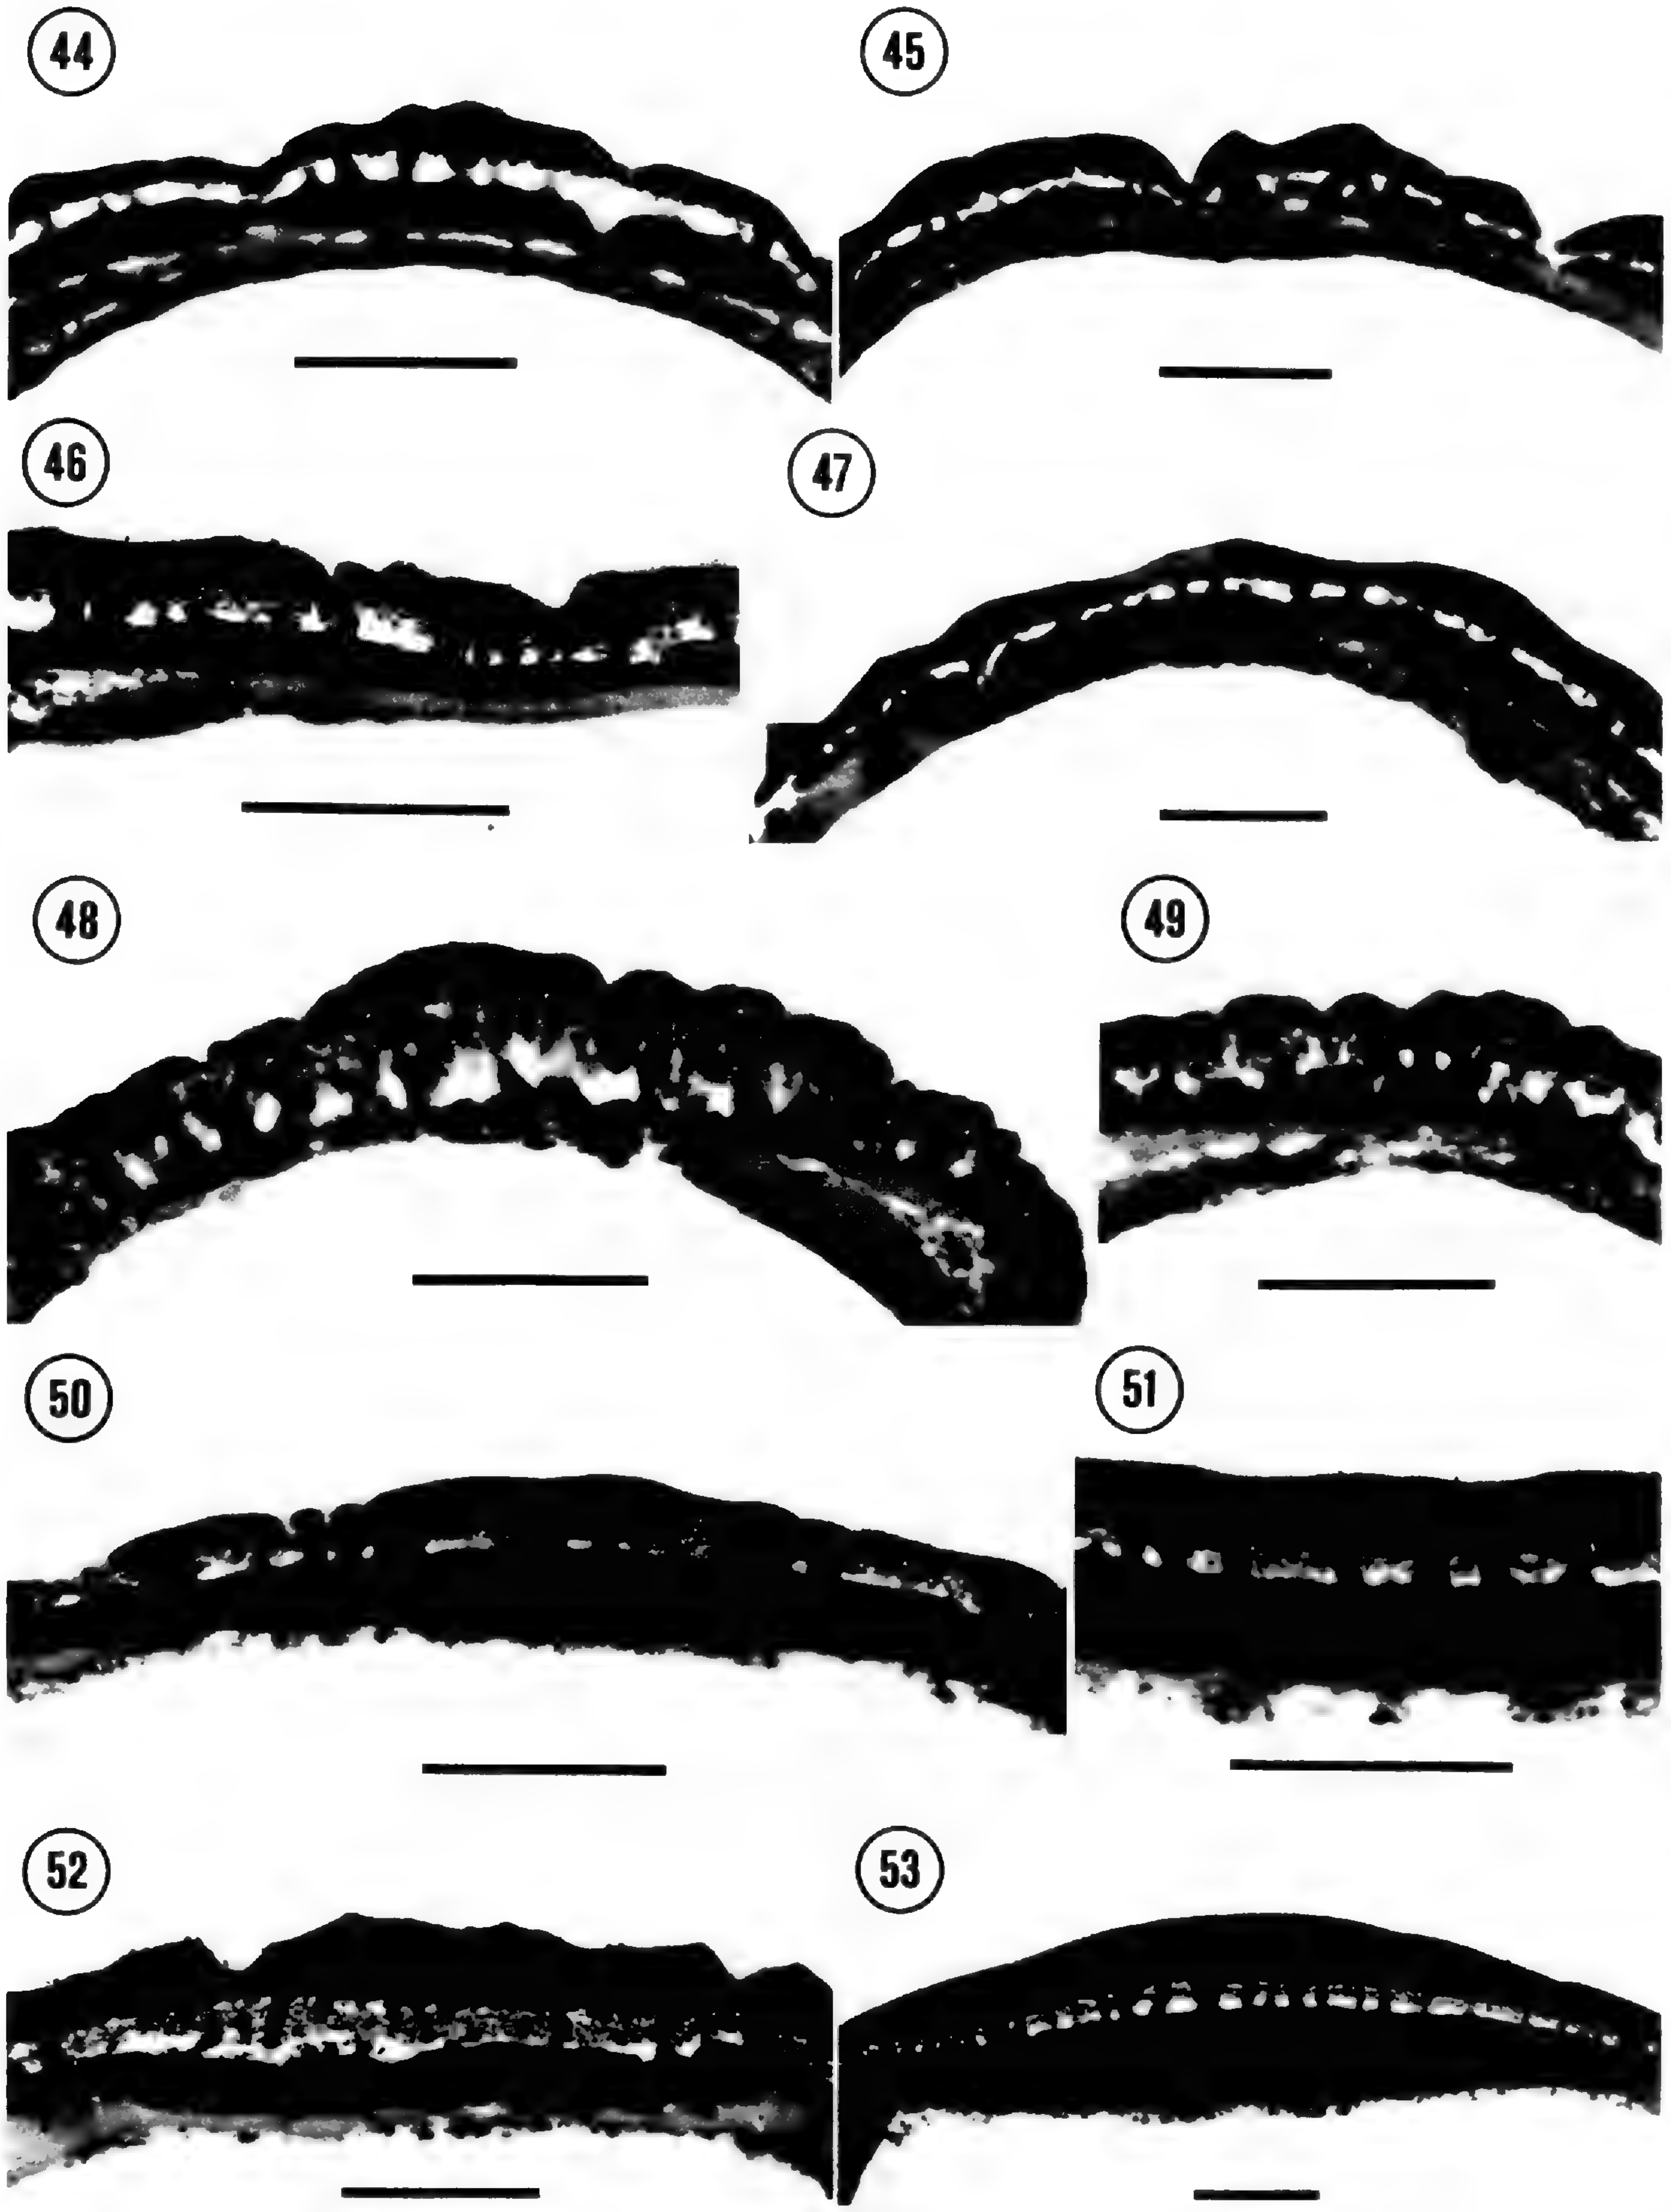


FIGURES 36–43. *Transmission electron micrographs of Anisophylleaceae pollen.—36.* Anisophyllea disticha. *In the center of the mesocolpium the columellae layer is undulating and the corresponding foot layer shows "hills" and "valleys." Toward the colpi the foot layer becomes thin and the columellae are straight. The outer margin of the tectum appears lobed due to perpendicularly sectioned striae.—37.* Combretocarpus rotundatus. *Section of a mesocolpium near an endoaperture (arrow). The tectum is incomplete, the columellae simple, the foot layer uniform, and the endexine disrupted.—38, 39.* Anisophyllea obtusifolia. *The undulating columellae (as in Fig. 38) are present only in some areas of the grain, possibly near the equator. In other sections, the middle part of the mesocolpium also has straight columellae (as in Fig. 39, to the left).—40.* A. fallax. *The tectum is thick and incomplete, the columellae thin and short, and the foot layer and endexine uniform.—41.* A. laurina. *The columellae are well developed.—42.* Polygonanthus amazonicus. *The foot layer is thick and tapering toward the endoaperture (left).—43.* Poga oleosa. *The tectum is incomplete and thick; the columellae are tall, becoming granular distally; the foot layer is thin; and the endexine is thicker than the foot layer and is uniform. Scale bars = 1 μm.*



FIGURES 44–53. *Transmission electron micrographs of Gynotrocheae (44–49) and Macarisieae (50–53) pollen.—44.* Carallia brachiata *and 45.* C. eugenioides. *In both, the tectum is thin, the columellae are short and unbranched, the foot layer is uneven in thickness and the endexine is uniform but has long, narrow gaps in Figure 44.—46.* Crossostylis grandiflora. *A thin granular layer is present just below the tectum. The endexine is thicker and has irregular open spaces near a colpus (left).—47.* Gynotroches axillaris. *The exine is similar to that in* Carallia.*—48.* Pellacalyx pustulata. *The tectum is thin, the short columellae are extensively branched, and the foot layer is thin and irregular. A line separates the foot layer from the endexine. The latter becomes very thick near the colpus, where it has a large, irregular gap.—49.* P. *cf.* saccardianus. *The exine is similar*

DISCUSSION

Lack of endoaperture fusion is the only feature of Anisophylleaceae pollen that does not overlap variation within Rhizophoraceae. Therefore, the phenetic gap between the two families results from the combined effects of many characters. With LM, for example, Anisophylleaceae OTUs have the highest or lowest average (or median) in 8 of 10 characters (1, 2, 4–8, and 10) and the same high average as Rhizophoreae for character 3. Anisophylleaceae OTUs also have the highest or lowest average for six TEM characters (24–26, 29–31) and the second highest average for characters 27 and 28. Also with TEM, Anisophylleaceae pollen can be separated from Gynotrocheae by a much lower endexine thickness ratio, and from Macarisieae by lack of intercolumellar granulation.

SEM analysis reveals the punctate-only sculpture of four Anisophylleaceae OTUs. *Combretocarpus rotundatus* (A4) differs slightly by having psilate mesocolpial margins. The striate sculpture of *Anisophyllea disticha* (A1) is strikingly different from any other in this study and is primarily responsible for isolating *A. disticha* along component III. In contrast, punctate pollen within Rhizophoraceae is usually psilate–punctate or punctate–rugulate. Exceptions include *Cassipourea elliptica* (M3), which is punctate-only, and *Dactylopetalum sessiliflorum* (M5), which has the same SEM character states as *C. rotundatus* (A4). The similarity in exine sculpture between *D. sessiliflorum* and *C. rotundatus* partially accounts for their connection on the minimum spanning tree.

Pollen of Anisophylleaceae can therefore be distinguished from Rhizophoraceae by the following combination of character states: larger polar axis and breadth, greater variation in polar axis and breadth, higher P/E ratio (in the subprolate–prolate range), narrow or nonexistent endoapertures, lack of endoaperture fusion, relatively small polar area (including some syncolpate grains), punctate sculpture, thicker tectum, taller and wider columellae, the highest tectum thickness and columellae height ratios, the lowest foot layer ratio, a low endexine ratio, and absence of intercolumellar granulation. These results agree with separate familial status for Anisophylleaceae. On the other hand, Anisophylleaceae, even without *Anisophyllea disticha* (A1), is a relatively variable taxon with longer average links on the minimum spanning tree than the tribes of Rhizophoraceae.

Pollen of Gynotrocheae, Macarisieae, and Rhizophoreae can be generally characterized, but these tribes cannot be separated based on palynological evidence. Characteristics generally distinguishing pollen grains of Rhizophoreae from those of Macarisieae and Gynotrocheae are larger size, lower P/E ratios (averaging 100), greater distances between colpal ends, higher polar area indexes, punctate–rugulate sculpture, thicker tecta, taller and wider columellae, and thicker foot layers. At the opposite end of the continuum are Gynotrocheae with the smallest grains, highest P/E ratios (average 119), psilate–punctate sculpture, highest endoapertural indexes, lowest foot layer ratios, and highest endexine ratios. Results of the phenetic analysis are not consistent with the proposed separation of *Crossostylis grandiflora* (G3) from Gynotrocheae (see other symposium papers, this volume). In both the ordination and minimum spanning tree, *C. grandiflora* is located within the group of Gynotrocheae OTUs.

Macarisieae OTUs are widely distributed in phenetic space, partly because of the many exceptions to the predominant SEM character states. There is essentially no phenetic gap between Macarisieae and either Rhizophoreae or Gynotrocheae. Macarisieae is also most similar to Anisophylleaceae. In many measurements and ratios, the Macarisieae average is between Rhizophoreae and Gynotrocheae, including polar axis and breadth, P/E ratio, distance between colpal ends, polar area index, tectum and foot layer thickness, height and width of columellae, columellar height ratio, and foot layer and endexine thickness ratios. Macarisieae pollen is also characterized by the presence of intercolumellar granulation. Only two OTUs outside Macarisieae, *Crossostylis grandiflora* (G3) and *Pellacalyx* cf. *saccardianus* (G5), have this feature, and only one Macarisieae OTU, *Cassipourea elliptica* (M3), lacks granulation.

The thin endexine is difficult to distinguish.*—*69.* Ceriops tagal. *Tectum incomplete, foot layer very thick, and endexine thin and disrupted. Scale bars = 1 µm.*

CONCLUSION

Principal components analysis using palynological data clearly separates Anisophylleaceae from Rhizophoraceae and supports the hypothesis of separate familial status for Anisophyllaceae. If Macarisieae pollen data were not considered, Rhizophoreae and Gynotrocheae OTUs would also form discrete phenetic groups. Including Macarisieae pollen data changes this picture to one of continuous phenetic variation from Rhizophoreae through Macarisieae to Gynotrocheae.

The majority of pollen morphological characteristics in Anisophylleaceae and Rhizophoraceae occur in a broad range of families throughout the angiosperms. Therefore, it was not possible within the limits of this study to suggest relationships with other taxa. It seems particularly significant that neither family we investigated can be connected to Myrtales on palynological grounds. Light and ultrastructural data on Myrtales pollen (Patel et al., 1985) are generally comparable to data in this study. The colporoidate or fused endoapertures possessed by Anisophylleaceae or Rhizophoraceae have no counterpart in Myrtales, however, and the pseudocolpi of Myrtales pollen do not correspond to features of either Anisophylleaceae or Rhizophoraceae pollen.

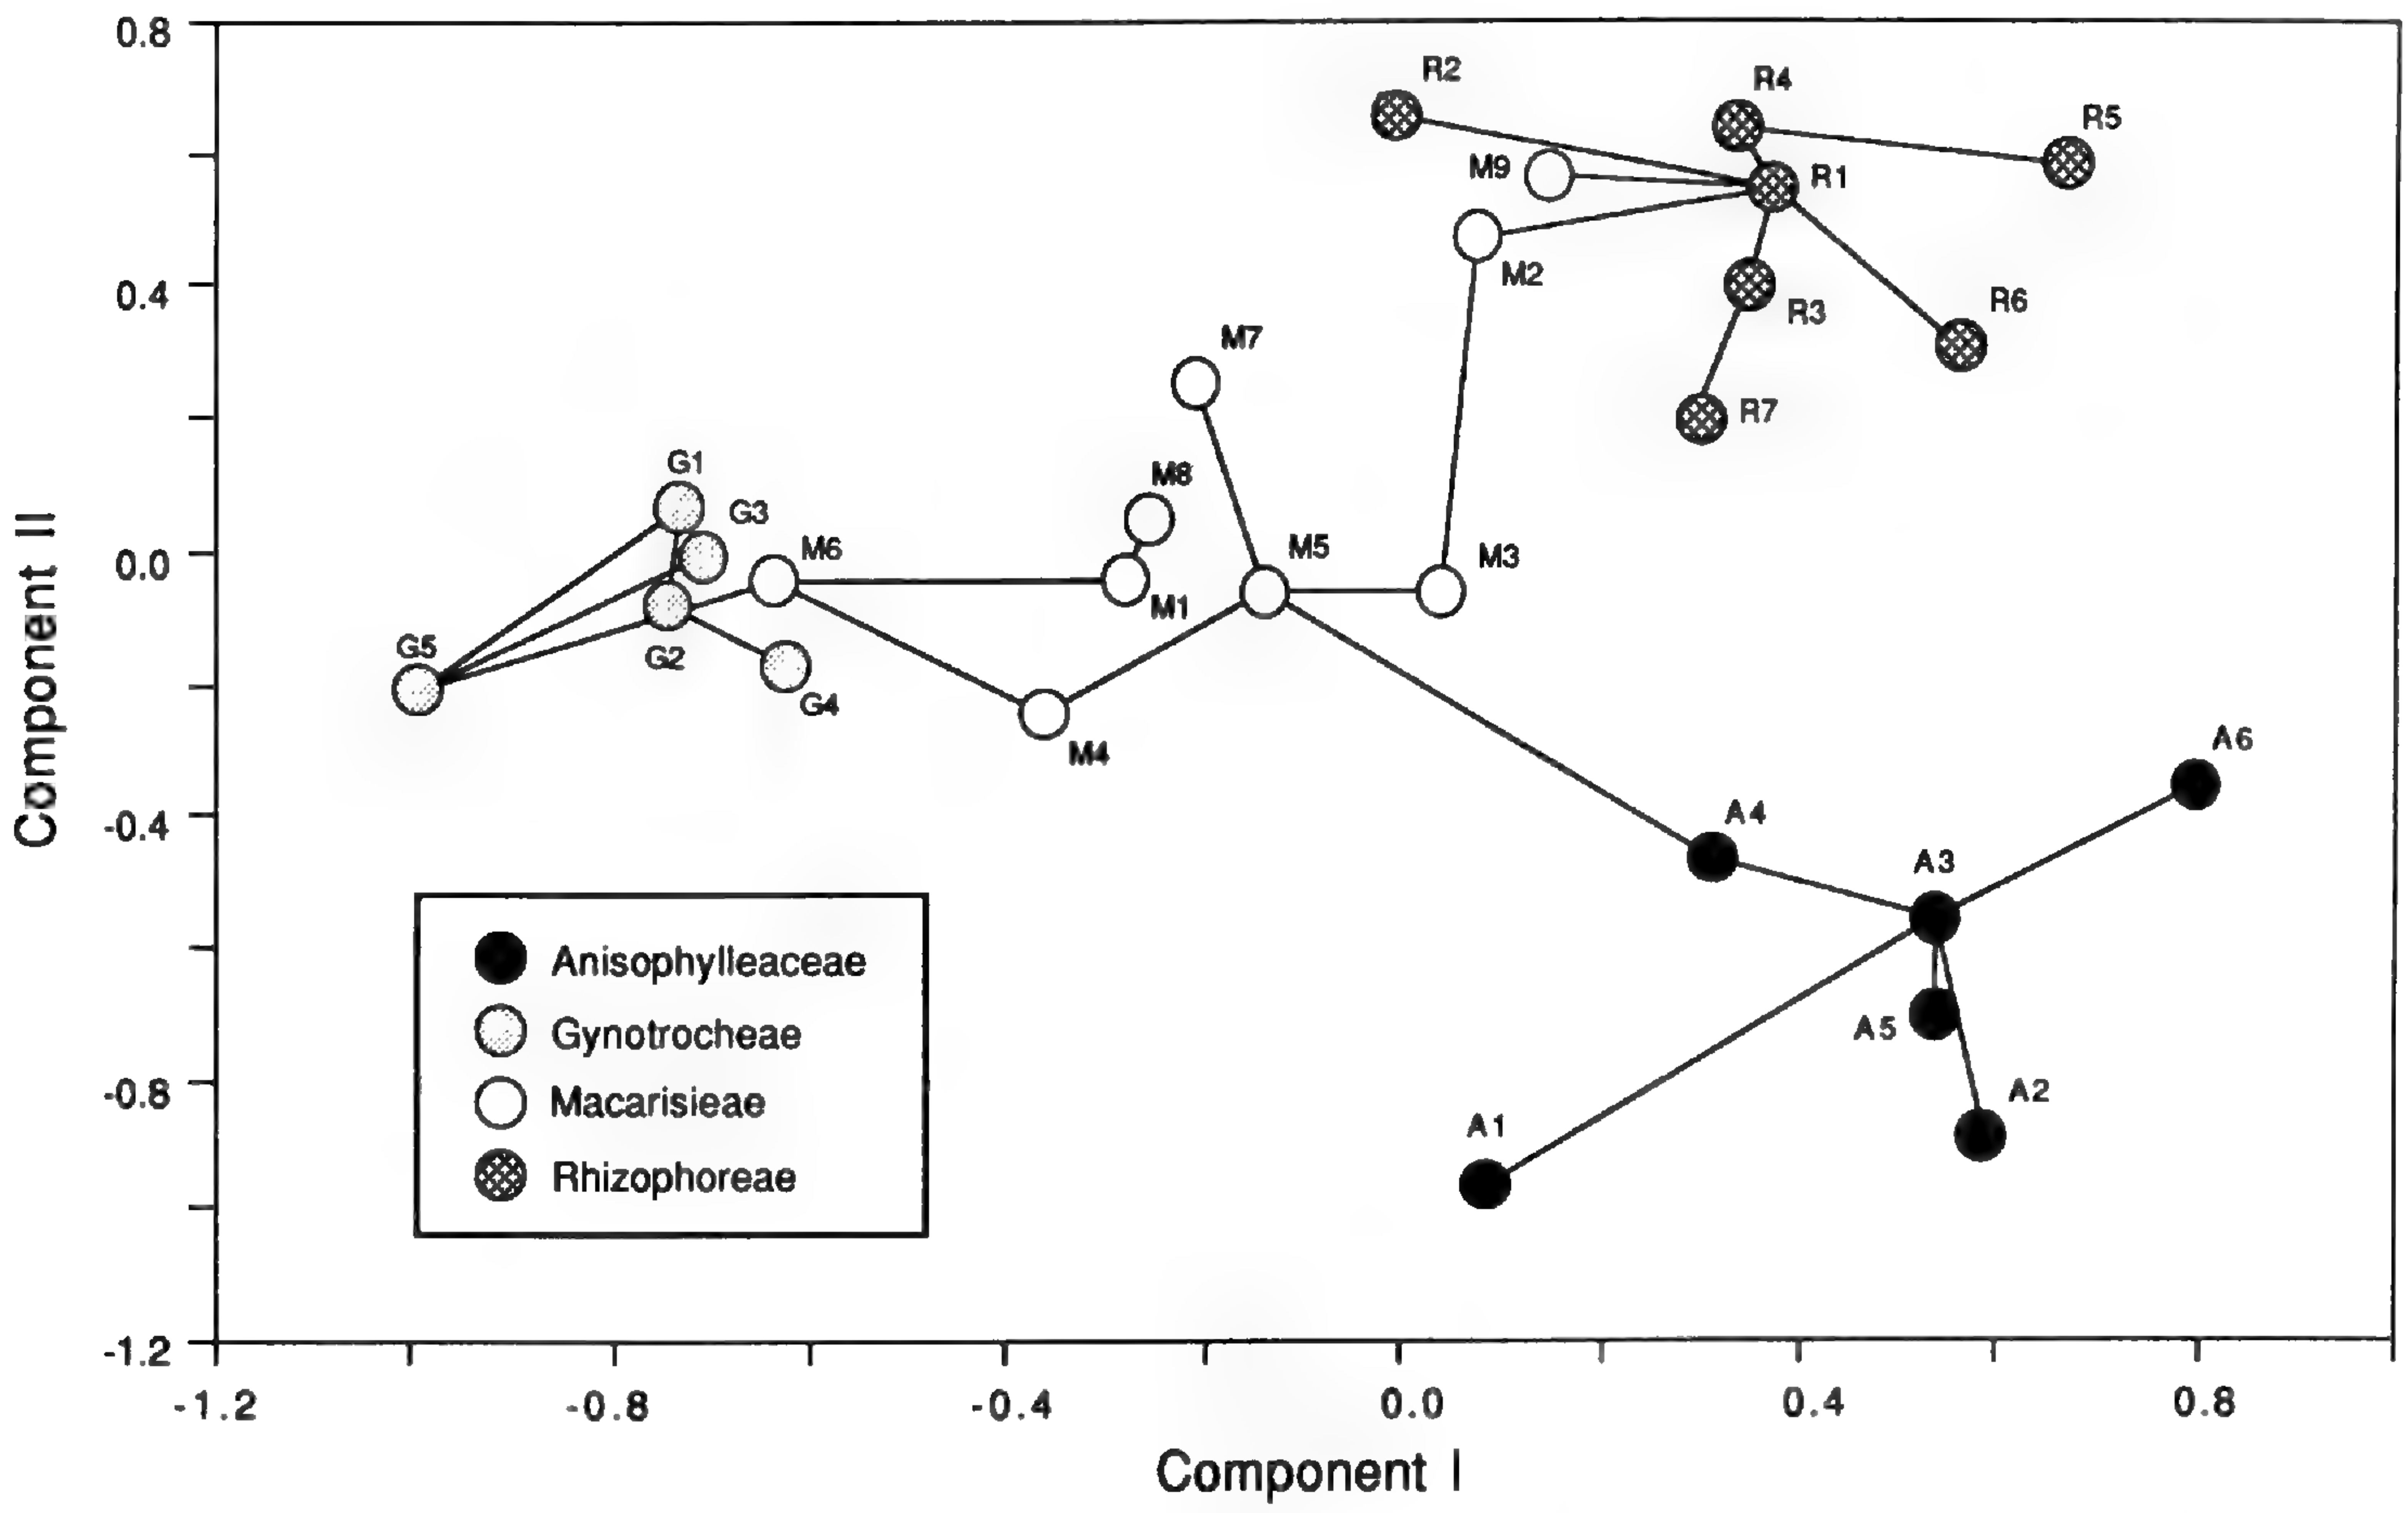

FIGURE 70. *Projection of 27 OTUs onto the first two principal components (data from Table 3). Percent of total variation explained is 25.5 for component I and 20.7 for component II. The superimposed minimum spanning tree was calculated from an average taxonomic distance matrix.*

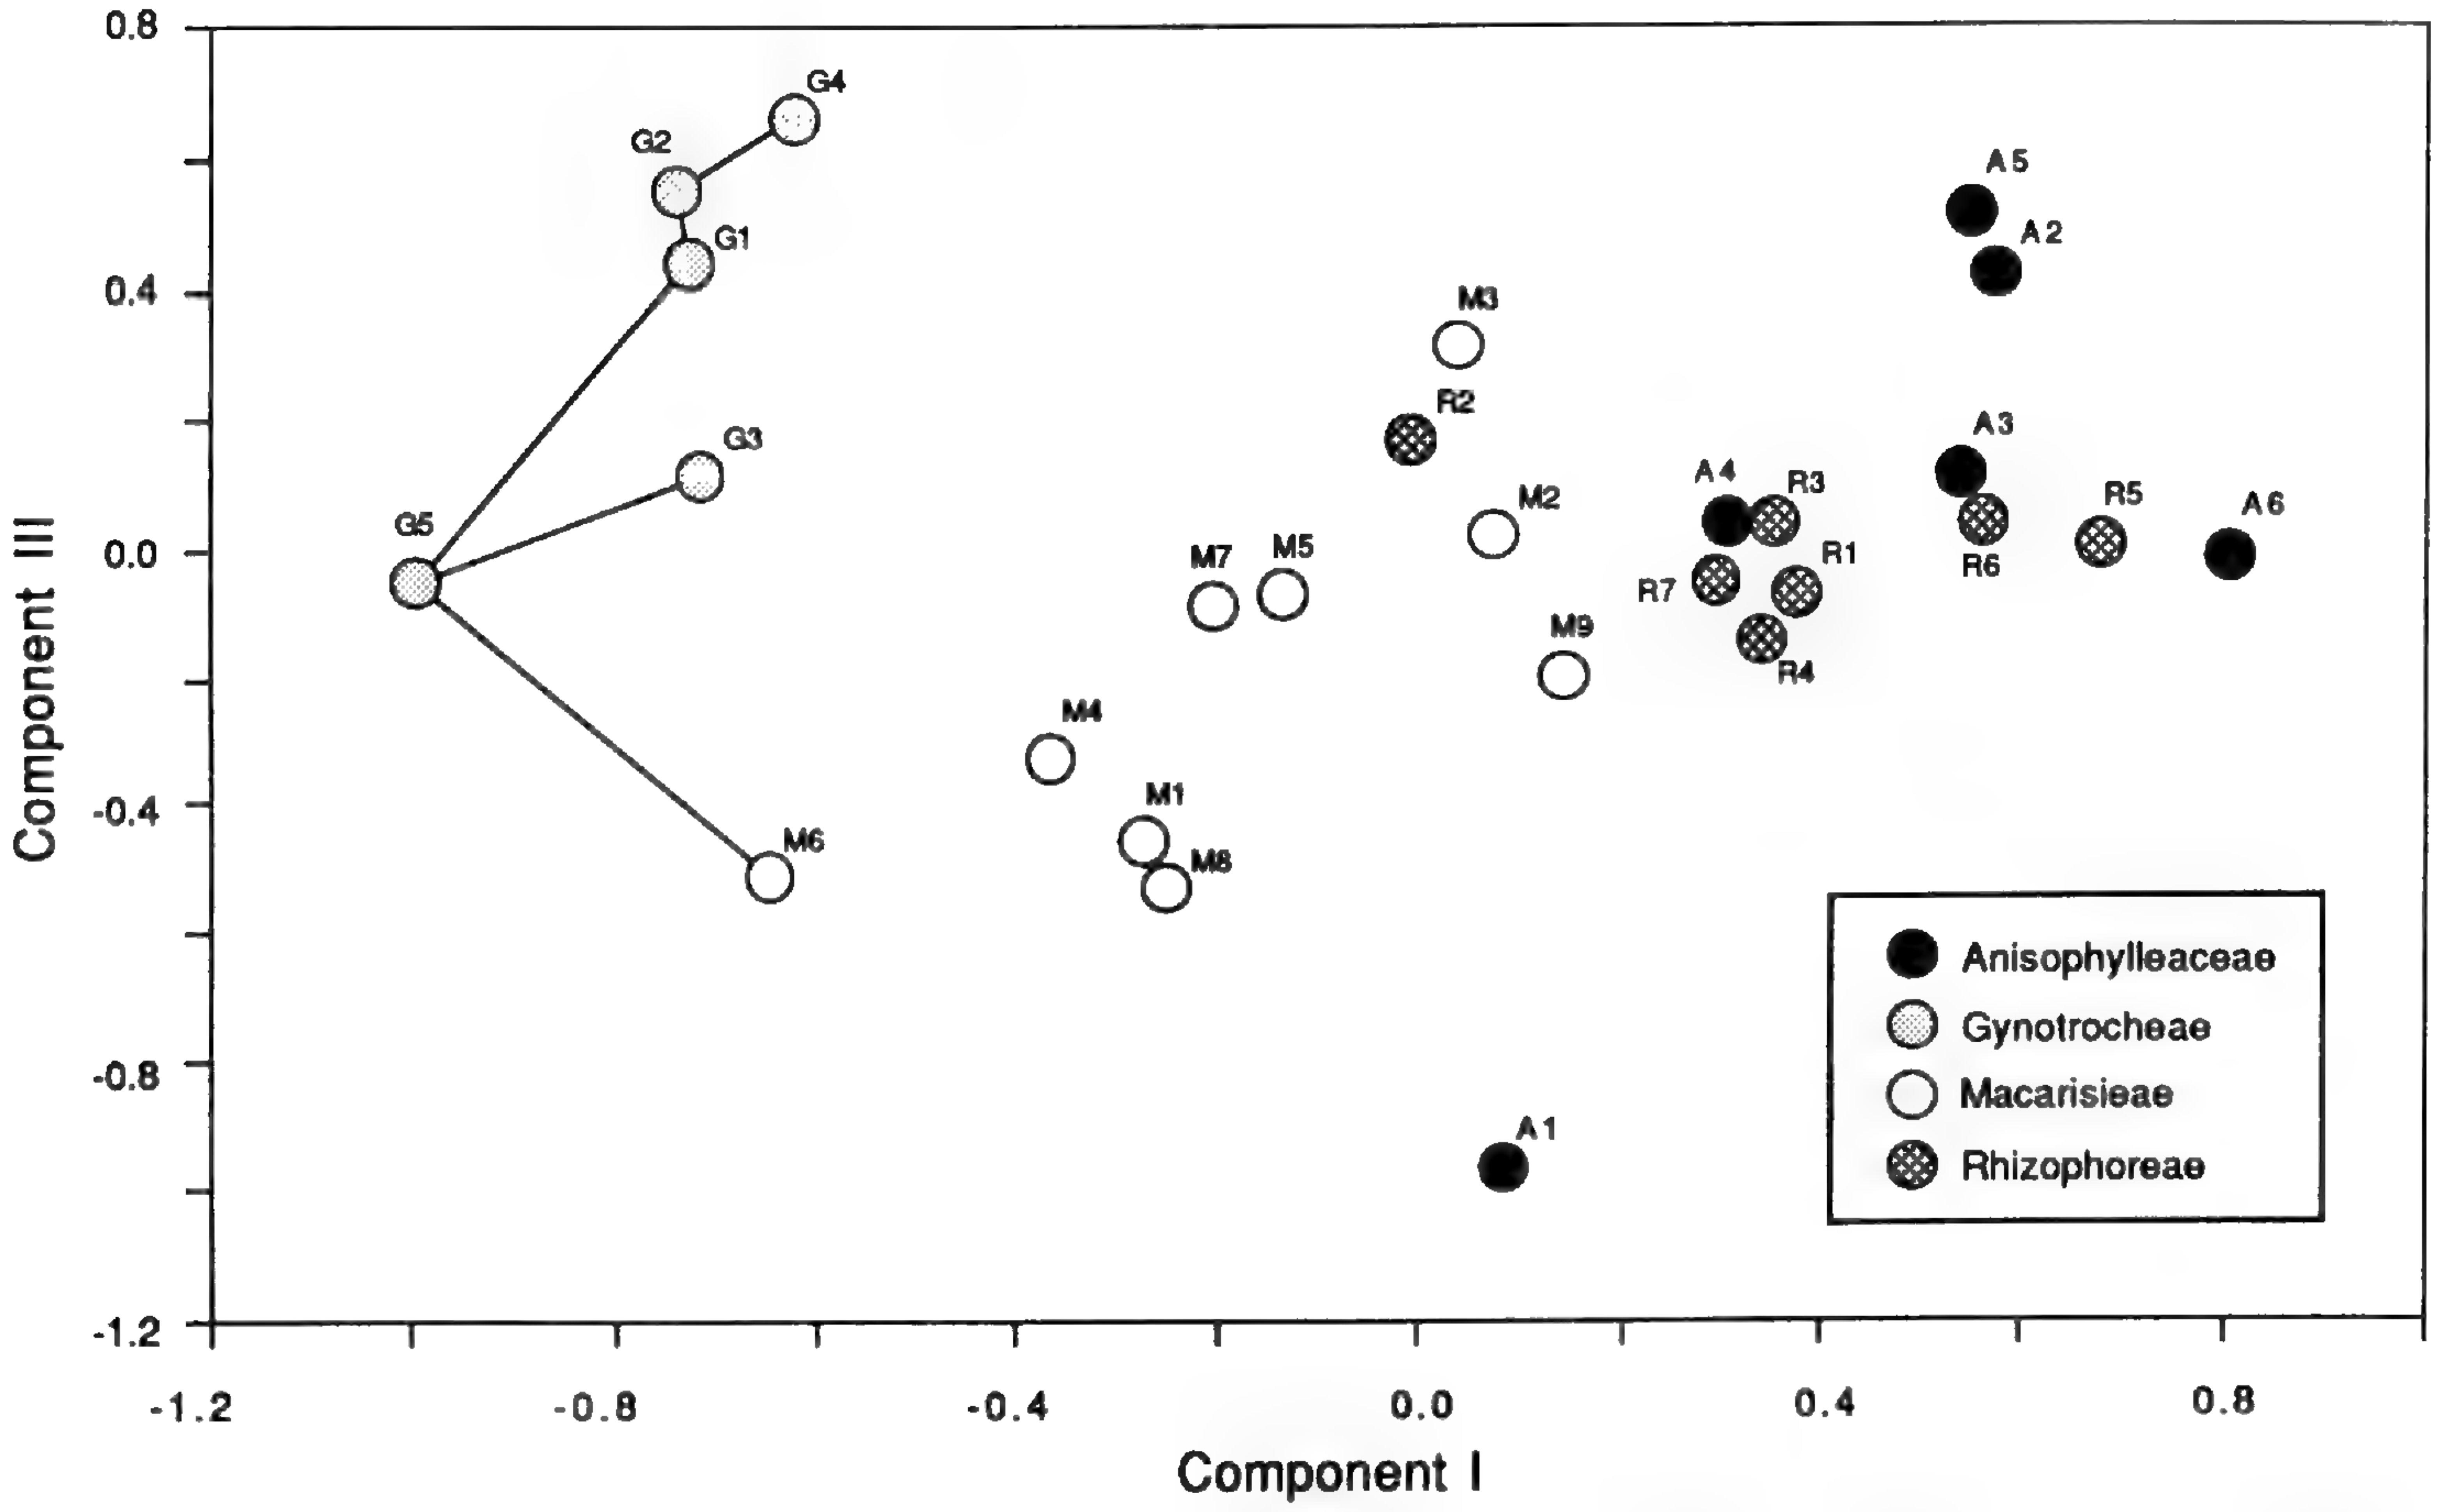

FIGURE 71. *Projection of same 27 OTUs (Fig. 70) onto principal components I and III. Percent of variation expressed by component III is 13.0. A partial minimum spanning tree has been included to clarify relationships within Gynotrocheae.*

SIEVE-ELEMENT PLASTIDS AND SYSTEMATIC RELATIONSHIPS OF RHIZOPHORACEAE, ANISOPHYLLEACEAE, AND ALLIED GROUPS[1]

H.-Dietmar Behnke[2]

ABSTRACT

One hundred fifty-five species of 41 families belonging to the proposed ordinal composition around and including the families Rhizophoraceae and Anisophylleaceae have been studied with respect to their sieve-element plastids. The great majority of taxa, including the Anisophylleaceae, contain S-type plastids. P-type sieve-element plastids were found in Humiriaceae, Rhizophoraceae, and Erythroxylaceae (all with specific subtype-P5), and (with P-forms not readily assigned to a specific subtype) in Eucryphiaceae, Neuradaceae, Oxalidaceae (s.l.), Rhabdodendraceae, and part of Zygophyllaceae. A critical evaluation of sizes and specific contents of their sieve-element plastids negates close relationships between Rhizophoraceae and Anisophylleaceae, integrates the Rhizophoraceae in the Geraniales, but is not able to suggest a position for the Anisophylleaceae. Within the Geraniales the family sequence Humiriaceae (form-P5cs plastids)–Erythroxylaceae (P5c)–Rhizophoraceae (P5c) is proposed to be paralleled by another P-type containing sequence Lepidobotryaceae (S-type)–Hypseocharitaceae (S)–Oxalidaceae (S, Pc)–Averrhoaceae (Pcfs), both being linked to the S-type Linaceae s.l. Sieve-element data do not support the inclusion of Rhizophoraceae in the Celastrales; however, such data corroborate the exclusion of the new celastralean family Elaeocarpaceae from the Malvales. Among the taxa proposed by Dahlgren, Anisophylleaceae would be best placed in vicinity to the S-type families of the Rosales, not in close association to P-type Neuradaceae. The presence of P-type sieve-element plastids in Zygophyllaceae, Neuradaceae, and Humiriaceae is reported here for the first time.

---

[1] *This investigation was made possible only by the unselfish repeated help of my colleagues who collected and sent fresh or fixed samples from various areas of the world—V. Armer (Kuwait), J. Aronson (Beer-Sheva, Israel), H. Balslev (Aarhus, Denmark), K. Barringer (Chicago, Illinois, U.S.A.), P. Berry (Caracas, Venezuela), D. E. Boufford (Pittsburgh, Pennsylvania, U.S.A.), P. Chai (Kuching, Malaysia), A. C. Gibson (Tucson, Arizona, U.S.A.), G. & I. S. Gottsberger (Giessen, F.R.G.), M. H. Grayum (San José, Costa Rica), I. A. U. N. Gunatilleke (Peradeniya, Sri Lanka), C. Huckins (Phoenix, Arizona, U.S.A.), S. B. Jones (Athens, Georgia, U.S.A.), A. Juncosa (Petersham, Massachusetts, U.S.A.), W. J. Kress (Durham, North Carolina, U.S.A.), K. Kubitzki (Hamburg, F.R.G.), C. Marticorena (Concepción, Chile), G. J. Muller (Cape Ferguson, Australia), B. Nelson (Manaus, Brazil), G. Persch (Bonn, F.R.G.), L. J. Poveda (San José, Costa Rica), G. T. Prance (Bronx, New York, U.S.A.), J. S. Pringle (Hamilton, Ontario, Canada), A. E. Radford (Chapel Hill, North Carolina, U.S.A.), A. Schultz (Porto Allegre, Brazil), D. W. Thomas (Kumba, Cameroon), R. F. Thorne (Claremont, California, U.S.A.), R. Tracey (Indooropilly, Australia), E. A. Ulrich (Mexico City), K. R. Woolliams (Haleiwa, Hawaii, U.S.A.), A. E. van Wyk (Pretoria, R.S.A.)—or who helped the author during his collections at original locations (H.D.B., followed by date, in Table 1) and in many botanical gardens (abbreviations given under "origin" in Table 1)—J. Benson (Sydney, Australia), W. Ferren (Santa Barbara, California, U.S.A.), P. Hind (Sydney, Australia), J. Jacobs (Sydney, Australia), J. L. S. Keesing (Kew Gardens, U.K.), K. Kramer (Bonn, F.R.G.), Lee Ying Fah (Sandakan, Malaysia), W. Stubbe (Düsseldorf, F.R.G.), U. Sutisma (Bogor, Indonesia). P. H. Raven (St. Louis, Missouri, U.S.A.) gave invaluable support in finding sources and collectors for fresh material. Ute Kiritsis and W. Siller helped with collections and fixations during the author's stay at Bogor (Indonesia); Marianne von der Decken, Doris Laupp, and Liliana Pop (all Heidelberg) processed the material on its long way from the fixation to the electron micrograph. The Deutsche Forschungsgemeinschaft gave continued travel and research support for these investigations. My sincere gratitude is extended to all the aforementioned persons and institutions without whose help this research would not have been possible.*

ANN. MISSOURI BOT. GARD. 75: 1387–1409. 1988.

The family Rhizophoraceae is distinct from other dicotyledon taxa by the formation of rather extraordinary P-type sieve-element plastids (Behnke, 1982a). Their specific form-P5c plastids contain some twenty more or less rectangular protein crystals—i.e., an accumulation of proteins to a degree found nowhere else in P-type plastids—and were originally reported for seven species of the family and an additional four species of the Erythroxylaceae. A closely related form-P5cf (containing protein filaments in addition to the crystals) was found in the family Cyrillaceae (*Cliftonia* and *Cyrilla*). These unique subtype-P5 plastids raised questions about the systematic position of the three families (Behnke, 1982a) and initiated further research on sieve-element plastids and other characters.

A first study of the distribution of types of sieve-element plastids of Myrtales and allied groups (an association of taxa into which the family Rhizophoraceae had been placed most commonly) revealed that (1) all core families of the Myrtales and all of those closely related contained S-type plastids, and (2) within the Rhizophoraceae (an additional seven species were investigated) the two genera *Anisophyllea* and *Combretocarpus* also contained S-type plastids (Behnke, 1984). This gave support to various efforts to separate the tribe Anisophylleeae from the Rhizophoraceae and to erect the family Anisophylleaceae (Cronquist, 1981; Dahlgren, 1983; Tobe & Raven, 1987).

The present additional report on sieve-element plastids in Rhizophoraceae, Anisophylleaceae, and allies is an extension of the previous investigations taking also into account all the higher taxa, i.e., ordinal compositions and their associates, to which the two families have been affiliated (see Dahlgren, this volume).

MATERIALS AND METHODS

One hundred fifty-five species of 41 families, all proposd by Dahlgren (this volume) for placement around Rhizophoraceae and Anisophylleaceae were investigated (see Table 1).

Living material recently removed from the plant or shipped within a few days under special care is a prerequisite for a fixation of sieve elements and the eventual investigation of their plastids with the transmission electron microscope. Thin hand sections were made with a razor blade from preferably young herbaceous shoots or end parts of tree branches less than 1 cm in diameter. The sections were immersed into a fixing solution containing formaldehyde and glutaraldehyde and processed according to standard methods (see Behnke, 1982b). Material made available by collections at original locations was sent to Heidelberg either fresh (causing a delay of up to a week between sampling and start of fixation) or as formaldehyde/glutaraldehyde prefixed hand sections (causing an equally long delay between primary and postfixation).

RESULTS

A SHORT OUTLINE OF CHARACTERS OF SIEVE-ELEMENT PLASTIDS USED TO CHARACTERIZE THE TAXA INVESTIGATED

Sieve-element plastids are separated into two *types* by presence (P-type) or absence (S-type) of protein crystals and/or filaments, while starch grains may or may not be present. *Subtypes* of P-type sieve-element plastids are identified by any unmistakable feature of their protein inclusions, e.g., the subtype-P5 by a high number of generally rectangular protein crystals. *Forms* of sieve-element plastids are defined by any combination of the three inclusions: c = protein crystals, f = protein filaments, s = starch grains, e.g., P5cf. In addition, all sieve-element plastids within a family will be characterized by their average diameter and average amount of protein vs. starch content (Table 2), both calculated from the respective data of the different species listed in Table 1.

Recent studies of the sieve-element plastids of the Acanthaceae (Behnke, 1986a) and within all families of the Magnoliidae (Behnke, 1988)—the latter for the first time taking into account diameters and quantitative data of the plastids—resulted in a general model for the interrelationships between the different forms of plastids. It was concluded that at least in these groups, P-type plastids may have derived from S-type plastids (for details see Behnke, 1988, but compare with Behnke, 1981).

In his summary statement of Rhizophoraceae and Anisophylleaceae and their systematic relationships, Dahlgren (this volume) proposes a revised classification and lists the ordinal composition around each of the two families. The following description of the sieve-element plastids in these taxa follows his sequence of families.

DISTRIBUTION OF THE DIFFERENT SIEVE-ELEMENT PLASTIDS AMONG THE FAMILIES GROUPED AROUND RHIZOPHORACEAE

Zygophyllaceae (ZYG; Fig. 1: *Guaiacum, Larrea*). Five species in four genera investigated, one with P-type, the others with S-type plastids. Plastid diameter is 1.2 μm. *Larrea divaricata* contains form-Pcs sieve-element plastids with two protein crystals of different diameters (0.4 and 0.3 μm) and different crystal spacing. There are about five typically disc-shaped starch grains in addition. The S-type plastids of other species studied contain up to ten starch grains of different diameters and shapes, including typically disc-shaped ones.

In this family the plastids of the mature sieve element are often disrupted, making it impossible to record some protein crystals. Therefore, after the detection of P-type plastids in both collections of *Larrea* (Table 1), all species have been studied once more.

Nitrariaceae (NIT; Fig. 1: *Nitraria*). This monogeneric family, represented here by *Nitraria retusa*, contains S-type plastids with characteristics slightly different from those of ZYG, i.e., with a diameter of 1.0 μm and about five more or less globular starch grains.

Peganaceae (PEG; Fig. 1: *Peganum*). *Peganum harmala* likewise contains S-type plastids with a diameter of 1.2 μm and about five starch grains.

Balanitaceae (BLT; Fig. 1: *Balanites*). Two species investigated in the monogeneric family both contain S-type plastids with about ten globular starch grains. Plastid diameters are 1.7 μm in one and 1.1 μm in the other (Table 1).

Vivianiaceae (VIV; Fig. 1: *Caesarea*). *Caesarea albiflora* contains S-type plastids with up to five typically disc-shaped starch grains. Plastid diameter is 1.1 μm. (See also Behnke & Mabry, 1977.)

Geraniaceae (GER; Fig. 1: *Pelargonium*). Five species in three genera investigated, all with S-type plastids. There are about five disc-shaped starch grains within a plastid, the average diameter of which is 1.2 μm (range 1.0–1.6 μm). (See also Behnke & Mabry, 1977.)

Ledocarpaceae (LDC; Fig. 1: *Wendtia*). *Wendtia gracilis* contains small S-type plastids (diameter 0.9 μm) with a few starch grains of variable sizes. The plastids appear distinctly different from those of the Geraniaceae.

Ixonanthaceae (IXO; Fig. 2: *Ixonanthes*). The two species of *Ixonanthes* investigated contain S-type plastids of an average diameter of 1.1 μm and with an average of ten small and large, more or less globular starch grains.

Humiriaceae (HOU; Fig. 2: *Humiria*, *Endopleura*, *Sacoglottis*). Four species in three genera investigated: all with P5cs sieve-element plastids. This form is characterized by numerous (average more than ten) irregular to rectangular protein crystals and about ten small starch grains. The average measurements are: plastid diameter 1.2 μm and protein crystals 0.3 μm.

Hugoniaceae (HUG; Fig. 2: *Indorouchera*). The two species investigated represent two genera, and both contain S-type plastids with about ten starch grains, among them one or two large ones. The average plastid diameter is 1.1 μm.

Erythroxylaceae (ERX; Fig. 2: *Erythroxylum*). The four species of *Erythroxylum* investigated are characterized by P5c sieve-element plastids. This highly specific form contains about ten up to 0.7 μm large rectangular protein crystals (and no starch), which are densely packed within the comparatively small plastids (diameter 1.1 μm). (See also Behnke, 1982a.)

Linaceae (LIN; Fig. 2: *Linum*). Three species in two genera investigated, all containing S-type plastids with an average of about five starch grains (often including a large globular one), which may disintegrate into small particles. The average plastid diameter is 1.2 μm (range 1.0–1.5 μm).

Lepidobotryaceae (LPB; Fig. 2: *Lepidobotrys*). The monotypic *Lepidobotrys staudtii* contains S-type plastids with up to ten starch grains disintegrated into small particles. The plastid diameter is 1.2 μm.

Oxalidaceae (OXL; Fig. 3: *Averrhoa*, *Oxalis*, *Sarcotheca*). Twelve species in five genera investigated. Sieve-element plastids not uniform: two types including three different forms occur in the family.

Averrhoa and *Sarcotheca* contain form-Pcfs plastids with an average diameter of 1.1 μm. This P-form, not specified to belong to a distinct P-subtype, contains protein filaments (f), two rectangular or cubic protein crystals (c) up to 0.4 μm in diameter, and about five globular starch grains (s), of which one may be very large.

Oxalis (8 species tested) is characterized by very small (average diameter 0.8 μm) form-Pc sieve-element plastids with two protein crystals, a very prominent (diameter about 0.5 μm) cubical one and a second, smaller one.

Biophytum and *Hypseocharis* contain S-type plastids of different sizes and different starch contents (see Table 1 and Behnke, 1982c).

Form-Pcfs and -Pc sieve-element plastids (and/or -Pcs not found in the Oxalidaceae) are reported in other dicots, e.g., in Vitaceae, Rhabdodendraceae, Connaraceae, Eucryphiaceae, Acanthaceae, Gunneraceae (Behnke 1974, 1976a, 1982c, 1985, 1986a, b), and Neuradaceae (see below).

TABLE 1. *Sieve-element plastid data of the investigated species. Family = families recognized by Dahlgren (this volume), family acronyms after Weber (1982); D'1989 = number of family in Dahlgren (in press) and family acronym if different from "family"; Herbarium = deposit of vouchers. The following data characterize the sieve-element plastids: Type (and form); DIA = diameter in µm; N = number of protein crystals; PMA = maximum diameter of protein crystals in µm; SN = average number of starch grains. "Publication" refers to previous works of the author.*

[1] Erroneously listed in Table 1 of Behnke (1984) as PVc.

Celastraceae (CEL; Fig. 4: *Catha, Pterocelastrus*). Fourteen species in 13 genera investigated, all with S-type plastids. There are 5–10 mostly globular starch grains recorded within these plastids, but their diameter is not uniform (average: 1.3 μm; range 1.0–1.8 μm). The sieve elements of *Goupia* contain crystalline, persistent p-protein bodies, a feature that characterizes a number of different dicotyledonous taxa (see Behnke, 1981) but is not found elsewhere in Celastraceae. *Hippocratea* and *Salacia,* as well as *Siphonodon,* sometimes separated as Hippocrateaceae and Siphonodontaceae, respectively, do not differ significantly in sieve-element characters.

Elaeocarpaceae (ELC; Fig. 4: *Aristotelia, Elaeocarpus*). The five species in four genera investigated contain S-type plastids. Their sizes (1.1–1.7 μm; average 1.4 μm) and number of globular starch grains (5–10) resemble those in CEL.

Rhizophoraceae (RHZ; Fig. 5: *Cassipourea, Ceriops, Crossostylis, Rhizophora, Sterigmapetalum*). Thirteen species of eight genera investigated, all with the specific form-P5c sieve-element plastids. Twenty or more rectangular to irregular protein crystals (0.2–0.5 μm) fill the plastid interior. The average plastid diameter is 1.4 μm. In *Rhizophora* the protein crystals are irregular, only rarely showing exact rectangular outlines. It is demonstrated, at least for *R. mangle,* that during the development of a sieve-element plastid, protein accumulates first as a large granular body (see Fig. 5, lower left micrograph) and only thereafter 'crystallizes' into several distinct parts.

In this study of their sieve-element plastids, all of the tribes recognized within the family were covered. Except for the crystal outlines mentioned for *Rhizophora,* there is almost no distinction possible between the plastids of the different species. The comparatively large protein crystals depicted in *Ceriops* (Fig. 5), which come very close in size to those shown in *Erythroxylum* (Fig. 2), are not restricted to this species. Similar views could have been chosen from other Rhizophoraceae. (See also Behnke, 1982a, 1984.)

DISTRIBUTION OF THE DIFFERENT SIEVE-ELEMENT PLASTIDS AMONG THE FAMILIES GROUPED AROUND ANISOPHYLLEACEAE

Cunoniaceae (CUN; Fig. 6: *Cunonia, Weinmannia*). Five species of five genera investigated, all with S-type plastids. The diameter of the plastids is about 1.2 μm; their contents are up to

[1] PSP = number of P-type species; PDIA = average diameter of P-type plastids; N = average number of protein crystals; PS = average number of starch grains in P-type plastids; SSP = number of S-type species; SDIA = average diameter of S-type plastids; SN = average number of starch grains in S-type plastids; SO = number of form-So plastids; SODI = average diameter of form-So plastids; Dahlgren = family acronym and position of family in Dahlgren (in press).

10 globular starch grains, often surrounded by additional tiny granules. (See also Behnke, 1985.)

Baueraceae (BAU; Fig. 6: *Bauera*). *Bauera rubioides* as representative of the monogeneric family contains very small (diameter 0.8 μm) S-type plastids with up to five small irregular starch grains.

Brunelliaceae (BNL; Fig. 6: *Brunellia*). The three species of *Brunellia* investigated contain S-type plastids. Their globular starch grains (about 10 in the average) often seem to disintegrate into tiny pieces. The plastid diameter is 1.4 μm.

Davidsoniaceae (DVS; Fig. 6: *Davidsonia*). The monotypic *Davidsonia pruriens* contains S-type plastids with about 10 strictly globular starch grains. The plastid diameter is 1.4 μm.

Eucryphiaceae (ECR; Fig. 6: *Eucryphia*). Four of the five species of this monogeneric family and one hybrid were found to contain form-Pc sieve-element plastids with two protein crystals, one with a diameter of about 0.3 μm. The sieve-element plastids of *Eucryphia* are among the tiniest recorded within the dicotyledons (average diameter of 0.6 μm). (See also Behnke, 1985.)

Crossosomataceae (CRO; Fig. 8: *Crossosoma*). Three species in two genera investigated, all with S-type plastids. The two *Crossosoma* species are identical, both in respect to their plastid diameter (1.8 μm) and the starch content (about 10 globular grains). *Forsellesia* has smaller plastids (diameter 1.0 μm) and fewer starch grains.

Rosaceae (ROS; Fig. 7: *Duchesnea*). Sixteen species in 16 genera investigated; all species with S-type plastids, but nine of them without starch (with form-So plastids). The average diameter of the plastids is 1.0 μm, with an average of 0.9 μm for the So form and of 1.2 μm for those with starch grains. The average number of grains in the starch-containing species is six.

Neuradaceae (NRD; Fig. 8: *Neurada*). *Neurada procumbens* contains form-Pcs sieve-element plastids with one rectangular protein crystal (diameter 0.4 μm) and up to five large starch grains. The diameter of the plastids is 1.5 μm. With these characteristics, there is resemblance to the sieve-element plastids of *Gunnera*. (See Behnke, 1986b.)

Anisophylleaceae (ANS; Fig. 8: *Anisophyllea*, *Combretocarpus*, *Poga*, *Polygonanthus*). Five species in four genera investigated; all have S-type plastids. With diameters of about 1.2 μm and some ten globular starch grains, the sieve-element plas-

tids of the Anisophylleaceae are rather homogeneous and very distinct from those of the Rhizophoraceae. The difference in the plastid types supports elevation of the former tribe Anisophylleeae to family status. (See also Behnke, 1984.)

Malaceae (MAL; Fig. 7: *Amelanchier*). Thirteen species in 13 genera investigated; all have S-type plastids. The average diameter of the plastids is 1.2 μm, and the average number of starch grains eight. These data do not differ from those of the S-type Rosaceae. No form-So plastids are found in the Malaceae.

Amygdalaceae (AMY; Fig. 7: *Prunus*). Four species in two genera investigated, all with S-type plastids. The plastids in this family are smaller (average diameter 1.0 μm) than those in ROS and MAL, although their starch content is similar.

Rhabdodendraceae (RHB; Fig. 8: *Rhabdodendron*). The two species investigated of this monogeneric family contain form-Psc sieve-element plastids. Their single protein crystal is rectangular and about 0.2 μm in diameter. There are about five irregular starch grains. The average plastid diameter is 1.2 μm. (See also Behnke, 1976a.)

Saxifragaceae (SAX; Fig. 7: *Bergenia*). Six species in six genera investigated, all with S-type plastids. The average plastid diameter is 1.3 μm; there are about eight irregularly shaped starch grains in the plastids.

Penthoraceae (PTH; Fig. 7: *Penthorum*). *Penthorum sedoides* as representative of the monogeneric family contains S-type plastids with characters almost identical to those in SAX, i.e., with a diameter of 1.2 μm and containing about eight starch grains.

Vahliaceae (VHL; Fig. 7: *Vahlia*). The S-type plastids recorded for *Vahlia capensis* show the same pattern as found in SAX—diameter 1.2 μm and containing about ten starch grains.

Francoaceae (FCO; Fig. 7: *Francoa*). The investigated *Francoa sonchifolia* contains S-type plastids only slightly different from those in SAX; their diameter is 1.4 μm; the number of starch grains is about three.

Greyiaceae (GRY; Fig. 7: *Greyia*). *Greyia sutherlandii* contains S-type plastids with about five globular starch granis. The plastid diameter is 1.2 μm.

Brexiaceae (BRX; Fig. 7: *Brexia*). *Brexia madagascariensis* was shown to contain S-type plastids about 1.1 μm in diameter with about five starch grains.

Grossulariaceae (GRS; Fig. 7: *Ribes*). *Ribes* *bracteosum* contains S-type plastids with about ten globular starch grains and a diameter of 1.2 μm.

Iteaceae (ITE; Fig. 7: *Itea*). Two species in the two genera investigated; both contain S-type plastids with about five starch grains that disintegrate into tiny particles. The average plastid diameter is 1.5 μm.

Cephalotaceae (CPH; Fig. 7: *Cephalotus*). The monotypic *Cephalotus follicularis* contains S-type plastids with about five starch grains and a diameter of 1.1 μm. The starch grains are slightly disc-shaped and surrounded by tiny particles.

Crassulaceae (CRS; Fig. 7: *Cotyledon*). Three species in two genera shown to contain form-So sieve-element plastids. Their average diameter is 0.9 μm. Many more species were investigated, but although the fixation of the material was satisfactory, repeated screening failed to detect sieve-element plastids. Most likely, the So-plastids easily break down during the differentiation of the sieve elements. Similar conclusions were made from studies with *Cucurbita* species that also contain form-So plastids (Buvat, 1963; Esau & Cronshaw, 1968).

In Crassulaceae the form-So plastids sometimes contain small inclusions, which rarely show a crystalline composition. Since they are probably related to protein crystals, sieve-element plastids of CRS were also defined as Po/So. (See Behnke, 1981.)

Podostemaceae (PDS; Fig. 7: *Podostemum*). *Podostemum ceratophyllum* contains S-type plastids with about eight starch grains, often surrounded by tiny particles. The diameter of the plastids is 2.3 μm, by far the highest found among the taxa studied for this report.

DISCUSSION

The results from investigations of the sieve-element plastids reported here unambiguously support separation of the tribe Aniosphylleeae from the Rhizophoraceae and its elevation to the rank of a family. The very distinct and remarkable form-P5c sieve-element plastids of Rhizophoraceae s. str.—without any incorporation of even traces of starch—has no direct relationhip to the pure S-type (lacking any amount of protein) as found in the Anisophylleaceae. According to a model demonstrating the interrelationships between the different forms of sieve-element plastids (proposed by Behnke, 1988), at least two evolutionary steps would be necessary to change the S-type into a form-Pc sieve-element plastid. Without the presence of in-

termediates the coexistence of both types within one family is not very likely.

While sieve-element plastids help discriminate between Rhizophoraceae and Anisophylleaceae, determination of their affiliations to other taxa is possible only to a limited extent. Therefore, the position of the two families relative to the taxa proposed by Dahlgren (this volume) to constitute the ordinal periphery will now be discussed.

GERANIALES SENSU LATO

In his last version of the system of classification of dicotyledons, Dahlgren (in press) divided the Geraniales s.l. into two orders, the Geraniales s. str. and the Linales. The following discussion makes use of this separation.

1. (= Geraniales s. str.). Dahlgren (in press) listed Zygophyllaceae, Peganaceae, Nitrariaceae, Geraniaceae, Vivianiaceae, Ledocarpaceae, Biebersteiniaceae, Dirachmaceae, and Balanitaceae in this alliance. Among the families available for our studies (see Table 2) S-type sieve-element plastids are most common and P-type plastids are found only in *Larrea* (Zygophyllaceae). The diameter of the plastids is rather uniform, varying around 1.1 μm. Some families contain disc-shaped starch grains as a specific marker: Geraniaceae, Vivianiaceae, and Zygophyllaceae (in part).

The S-type plastids of Balanitaceae diverge more from the above pattern (see also Fig. 1). Both Cronquist (1981) and Thorne (1983) placed *Balanites* within Zygophyllaceae; Takhtajan (1987) transferred to Rutales the Zygophyllaceae and those families that, like Balanitaceae, Nitrariaceae, and Peganaceae, were split off earlier. Neither of these assignments is strongly supported by the plastid data.

2. (= Linales). Dahlgren (in press), included Linaceae, Hugoniaceae, Humiriaceae, Ctenolophonaceae, Ixonanthaceae, Erythroxylaceae, Lepidobotryaceae, and Oxalidaceae in the Linales. With four S-type families, two P-type families, and one family containing both S-type and two different forms of P-type sieve-element plastids, this suborder is very heterogeneous (fresh material from *Ctenolophon* was not available).

The S-type plastids (in Linaceae, Hugoniaceae, Ixonanthaceae, Lepidobotryaceae, Biebersteiniaceae, and Oxalidaceae) are rather small: their average diameter is about 1.1 μm. From five to ten starch grains, often disintegrating into small particles and sometimes including a very large one, are found within these plastids (see Figs. 2, 3; Behnke, 1982c); a few species differ slightly from this pattern, e.g., in *Reinwardtia* (Linaceae) (Table 1).

The two different forms of P-type plastids recorded within the Oxalidaceae are restricted to different genera: *Averrhoa* and *Sarcotheca* contain form-Pcfs, while *Oxalis* has highly specialized and very small form-Pc sieve-element plastids. Diameters and compositions of these two forms are so different (see Table 1) that it seems justified from the plastid data to support the separation of the families Averrhoaceae (see Hutchinson, 1959) and Hypseocharitaceae (see Takhtajan, 1987).

The two remaining P-type families, Humiriaceae and Erythroxylaceae, contain P-forms not directly related to those of the Oxalidaceae. The form-P5cs plastids found in Humiriaceae are similar to the P4cs plastids of Fabales (cf. Fig. 2 with Behnke & Pop, 1981, figs. 5–15) and can be regarded as transitional between S-type and form-P5c plastids of the Erythroxylaceae. The latter are extraordinarily distinct from all other sieve-element plastids, and the only other family reported to contain this form is the Rhizophoraceae.

Cronquist (1981), Thorne (1983), and Takhtajan (1987) incorporated the Oxalidaceae and Lepidobotryaceae in the Geraniales s. str. Their Geraniales (Geraniineae of Thorne, 1983) differ from each other only slightly. The patterns of the S-type plastids in the Linales and Geraniales are not sufficiently different to favor one or other treatment—and the plastids of *Lepidobotrys*, *Biophytum*, and *Hypseocharis* are intermediate.

Therefore, in the familial sequence given in Table 2, which is arranged according to the data obtained with the sieve-element plastids, the order Geraniales s.l. is maintained.

CELASTRALES

Celastraceae and Elaeocarpaceae contain S-type sieve-element plastids to some extent alike in pattern but not very specialized. The families are not very uniform in their sieve-element plastids (e.g., see Fig. 4: *Aristotelia* and *Elaeocarpus*).

Rhizophoraceae contain form-P5c plastids, a highly specialized pattern that is found throughout all genera investigated. In addition, variation in the diameter of the plastids is very small. There seem to be no common sieve-element plastid characters between the Rhizophoraceae and the other two families of this order; the closest similarities are with plastids of Erythroxylaceae.

Thorne (1983) placed Rhizophoraceae in his Cornales; Cronquist (1981) and Takhtajan (1987) regarded their order Rhizophorales as a close ally of the Myrtales. Dahlgren in his last version (in press) put Rhizophoraceae together with Elaeocarpaceae into his order Rhizophorales and gave it a position after Geraniales/Linales and his newly defined Celastrales (including S-type families only).

Sieve-element plastid data suggest a close association of Rhizophoraceae with Humiriaceae and Erythroxylaceae (see Table 2).

CUNONIALES

The S-type sieve-element plastids present in four of the five families of this order are heterogeneous. Plastid diameter and starch content range from large with ten grains to very small with little starch (see Table 1). The sequence given in Table 2 suggests an evolution from the large unspecialized to the small specialized plastid and enables a connection to the only P-type family (Eucryphiaceae).

Exactly the same five families constitute Takhtajan's (1987) Cunoniales. Thorne (1983) added Staphyleaceae and Corynocarpaceae to his suborder Cunoniinae, while Cronquist distributed them among his Rosales.

SAXIFRAGALES

All families within this order contain S-type sieve-element plastids, of which Crassulaceae is special-

←

ized by form-So plastids. Sizes and starch content of the S-type plastids are rather homogeneous. The only exception is *Podostemum*, which has very large plastids (Fig. 7, Table 1) and does not fit into this order, nor in the entire alliance. Cronquist (1981) and Takhtajan (1987) separated the Podostemaceae in its own order. Thorne (1983) placed this family within his Saxifragineae. Until further evidence from other characters emerges, we prefer the treatment as a separate order, somewhat peripheral to the Saxifragales/Rosales.

ROSALES

S-type sieve-element plastids are recorded except for the two families Neuradaceae and Rhabdodendraceae. The pattern of the S-type plastids (diameter and starch content) is similar to that of the Saxifragales. One family includes form-So plastids: the Rosaceae. The presence of these So plastids in at least some genera (see Table 1 for details, e.g., smaller diameter) makes the Rosaceae s. str. distinct from the Malaceae and Amygdalaceae. The plastid pattern of the latter family is not different from that of the S-type genera in the Rosaceae.

Sieve-element plastids of the four genera tested from the Anisophylleaceae display a rather uniform pattern: while their sizes conform with that of both Saxifragales and Rosales, the amount of starch within a plastid is much higher than in the other taxa (cf. Figs. 7, 8). Therefore, on account of the plastid data, an association of Anisophylleaceae with either Saxifragales or Rosales is not excluded, but a positive decision cannot be made.

The remaining two P-type families of Rosales both contain Psc sieve-element plastids, but of different pattern.

Rhabdodendraceae contain in their sieve-element plastids a tiny rectangular protein crystal and up to five irregular starch grains, a pattern repeatedly found within the Magnoliiflorae (see Behnke, 1988).

Neurada is more distinct because of its larger crystal (diameter 0.4 μm) and higher starch content. Its sieve-element plastids come very close to those of the Gunneraceae (see Behnke, 1986b).

CONCLUSIONS DRAWN FROM THE PLASTID DATA

Given the periphery of families and orders around the Rhizophoraceae—including a few additional ones discussed during the preparation of this Rhizophoraceae symposium—and the distribution of types and forms of sieve-element plastids, the following annotations to the relationships between the different taxa can be made.

The ordinal placement of the Aniosphylleaceae. This is still uncertain as far as sieve-element plastids are concerned. Pattern similarities exist to S-type plastids in the Saxifragales–Rosales groups (not to the Cunoniales), but affinities to other taxa are not ruled out.

If a closer relation to the Rhizophoraceae is still considered, the diameter of the plastids (average of 1.3 μm in both families) would be the only supporting plastid data; otherwise their contents, as discussed, differ by at least two evolutionary steps.

The ordinal placement of the Rhizophoraceae. The identical sieve-element plastids in Rhizophoraceae and Erythroxylaceae, together with the fact that within the dicotyledons the form-P5c is exclusive to these two families, strongly favors their close alliance (see also the ordinal restriction of the subtype-P3 sieve-element plastids, Behnke, 1976b). Related plastid forms are found in the Cyrillaceae (P5cf) and the Humiriaceae (P5cs).

Sieve-element plastids of the Cyrillaceae are distinguished from those of the Rhizophoraceae by the presence of protein filaments in addition to protein crystals (Behnke, 1982a) and a larger diameter (average of 1.6 μm). Nevertheless, their similarity is reason enough to propose at least distant relationships. Traditionally, Cyrillaceae have been placed into Celastrales, Theales, and (recently more often) Ericales (cf. Behnke, 1982a). In view of Dahlgren's (this volume) proposal to associate closely the Rhizophoraceae with the Celastraceae, the inclusion of the Cyrillaceae within the Celastrales (see e.g., Melchior, 1964) may be worth reconsidering.

←

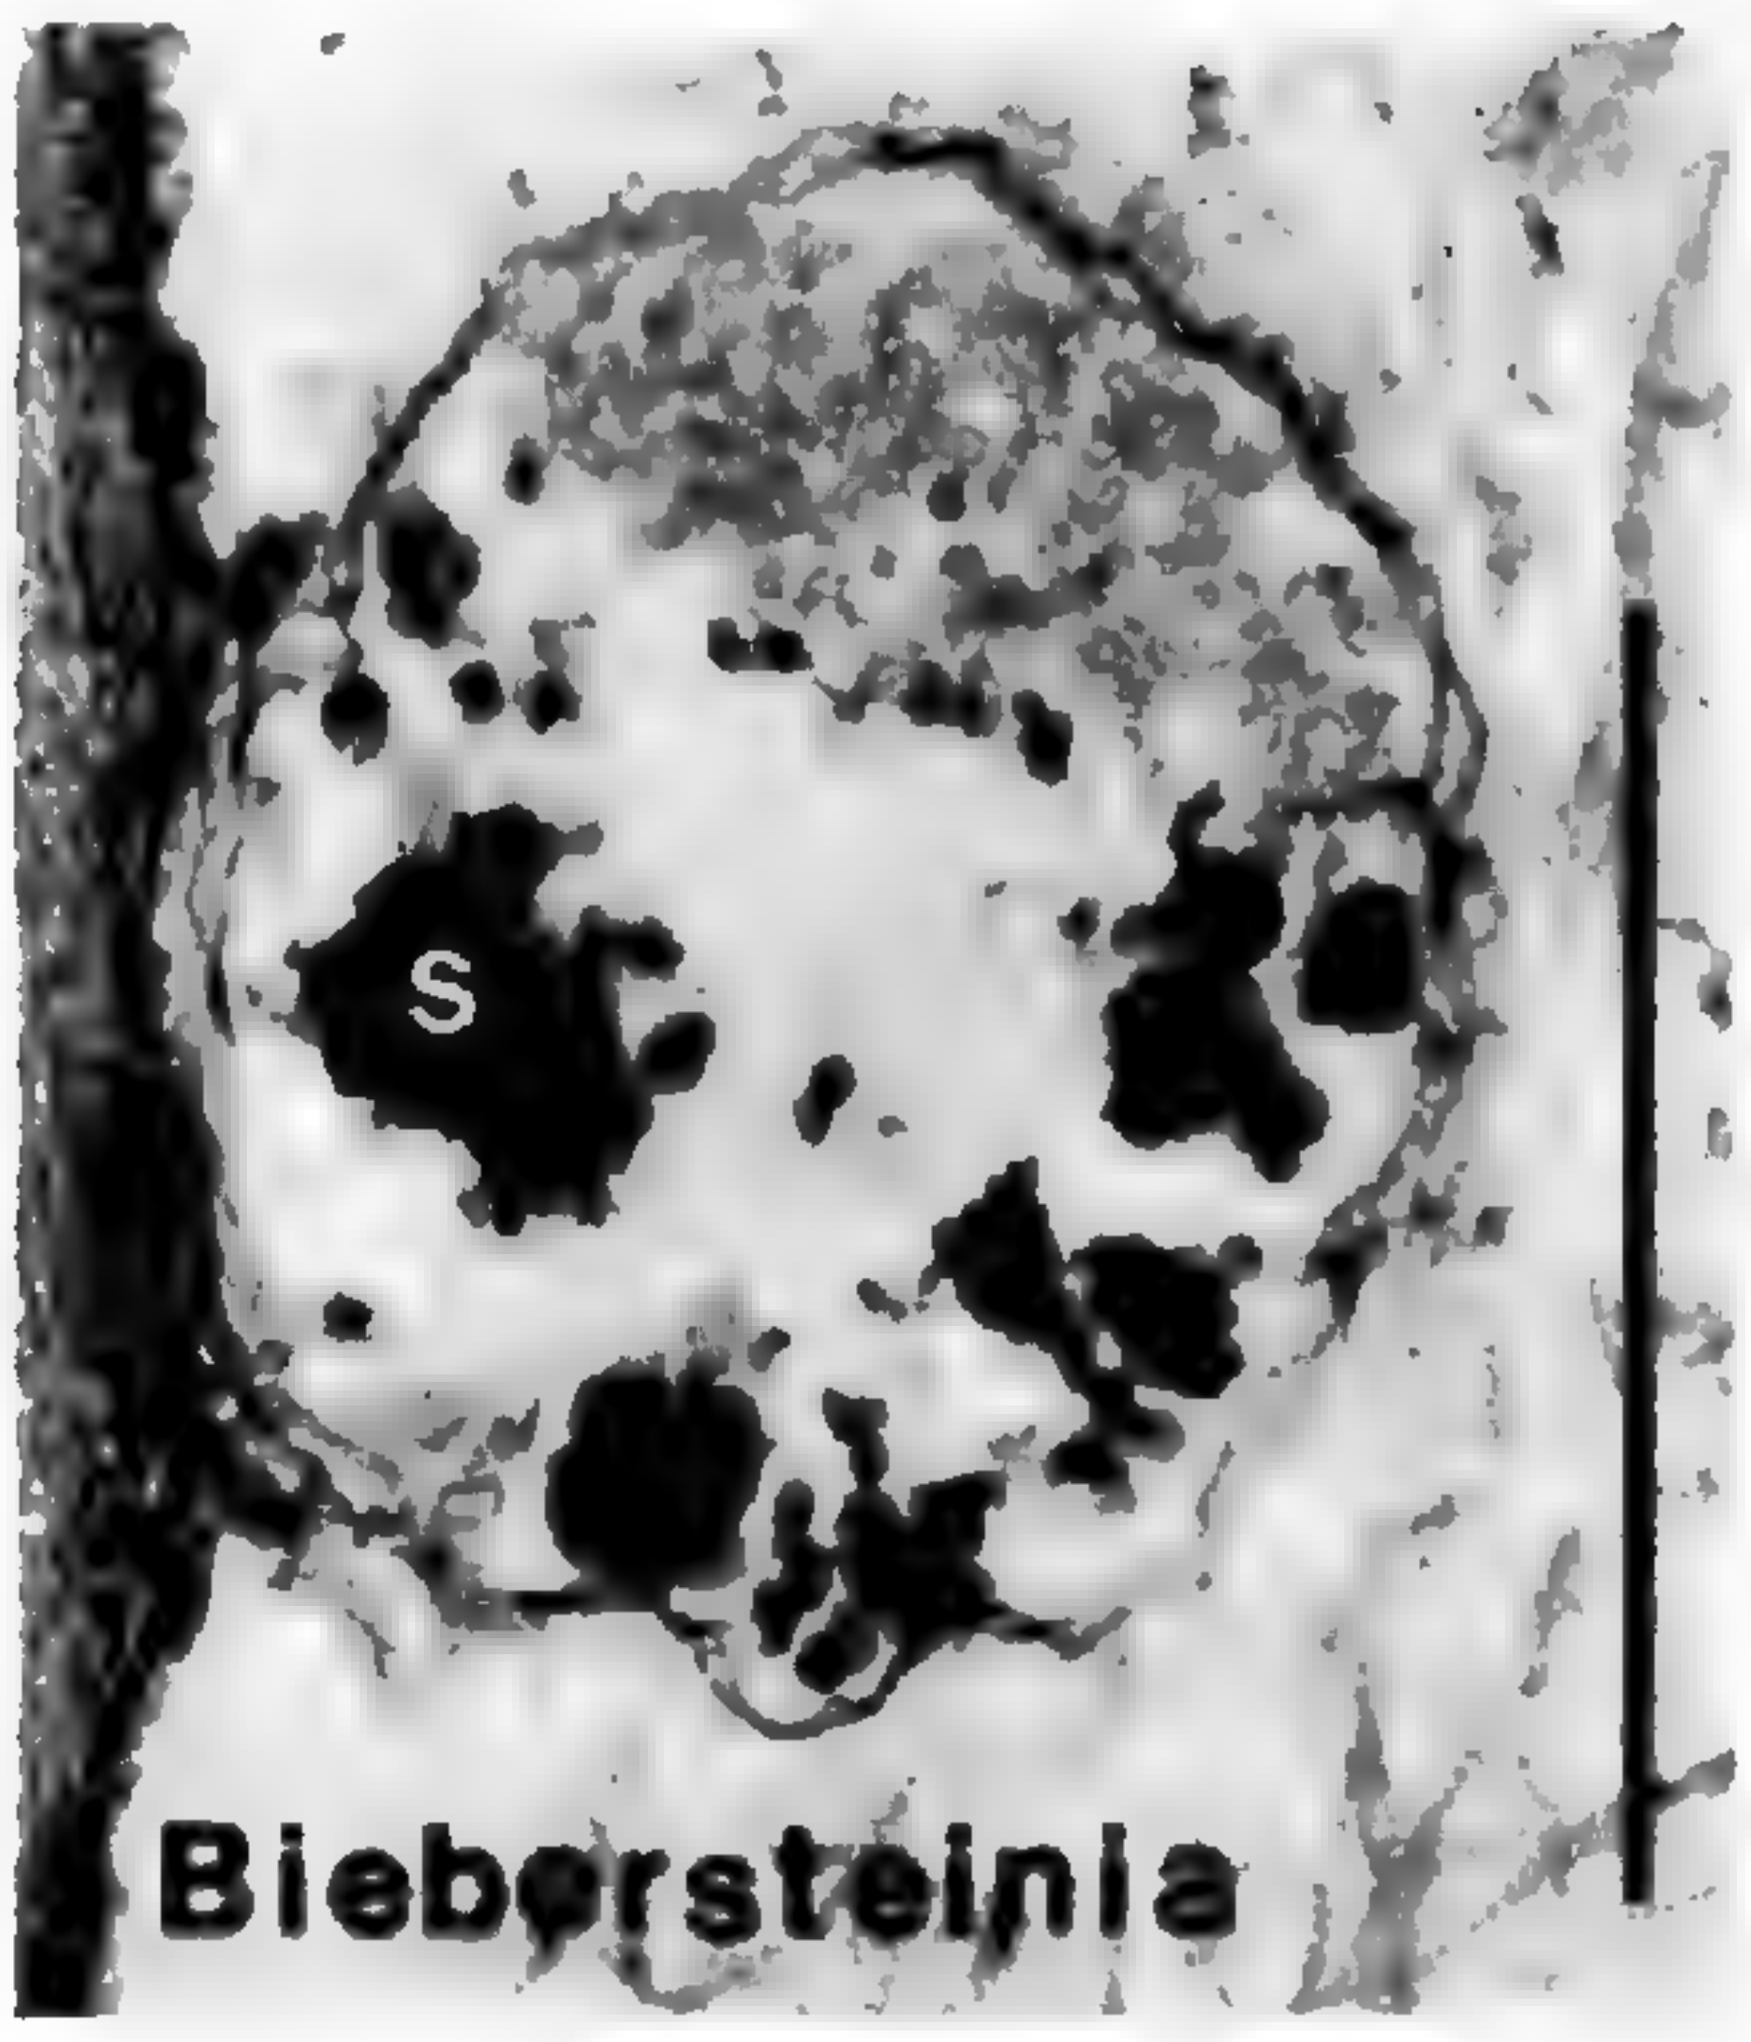

FIGURE 9. *S-type sieve-element plastid of* Biebersteinia multifida. *×30,000. s = starch grain. Scale bar = 1 μm.*

The first and only record for form-P5cs plastids in the Humiriaceae links the form-P5c plastids of the Rhizophoraceae and Erythroxylaceae to the S-type families in the Geraniales s.l. It has further potential in bridging the entire subtype-P5 to the subtype-P4 of the Fabales, thus making the subtype-P4/P5 a characteristic pattern of sieve-element plastids restricted to the Rutinae (sensu Dahlgren, this volume).

The form-P5cs plastids found in the Humiriaceae connect the form-P5c to the S-type plastids in the Geraniales: their number of protein crystals (more than ten on average) is the second highest recorded in the dicotyledons (after those in RHZ and ERY), their number of starch grains and average plastid diameter are compatible with the S-type plastids in the Geraniales. The shape of the protein crystals is not as distinctly rectangular as in the form-P5c plastids (cf. Figs. 2, 5), but even within *Rhizophora* the crystals have no sharp edges (Fig. 5).

The P5cs pattern is very close to that of the form-P4cs plastids present in the Fabales: both contain five or more irregular protein crystals in addition to a variable number of starch grains. It is suggested that from a common ancestor with the plastid inheritance several parallel lines lead to Fabales, Geraniales, Rhizophorales, and probably Celastrales.

However, data from sieve-element plastids do not contribute to the placement of Celastrales unless the inclusion of the Cyrillaceae (cf. Hutchinson, 1959; Melchior, 1964) is followed.

Dahlgren transferred Elaeocarpaceae from Malvales to either the newly defined Celastrales (Dahlgren, this volume: together with RHZ and CEL) or to his Rhizophorales (Dahlgren, in press: as the only other family of this order in addition to the RHZ). The data from sieve-element plastids support neither of the two arrangements. However, another phloem character corroborates the exclusion of Elaeocarpaceae from the Malvales: Bombacaceae, Malvaceae, Sterculiaceae, and Tiliaceae have within their sieve elements so-called persistent, crystalline p-protein bodies, which are absent from the Elaeocarpaceae. The persistent p-protein bodies are a typical character of the Malvanae/Violanae and a few other taxa (see Behnke, 1981).

In summary, data from sieve-element plastids suggest the following parallel sequences of families (those not yet investigated are in parentheses; cf. Table 2):

1. Balanitaceae, Zygophyllaceae, Nitrariaceae, Peganaceae, Geraniaceae, Vivianiaceae, Ledocarpaceae, (Biebersteiniaceae), (Dirachmaceae)
2. Linaceae, Hugoniaceae, (Ctenolophonaceae), Ixonanthaceae
   2.1 Lepidobotryaceae, Hypseocharitaceae, Oxalidaceae, Averrhoaceae
   2.2 Humiriaceae, Erythroxylaceae
      2.2.1 Rhizophoraceae
3. Celastraceae, Elaeocarpaceae
4. Cyrillaceae

Families excluded. On the basis of the sieve-element characters two families discussed during the preparation for this symposium as putative allies are to be definitely excluded: the Flacourtiaceae and Podostemaceae.

The Flacourtiaceae contain S-type sieve-element plastids, but their persistent p-protein bodies (cf. Behnke, 1981) place them in the Violales.

Podostemaceae differ from the discussed orders by their large S-type plastids and the pattern of starch grains.

NOTE ADDED IN PROOF

Fresh rhizomes of *Biebersteinia multifida* DC. kindly have been made available by E. Gabrielian (Erevan, USSR). The following paragraph should be read after Ledocarpaceae (on page 1389):

Biebersteiniaceae (BBS; Fig. 9) *Biebersteinia multifida* contains S-type plastids with one or few globular starch grains, often disintegrated into tiny particles. The plastid diameter is 1.2 μm.

EMBRYOLOGY OF TRIBE GYNOTROCHEAE (RHIZOPHORACEAE) AND ITS DEVELOPMENTAL AND SYSTEMATIC IMPLICATIONS[1]

Adrian M. Juncosa[2] *and Hiroshi Tobe*[3]

ABSTRACT

*A complete embryological description of the four genera traditionally circumscribed as tribe Gynotrocheae (*Carallia, Crossostylis, Gynotroches, *and* Pellacalyx*) is presented. Most of the character states are consistent with those known for other genera of the family that have been studied, but several are not. In* Crossostylis, Gynotroches, *and* Pellacalyx, *microsporogenesis occurs by both simultaneous and successive meiotic cytokinesis, even in a single flower. This is apparently previously unreported in any angiosperm and suggests that meiosis in the anther may be under tapetal, not sporocytic, control. Dioecy in* Gynotroches *results from late-developmental phenomena: in female flowers sporopollenin pollen walls fail to form, and in male flowers late ovule development and megagametogenesis are abnormal. Embryological and other morphological data indicate that Gynotrocheae are paraphyletic and could be narrowed to only* Gynotroches *and* Pellacalyx, *which are distinct from all other Rhizophoraceae in having tenuinucellate ovules and outer integuments that remain biseriate throughout ovule and seed development.* Crossostylis *is intermediate between these two genera and the ancestral tribe Macarisieae, and* Carallia *is probably intermediate between all other inland genera and the mangrove tribe (Rhizophoreae).*

The family Rhizophoraceae is generally accepted as comprising three tribes: Macarisieae (six or seven inland genera), Gynotrocheae (four inland genera), and Rhizophoreae (four mangrove genera). The four genera previously included as tribe Anisophylleeae or as a subfamily are now segregated as an unrelated family, a disposition originally suggested by Ridley (1922) and now supported by many lines of evidence (Behnke, 1982; Tobe & Raven, 1987a; Juncosa & Tomlinson, 1987, this volume).

Embryological evidence (Tobe & Raven, 1987a) and some aspects of vegetative anatomy (Juncosa & Tomlinson, this volume) suggest that the Anisophylleaceae may be related to Myrtales, but the infrafamilial systematics and extrafamilial phylogenetic relationships of the Rhizophoraceae remain uncertain. Much of this uncertainty results from the great variability in many systematic characters in this family and the paucity of information about certain key genera. While many later-developmental and sporophytic characters exhibit considerable adaptive radiation, embryological characters are usually more conservative. Furthermore, because embryological characters are inherently developmental, homologies are more reliable and the polarity of the characters can often be determined, lending additional weight to a phylogenetic hypothesis.

The Gynotrocheae are of pivotal systematic importance within the context of the family for several reasons. There is greater variability in conventional taxonomic characters within this tribe than in the other two: phyllotaxy, wood, flowers, fruits, and seeds all afford good examples (Schimper, 1893; van Vliet, 1976; Juncosa & Tomlinson, this volume). It has even been suggested that *Pellacalyx* could be excluded from the family (Marco, 1935; Dahlgren, pers. comm.). In another direction, the floral morphology of the Rhizophoreae is very sim-

[1] Material from the two Sarawak localities represented two distinct species (see text for details).

ilar to that of *Carallia* (Juncosa & Tomlinson, 1987; Juncosa, pers. obs.); so clues to the evolution of vivipary might be found indirectly among the embryological characteristics of this and other genera of the Gynotrocheae. Although data are not yet available for all genera of Macarisieae, they comprise a relatively homogeneous tribe in other respects (Schimper, 1893; Hutchinson & Dalziel, 1954; Floret, 1976; van Vliet, 1976; Juncosa & Tomlinson, this volume), and comprehensive embryological data for *Cassipourea* and *Sterigmapetalum* are available (Juncosa, 1984a; Tobe & Raven, 1987b). Fragmentary data are available for two genera of Gynotrocheae (Mauritzon, 1939), and seed coat anatomy of all four genera is now well known (Corner, 1976; Tobe & Raven, this volume).

MATERIALS AND METHODS

Species studied and collection data are listed in Table 1. Identification and nomenclature follow Ding Hou (1958). In this treatment, *Gynotroches* is considered to consist of one rather variable species, but material used for this study appeared to represent two very distinct ecotypes or species; differences are noted below. Adequate embryological material was available for only one species in each of the genera *Carallia* (eight species) and *Crossostylis* (six species). Only four of the nine species of *Pellacalyx* were examined, and although complete series of all developmental stages were not available for all four, the data obtained suggest that the genus is probably embryologically uniform.

Material was generally fixed in the field in formalin-acetic acid-60% ethanol (10:5:85 or 5:5:90), but some Brunei collections were fixed in whiskey and formalin (about 10:1). Most material was dehydrated in a tertiary butanol/ethanol series and embedded in paraffin, then sectioned at 8–10 μm and stained with either Heidenhain's iron hematoxylin or safranin followed by fast green (Johansen, 1940). Other material was dehydrated in ethanol, embedded in Polysciences JB-4 resin, sectioned with glass knives at 4–6 μm, and stained with iron hematoxylin.

OBSERVATIONS

Embryological character states are summarized in Tables 2 and 3. Detailed descriptions follow, including notes of occasional variations in character states and some features not always included in embryological summaries.

Carallia borneensis Oliver

Anthers of this species are medifixed, and the connective and the tips of the two halves of the anther are slightly prolonged. The anther consists of four microsporangia. The sporangial wall development is of the "basic" type, that is, having two middle layers, one sharing a common origin with the endothecium; the other, with the tapetum (Fig. 1). Neither the epidermis nor the middle layers persist to anthesis. The endothecial cell walls have very few thick bars of secondary wall (so-called "fibrous" thickenings; Fig. 2). The tapetum is glandular; its cells have two nuclei. Cytokinesis in microspore mother cells is simultaneous, producing tetrahedral tetrads. Anther dehiscence is introrse and occurs by longitudinal slits.

Pollen nuclei	2	2	2	2

Ovules of *C. borneensis* are bitegmic, and even at early stages of development each integument consists of more than two cell layers (Fig. 3). Early cell divisions in the integuments are irregularly oriented, as would be expected in a multiseriate, parenchymatous structure; by contrast, the anticlinal divisions in the biseriate integuments of other inland Rhizophoraceae are usually uniformly perpendicular to the surface, as would be expected in a structure consisting of two protodermal layers. The outer integument of *C. borneensis* thickens to 7–15 cell layers by the time of anthesis; the inner integument, to about 10 cell layers (Fig. 4). Both integuments contribute to forming the micropyle, and the endostome and exostome are not aligned. The outer integument is vascularized, but the inner integument is not (Fig. 5). The outer epidermis of the inner integument, which forms the prominent exotegmen in other genera, is distinctly differentiated, and a pronounced endothelium is formed as megagametogenesis begins; its cells are densely staining and palisadelike by the two-celled stage of gametogenesis (Fig. 4). At anthesis, the endothelium becomes tanninized and thick-walled.

The archesporial cell divides once periclinally, and the parietal derivative usually divides once anticlinally (Fig. 6). The ovule is thus crassinucellate. A cell wall is formed after meiosis I, and a linear, T-shaped, or irregular tetrad of megaspores is formed. The gametophyte develops from the chalazal megaspore. The observation of two-, four-, and eight-nucleate stages confirmed that gametogenesis occurs according to the *Polygonum*-type pattern. Three antipodal cells are formed, but their nuclei appear condensed or degenerate at anthesis. The mature synergids are pyriform and stain very densely. The polar nuclei are closely appressed but do not fuse to form a secondary nucleus before fertilization. Most of the nucellus, particularly its micropylar half, degenerates during megagametogenesis (Fig. 4).

Fertilization is porogamous, and endosperm formation is initially free-nuclear. Endosperm development and expansion of the fertilized ovule both proceed for some time before embryogenesis begins. The first division of the zygote was roughly transverse in all specimens studied (over 100 seeds in early developmental stages). However, the orientation of the second division was variable. In most cases it was parallel to the axis of the proembryos ("vertical" or longitudinal, although the axis of the proembryo was not usually parallel to the long axis of the ovule), but in many other specimens it was oblique (Figs. 7, 8). Although the basal cell subsequently divides transversely and these derivatives divide both transversely and longitudinally, none of the resultant cells contribute to the embryo proper. Thus, allowing for a slight relaxation of the definition of onagrad-type embryogenesis to accommodate the variability in orientation of the plane of division of the terminal cell, embryogenesis in *C. borneensis* can be described as being fundamentally of this type. During the early globular stage (proembryo consisting of up to about 20 cells in median longitudinal section), both the basal cell of the suspensor and the cells closest to the embryo proper divide longitudinally, producing a mostly multiseriate suspensor, sometimes with a uniseriate section in the middle (Fig. 8).

The mature embryo consists of two laminar cotyledons and a straight hypocotyl, this making up about two-thirds of the length of the embryo. The axial vascular cylinder is medullated throughout its length. The embryo is green and enveloped by abundant endosperm. The seed coat is mostly testal and 20–50 cell layers thick; its surface is bullate

[1] Integuments of species other than *C. borneensis* are thinner at maturity and possibly also at inception.
[2] Strictly biseriate outer integument was never observed, possibly because periclinal divisions begin very early.
[3] Presently known only in *C. borneensis*; not found in *C. brachiata* or *C. eugenioidea*.

due to localized growth of hypodermal parenchyma and expansion of the overlying epidermis (Fig. 9). Although the exotegmen is a distinctive cell layer in the unfertilized ovule, it does not persist to form a prominent sclerified layer in the mature seed, as in other inland genera of Rhizophoraceae; instead, the tegmen gradually degenerates and/or is crushed during later seed development.

Crossostylis grandiflora Brongn. & Gris.

The anther consists of four microsporangia. Periclinal divisions in the outer parietal cell layer produce the endothecium and a primary middle layer, which in turn divides to form two cell layers. Later, the inner parietal cells divide, producing the tapetum and a third middle layer (Fig. 10). Thus, anther wall development follows the basic type. The middle layers degenerate during microsporogenesis. The epidermis persists to anthesis, although tannins are deposited in its cells. A few thick bars of secondary wall are formed by the endothecial cells (Fig. 11). As in other Rhizophoraceae, the tapetum is glandular, and its cells are binucleate. However, unlike other genera, the tapetal cytoplasm in *C. grandiflora* stains more densely with hematoxylin and may include several to many unstained globules of uncertain composition.

Microsporogenesis occurs by both simultaneous and successive cytokinesis, but most cytokineses in a single microsporangium occur by only one pattern (Figs. 12, 13). Although any one cell in which simultaneous nuclear division (but not wall formation) has occurred may resemble a cell at the end of the nuclear division of meiosis I, careful examination at various focal levels of hundreds of meiotic figures in many serial sections of several different flowers revealed virtually no cells with tetrahedrally arranged nuclei in "successive" thecae, such as the one shown in Figure 13, and revealed virtually no binucleate cells or portions of cells in "simultaneous" thecae, such as that shown in Figure 12. The very large number of observations makes us confident that this conclusion is not due to orientation of the cells relative to the plane of sectioning, but rather reflects actual variability in the meiotic division pattern. In successively dividing cells, wall formation occurs after meiosis I but is not documented here for this genus (see also Fig. 25, *Pellacalyx*). Pollen tetrads of *C. grandiflora* are either tetrahedral or decussate. The mature anthers are strongly reniform, even semicircular, and dehisce introrsely by longitudinal slits.

The ovule is bitegmic. At inception and during early development, the inner integument is biseriate (Fig. 15). Later, numerous peripheral divi-

sions occur, and it becomes about 20 cells thick by the time of anthesis (Fig. 16). The exotegmen and endothelium are sharply differentiated throughout megagametogenesis. The outer integument is probably biseriate at its inception, although this stage was not observed. In the premeiotic stages that we studied in which the outer integument (or at least its abaxial portion) was present, its basal half was triseriate and the distal portion was biseriate. During the remainder of ovule development very few periclinal divisions occur in the outer integument, and at anthesis it is only about four cell layers thick. Its outer epidermal cells expand considerably and are filled with tannin.

Gynotroches axillaris Blume

Collections used for this study came from two sites in southern Sarawak. Study of plants from these and a number of other sites suggests that at least two ecotypes, probably constituting distinct species, are found in this region. This lends strong support to the suggestion by Ding Hou (1958) that, with further study, this highly variable and widely

distributed genus will be amenable to subdivision into several distinct species. Accordingly, brief descriptions of the taxa collected are given so that future readers will be able to ascertain to which species the embryological data pertain. Trees found in secondary vegetation on low altitude kerangas sites or peat swamps had smooth leaves about 6–9 cm long and reddish fruits about 4 mm in diameter at maturity, usually largely covered by a cracked periderm. Trees found along the banks of small streams in hill forest at 50–200 m elevation had bullate leaves 20–25 cm long and yellow, noncorky fruits at least 5–6 mm in diameter at maturity. In addition to these nonoverlapping color and size differences, the trees had very different habits and leaf colors. Both species produce aerial stilt roots, which are more numerous on trees growing in very swampy sites. Both taxa observed appeared to be dioecious. Absence of developing or mature fruits on trees bearing male flowers suggests that the apparent dioecy did not result merely from a temporal separation of the two types of flowers. Almost all of the embryological data reported herein were derived from study of specimens collected in the hill forest.

The anther of *Gynotroches* consists of four microsporangia. Only one middle layer is present between the endothecium and tapetum; because this layer shares its origin with the tapetum, anther wall development is of the "monocotyledonous" type (Fig. 17). The tapetum is glandular; its cells have two nuclei. In some microsporangia, meiotic cytokinesis was successive, producing isobilateral or decussate tetrads (Fig. 18), but in others, even within the same stamen, simultaneous cytokinesis occurred, producing tetrahedral tetrads (Fig. 19). As with *Crossostylis* (see above), numerous meiotic figures were examined to insure that we were not misled by an artifact of the plane of sectioning, although only a few cells are shown in the figures. Mature pollen grains in male flowers are binucleate. In female flowers, the anther as a whole develops more or less normally, having at least a partially functional tapetum and an endothecium with secondary wall thickenings (Fig. 20). Meiosis also occurs, forming numerous microspores, but the normal sporopollenin wall does not form around them (Fig. 20).

Functional ovules of *Gynotroches* are bitegmic and anatropous. Early in development, both integuments are two cell layers thick (Fig. 21). The inner integument thickens to 5–6 cell layers by the time of anthesis, but the outer integument remains only two cell layers thick in most places, except for its expanded micropylar portion (Fig. 22). A funicular (raphe) vascular bundle extends along the adaxial side of the outer integument, but neither integument proper is vascularized. An endothelium is formed early in megagametogenesis (Fig. 22). The micropylar half of the nucellus degenerates before gametogenesis is complete. The micropyle is quite short and is formed by both integuments. Occasionally, however, extension of the inner integument makes the micropyle endostomic. The single archesporial cell functions directly as the megaspore mother cell; thus, the ovule is tenuinucellate (Fig. 21). A cell wall forms after meiosis I, and the megaspore tetrad is usually T-shaped. The chalazal megaspore forms a normal 8-nucleate megagametophyte via *Polygonum*-type development. The synergids are large and pyriform, and the polar nuclei do not fuse to form a secondary nucleus. Antipodals are formed and persist to anthesis (Fig. 22).

In male flowers, early ovule development is more or less similar to that in female flowers, although the nonfunctional ovules are somewhat smaller and irregularly shaped compared with the fertile ones of female flowers, primarily due to irregularities in integument development (Fig. 23). A normal micropyle can rarely be seen. No obvious irregularities in megasporogensis were noted in the nonfunctional ovules, and megagametogenesis may either proceed normally through at least the four-nucleate stage (Fig. 23) or may be somewhat disordered. Gynoecial development is also modified in

male flowers. In particular, the style may become necrotic or may elongate abnormally, with the stigmatic lobes remaining inserted at its base (Juncosa, pers. obs.). Further details of floral development will appear separately.

In fertilized ovules of female flowers, both cell layers of the outer integument persist and form a distinctive testa, in which the outer epidermal cells are very large and tanniniferous, and the inner epidermal cells are small and compact, with prominent nuclei and dense cytoplasm. This latter layer of cells may play an important role in controlling the process of imbibition. The exotegmen is very prominent and sclerified; radial elongation of some of its cells makes its outline undulate. Several internal cell layers of the inner integument also persist but remain unspecialized. Mature endosperm cells contain many large inclusions of undetermined composition. These inclusions stain weakly with safranin and are not birefringent. As in other Rhizophoraceae, the embryogenetic cell division pattern in *Gynotroches* is variable. However, in this genus, the overwhelming majority of proembryos observed had developed according to the typical onagrad-type pattern (Fig. 24), and only a few exhibited an oblique division of the terminal cell. The mature embryo is straight, and both the hypocotyl and cotyledons are well developed; they are of roughly equal length. The provascular cylinder in the radicle is not medullated.

Pellacalyx species

Complete prefertilization embryological data were determined from studies of *P. cristatus* Hemsl. Using the scanty available material of *P. symphiodiscus* Stapf, we confirmed that in anther wall, pollen tetrad, and ovule integument characters, it agreed exactly with *P. cristatus*. Ovules of *P.* cf. *saccardianus* Scort. were examined, and seeds of *P. cristatus* and *P. lobbii* (Hook. f.) Schimp. were studied.

The anther in species of *Pellacalyx* has four microsporangia, the exterior walls of which develop according to the basic-type pattern. The two middle layers degenerate before pollen develops, but the

epidermis persists to anthesis, although its cells are somewhat collapsed by that time. Secondary wall thickenings are found in the endothecial cells. The tapetum is glandular and composed of binucleate cells. Both successive and simultaneous meiotic cytokineses occur (Figs. 25, 26), producing decussate and tetrahedral pollen tetrads, respectively. Generally, only one type of cytokinesis occurred in any one microsporangium, but incongruent divisions were observed (Fig. 25). Pollen grains are binucleate when dispersed. Anther dehiscence is introrse, occurring by longitudinal slits.

Both integuments of the ovule of *P. cristatus* and *P. saccardianus* are initially two cell layers thick (Fig. 27), but divisions in the inner layer of the inner integument soon form three, then eight to ten cell layers (Fig. 28). The outer integument remains biseriate. Neither integument is vascularized, and both contribute to forming the micropyle. A prominent endothelium is formed during megagametogenesis. The single archesporial cell functions directly as the megaspore mother cell (Fig. 27); thus, the ovule is tenuinucellate. A cell wall is formed after meiosis I, and the megaspore tetrad is usually linear. The chalazal megaspore forms a normal megagametophyte via *Polygonum*-type megagametogenesis. Antipodals are formed but become condensed by the time of anthesis. The polar nuclei remain separate until fertilization. The synergids are pyriform, with prominent chalazal vacuoles.

DISCUSSION

Although this study was limited to one of the two inland tribes of the familiar but poorly understood family Rhizophoraceae, some of the characteristics observed are strongly discordant with embryological dogma and may have significant implications in the study of the control of critical stages of plant development. These features are discussed separately at the end of this section.

SYSTEMATIC SIGNIFICANCE

The data reported here combined with information from other sources (Karsten, 1891; Mauritzon, 1939; Tobe & Raven, 1987a, b, this volume; Juncosa, 1982b, 1984a, b) permit a relatively complete embryological characterization of the family Rhizophoraceae. Reports for African genera of tribe Macarisieae are not yet available, but data from *Cassipourea* and *Sterigmapetalum* (Tobe & Raven, 1987b) are taken as representative of that tribe.

Despite the occurrence of certain derived character states in some genera, the family is remarkably homogeneous embryologically. This contrasts somewhat with the wide range of variation in wood anatomy, mature floral morphology, and chromosome number (Juncosa & Tomlinson, this volume). Allowing for some exceptions, a generalized embryological summary is as follows:

Anthers tetrasporangiate, wall development basic-type (monocotyledonous-type in *Gynotroches*), endothecium with few secondary wall thickenings (more numerous in Macarisieae), middle layers degenerate, tapetum glandular, its cells binucleate; microspore cytokinesis simultaneous (or also successive, in most Gynotrocheae); pollen tetrads tetrahedral or decussate, pollen binucleate. Ovules anatropous, bitegmic, crassinucellate (tenuinucellate in *Gynotroches* and *Pellacalyx*), integuments two cell layers thick at inception (multiseriate in *Carallia* and Rhizophoreae), usually thickening subsequently, endothelium present, micropyle diplostomic, nucellus ephemeral; megagametogenesis chalazal-monosporic (*Polygonum*-type), synergids pyriform with large chalazal vacuoles, antipodals usually degenerate (persistent in *Gynotroches* and *Pellacalyx*). Fertilization porogamous, endosperm initially free-nuclear, embryogenesis variable within species. Mature seeds usually with sclerified exotegmen and abundant nonstarchy endosperm; embryo chlorophyllous, straight, with prominent cotyledons and hypocotyl; radicular vascular cylinder usually medullated; germination epigeal or *Durian*-type.

For most of these characters, the states given above are merely the most common ones among dicotyledons and are regarded as plesiomorphic and therefore not phylogenetically diagnostic. However, the presence of an endothelium is relatively rare in bitegmic ovules (Kapil & Tiwari, 1978). Also, variable orientation of the first and second embryogenetic cell divisions has almost never been reported in families other than Rhizophoraceae, although it may be common in woody plants with large proembryos (Nast, 1941; Souèges et al., 1967). Among temperate herbs, it is apparently common only in Dipsacaceae (Souèges, 1957). Nucellar degeneration, which occurs in all Rhizophoraceae yet studied, is of some diagnostic value. Sclerified exotegmen is not common (Corner, 1976).

The new data reported here support the contention that Rhizophoraceae and Anisophylleaceae are not related (Juncosa, 1982a; Juncosa & Tomlinson, 1987, this volume; Tobe & Raven, 1987a). This latter family differs sharply from the former in all of the apomorphic character states just enumerated (endothelium, degenerate nucellus, exotegmen) as well as in others that are of more general occurrence in dicotyledons. Also, as previously pointed out (Tobe & Raven, 1983), Rhizophoraceae are embryologically out of place in either Myrtales or Cornales, two orders in which the family has often been placed by phylogeneticists (Cronquist, 1968; Thorne, 1976; Takhtajan, 1980). Assignment of the Rhizophoraceae to their own order (Cronquist, 1981; Dahlgren, 1983) merely raises the question of the proper placement of that order. As suggested and discussed by Dahlgren (this volume), the alignment of the Rhizophoraceae with the Celastraceae, Elaeocarpaceae, Erythroxylaceae, and possibly other families is well supported by the embryological data.

These data also have clear implications for intrafamilial systematics. Among the ten genera of Rhizophoraceae so far investigated, only *Gynotroches* and *Pellacalyx* have tenuinucellate ovules and an outer integument that remains two-layered throughout development; the histology of the seed coats in these two genera is similar and differs from that of all other genera in the family (see also Tobe & Raven, this volume). These embryological synapomorphies also correlate with distinctive characteristics of the inflorescence and floral anatomy that are unique to these two genera, such as fasciculate monochasial inflorescences, multiovulate carpels, and idioblastic laticifers (Juncosa & Tomlinson, this volume). Therefore, we conclude that *Gynotroches* and *Pellacalyx* are sister genera, despite the pronounced differences in mature floral morphology that have led some to question even the inclusion of the latter in the family.

As judged by embryological criteria, the systematic position of *Crossostylis* is likely to be intermediate between the Macarisieae and the *Gynotroches/Pellacalyx* clade. The outer integument of the mature ovules of *Crossostylis* is about four cell layers thick, as in *Cassipourea* and *Sterigmapetalum* (Juncosa, 1984a; Tobe & Raven, 1987b). Further, seeds of *Crossostylis* are arillate (Fig. 16; Corner, 1976; Smith, 1981; Tobe & Raven, this volume); seeds of Macarisieae are invariably winged or arillate. This suggests the possibility of merely reassigning *Crossostylis* to the Macarisieae. However, the number of secondary wall thickenings of endothecial cells of *Crossostylis* and other Gynotrocheae is quite low (one to three), whereas five or more such bars are found in *Cassipourea* (Juncosa, pers. obs.). Also, microsporogenesis in *Crossostylis grandiflora* occurs by both simultaneous and successive cytokinesis, a circumstance reported here for *Gynotroches* and *Pellacalyx* but otherwise unknown in the family. Furthermore, there are many important vegetative and floral morphological characters common to *Crossostylis* and other Gynotrocheae that do not occur in Macarisieae (Juncosa & Tomlinson, this volume). Therefore, a reassignment of *Crossostylis* based solely upon the outer integument and aril seems incorrect, despite the importance traditionally ascribed to this character.

Carallia seems also to be phylogenetically intermediate, standing between the *Gynotroches/Pellacalyx* clade and the mangrove tribe (Rhizophoreae). Within the Gynotrocheae, only *Carallia* has a prolonged anther connective and acute sterile tips on the two halves of the anther, characters also found in some Rhizophoreae (Juncosa & Tomlinson, 1987). Nonappendaged seeds and baccate fruits are found throughout the "higher" Gynotrocheae (that is, excepting *Crossostylis*) and Rhizophoreae and thus do not help clarify relationships among these seven genera. Seed coat anatomy of *C. eugenioidea* resembles that of other Gynotrocheae (Tobe & Raven, this volume), but that of *C. borneensis* is vascularized and quite thick, like those of the Rhizophoreae. The seed coat of *C. brachiata* is intermediate between these two in at least some respects (Tobe & Raven, this volume). The seed coat apomorphies of *C. brachiata* (degenerate tegmen) and especially *C. borneensis* may be homoplastic with those of the Rhizophoreae, but it is also possible that the genus *Carallia* is paraphyletic. Embryological data do not resolve this question, but *Carallia* and the Rhizophoreae do share several floral synapomorphies (Juncosa & Tomlinson, this volume and unpubl. obs.), and only one putative autapomorphy distinguishes the genus *Carallia* (stalked extrastipular glands). This character is known to occur only in *C. longipes* (Ding Hou, 1960) and *C. borneensis* (Juncosa & Tomlinson, this volume), but other species have yet to be examined critically; if these glands prove not to be ubiquitous in the genus, its monophyly will be questionable. With the possible exception of the vascularized integument of *C. borneensis*, we observed no embryological peculiarities in *Carallia* that could be construed as any kind of preadaptation to vivipary, which therefore appears to have arisen entirely within the mangrove tribe.

DEVELOPMENTAL IMPLICATIONS

It is generally believed that nearly all fundamental embryological characters are invariant for a given species (Davis, 1966). For example, the extensive literature on angiosperm embryogenesis is based upon this supposition (Schnarf, 1929; Johansen, 1950). However, variability in cell division pattern has been reported in two genera with relatively large embryos (*Juglans*: Nast, 1941; *Laurus*: Souèges et al., 1967) and is characteristic of all Rhizophoraceae yet studied (Juncosa, 1982b, 1984a, b). Interestingly, among Rhizophoraceae, the genus that most consistently exhibits the familiar onagrad-type pattern (as traditionally described) is *Gynotroches*, which has quite small embryos in comparison with those of other genera. This suggests a correlation between small embryo size at cotyledonary initiation and consistency in orientation of cell divisions that has not previously been recognized. Unfortunately, most of the embryogenetic literature pertains to temperate, herbaceous species with small seeds and embryos, so it is not clear from this limited example whether this correlation is generally true or not.

Another embryological characteristic that may have developmental implications is variability in meiotic cytokinesis in the anthers of all Gynotrocheae except *Carallia*. This has not previously been reported in any angiosperm, although the variation in pollen tetrad configuration that has occasionally been noted (Davis, 1966) suggests that variable cytokinesis may occur widely. However, it is not merely the occurrence of this variation in Gynotrocheae, but especially the pattern of variation that is developmentally significant: nearly all meioses in a single microsporangium occur by only one cytokinetic pattern, yet adjacent sporangia in a single stamen may exhibit different patterns (Figs. 12, 13, 18, 19, 25, 26). This suggests strongly that the pattern of cytokinesis is controlled by tapetal secretions, not by the individual microspore mother cells. Further investigation of this system is certain to yield significant new insights into the process of meiosis in angiosperms.

ADDITIONAL NOTES ON THE EMBRYOLOGY OF *POLYGONANTHUS* (ANISOPHYLLEACEAE) AND RELATIONSHIPS OF THE FAMILY[1]

Hiroshi Tobe[2] *and Peter H. Raven*[3]

ABSTRACT

Polygonanthus *is reported here to have a* Polygonum*-type embryo sac, like* Anisophyllea *but unlike* Combretocarpus *(with an Allium-type embryo sac). This, together with the results of comparisons of other embyrological character states reported earlier, indicates an isolated position for* Combretocarpus *within the family Anisophylleaceae. On the basis of the available embryological data, we suggest that Anisophylleaceae appear to be distinct from both Rosales sensu stricto and Saxifragales. The family shares many embryological features with Myrtales and may be regarded, at least for the time being, as constituting a distinct order in that phylogenetic lineage.*

In the course of our earlier study of the embryology of Anisophylleaceae (comprising *Anisophyllea, Combretocarpus, Poga,* and *Polygonanthus*), we were unable to determine several important characters for *Polygonanthus* (Tobe & Raven, 1987a). The collection of an additional sample of *Polygonanthus amazonicus* has made it possible for us to report supplemental embryological results here.

Although we have already discussed the embryology and the floral morphology and anatomy of Anisophylleaceae (Tobe & Raven, 1987a, 1988a), our new results, together with the analysis of wood anatomical characters made by Dr. Elisabeth A. Wheeler on the basis of computerized databases and the suggestion by Dahlgren (this volume) that the family belongs in his narrowly defined order Rosales, necessitate further analysis. We have, therefore, returned to the question of the relationships of Anisophylleaceae in the present paper.

The fixed female flower buds of *Polygonanthus amazonicus* Ducke used in this study were collected by Bruce W. Nelson at Maue, Amazonas, Brazil (voucher *J. L. Zarucchi 3138,* MO) and fixed in FAA. Microtome sections for observations were made following the standard methods discussed in the previous paper (Tobe & Raven, 1987a).

EMBRYO SAC FORMATION IN *POLYGONANTHUS*

As previously reported, the ovule is anatropous and crassinucellate. At least one parietal cell is observed above a megaspore mother cell, and the occurrence of periclinal cell division in the nucellar apical epidermis is also confirmed (Fig. 1). The megaspore mother cell divides into two cells, with the upper micropylar cell much smaller than the lower chalazal cell (Fig. 2). Subsequent division occurs only in the chalazal cell, giving rise to a triad of megaspores (Fig. 3). Only the chalazal megaspore functions, developing into a monosporic eight-nucleate embryo sac; therefore, embryo sac formation of *Polygonanthus* conforms to the *Polygonum*-type, in agreement with that of *Anisophyllea* but not with that of *Combretocarpus,* which has a bisporic *Allium*-type embryo sac (Tobe & Raven, 1987a).

With respect to other embryological characters,

---

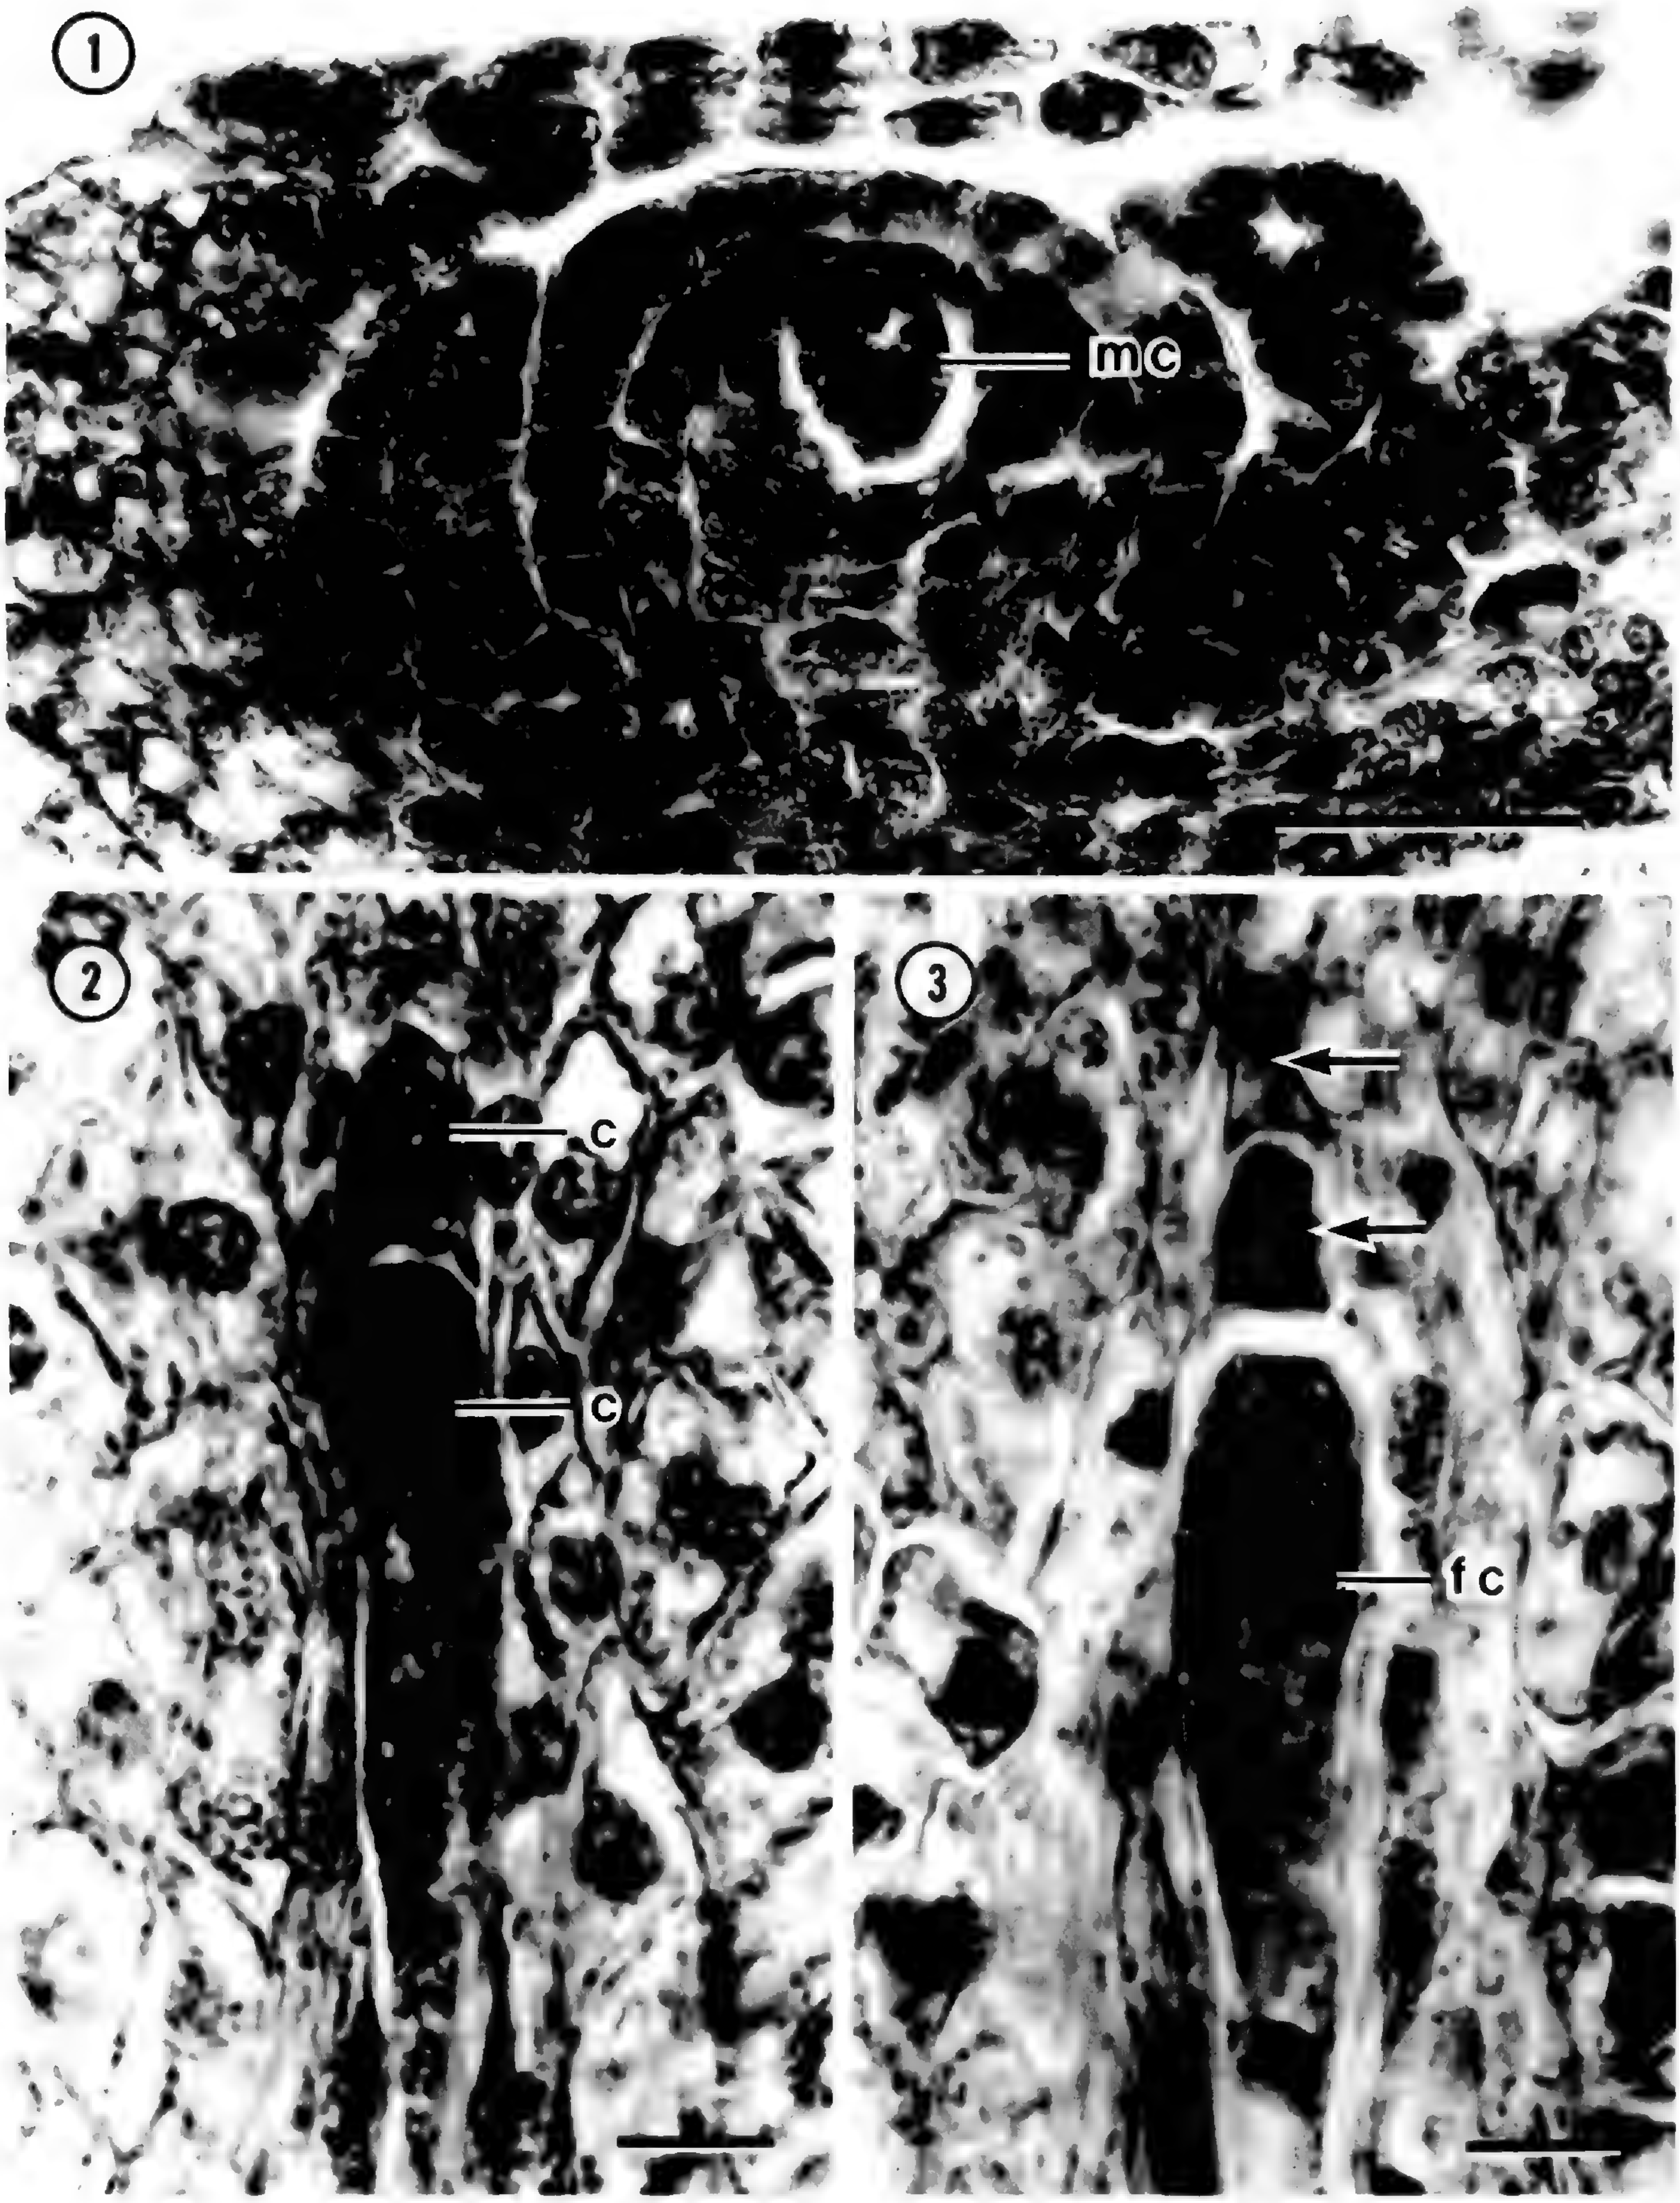
ANN. MISSOURI BOT. GARD. 75: 1425–1428. 1988.



FIGURES 1-3. *Longitudinal sections of young ovules of* Polygonanthus *showing megasporogenesis.—1. Megaspore mother cell stage.—2. Dyad of megaspores.—3. Triad of megaspores. Abbreviations:* mc, *megaspore mother cell;* c, *megaspore;* fc, *functioning megaspore. Arrows in Figure 3 indicate degenerating megaspores. Scale bars equal 50 μm, 10 μm, and 10 μm, respectively.*

Polygonanthus and *Poga* share many plesiomorphies, most of which are common even to *Anisophyllea* (see cladogram in Tobe & Raven, 1987a, fig. 71). In view of these features, the occurrence of *Polygonum*-type embryo sac formation in *Polygonanthus* (also in *Anisophyllea*) indicates an isolated position for *Combretocarpus* within the family. *Combretocarpus* is characterized by many apomorphies, including *Allium*-type embryo sac formation. *Polygonanthus*, like *Poga*, seems to be a relictual genus whose embryological features were mostly inherited from ancestral Anisophylleaceae (Tobe & Raven, 1987a).

RELATIONSHIPS OF ANISOPHYLLEACEAE

We discussed the relationships of Anisophylleaceae (and Rhizophoraceae) earlier (Tobe & Raven, 1987a, b, 1988a), as have other authors in this symposium (e.g., Juncosa & Tomlinson, this volume). Historical views on these relationships are reviewed in these papers, and it seems unnecessary to repeat them here. Instead, we shall use recent suggestions (Tobe & Raven, 1987a, 1988a; Baas, pers. comm.; Dahlgren, this volume) as our point of departure.

Anisophylleaceae have traditionally been assigned to Rhizophoraceae as a subfamily or a tribe. The close resemblance with Rhizophoraceae (particularly with *Carallia*) has been strongly supported by evidence from wood anatomy (van Vliet, 1976; Baas, pers. comm.). Additionally, the result of the computer search by Dr. Wheeler, which incorporated wood anatomical data of about 5,000 dicotyledonous species representing all major and many minor woody genera, confirms that Anisophylleaceae agree completely with *Carallia* and largely with *Crossostylis* and *Gynotroches*; all three of these genera are Rhizophoraceae sensu stricto. In terms of wood anatomy, therefore, Rhizophoraceae undoubtedly agree most closely with Anisophylleaceae, and Baas (pers. comm.) suggested that this evidence rules out many other families as close relatives. Nonetheless, overall evidence from many other lines of investigation, including embryology, makes it absolutely clear that Rhizophoraceae and Anisophylleaceae belong to different evolutionary lines (Tobe & Raven, 1987a, 1988a; Dahlgren, this volume).

What then are their relatives? Dahlgren (this volume) proposed that Rhizophoraceae be placed in Celastrales along with Celastraceae and Elaeocarpaceae, and we agreed with this suggestion on the basis of embryological evidence (Tobe & Raven, this volume). It seems, therefore, to be the best available hypothesis. Concerning the affinities of Anisophylleaceae, we proposed Myrtales on the basis of embryological evidence (Tobe & Raven, 1987a); in contrast, Dahlgren (this volume) suggested that they belonged in Rosales sensu stricto. On the basis of our analysis (Tobe & Raven, 1988a), Dahlgren concluded that the floral structure of Anisophylleaceae agreed completely with that of Rosales sensu stricto.

Rosales sensu Dahlgren (= Rosales sensu stricto in the following discussion), for comparison with Anisophylleaceae, comprise Crossosomataceae, Rosaceae, Malaceae, Neuradaceae, and Amygdalaceae (Dahlgren, 1983, this volume). Crossosomataceae have often been placed in Dilleniales (e.g., Melchior, 1964; Takhtajan, 1980). On the basis of embryological evidence, Kapil (1970) supported this traditional treatment and rejected the inclusion of Crossosomataceae in Rosales. Despite this, we are not aware of any essential difference in embryological features between Crossosomataceae and Rosaceae, and therefore disagree with Kapil's view. Except for Crossosomataceae, these families are closely related; they are often grouped into a broadly defined family Rosaceae (e.g., Thorne, 1983). Among them, Crossosomataceae, Rosaceae, and Malaceae are relatively well known embryologically, but Neuradaceae and Amygdalaceae are poorly known. The embryological features of Rosales sensu stricto, on the basis of available data, are surveyed in our paper on the embryology of Rhabdodendraceae (Tobe & Raven, 1988b), which is also assigned by Dahlgren (1983) to Rosales sensu stricto. If we compare the embryological features of Anisophylleaceae (see Tobe & Raven, 1987a, for data) with those of Rosales sensu stricto (see Tobe & Raven, 1988b, for data), we find that although Anisophylleaceae share many embryological features with Rosales sensu stricto, the family is distinguished from Rosales sensu stricto in having vascularized integuments, no hypostase, no persistent nucellar tissue in the mature seed, a two-cell-layered thin inner integument (mostly thicker in Rosales sensu stricto), no obturator, and no endosperm in the mature seed. These embryological features suggest strongly that Anisophylleaceae, even though there are some points of similarity to Rosales sensu stricto, do not belong in that order.

We have searched for combinations of embryological features similar to that found in Anisophylleaceae among groups related to Rosales sensu stricto such as Saxifragales sensu Dahlgren. This order comprises 11 families, including several families of "Glossulariineae," a group to which Cronquist (1981, 1983) considered Anisophylleaceae to belong. We also considered Cunoniales sensu Dahlgren (five families) as possible relatives. We found that Anisophylleaceae are clearly distinct from Saxifragales in lacking the Cellular- or Helobial-type endosperm formation and a persistent endosperm in the mature seed, characteristic features of Saxifragales. As regards Cunoniales, the five constituent families (Cunoniaceae, Baueraceae, Brunelliaceae, Davidsoniaceae, and Eucryphiaceae) are so poorly known embryologically that an adequate comparison with Anisophylleaceae on this basis is not possible at present.

As discussed above, Anisophylleaceae differ strongly from Rosales sensu stricto and Saxifragales in their very different combinations of embryological features. Once more, we emphasize that Anisophylleaceae, on the basis of their embryological features, most closely resemble Myrtales (see Tobe & Raven, 1987a), although Anisophylleaceae do not share the characteristic wood anatomical features of Myrtales (i.e., intraxylary phloem and vestured pitting; see van Vliet & Baas, 1984). Myrtales are generally considered to be allied to Rosales(–Saxifragales–Cunoniales) (e.g., Takhtajan, 1980; Cronquist, 1981; Dahlgren & Thorne, 1984). Compared with Rosales sensu stricto and with Saxifragales, Anisophylleaceae and Myrtales apparently share at least one apomorphy, namely, the lack of endosperm in mature seeds. In contrast, Rosales sensu stricto and Saxifragales are apparently more specialized than Anisophylleaceae and Myrtales in other embryological characteristics. For example, in Rosales sensu stricto the inner integument is thicker than the outer one, a feature found only in derived families (Boesewinkel, 1981); and Saxifragales have a Cellular- or Helobial-type endosperm formation, which predominantly occurs in sympetalous groups with a tenuinucellate ovule (Dahlgren, 1975). Therefore, even though the floral morphology of Anisophylleaceae closely resembles that of Rosales sensu stricto(–Saxifragales) (Dahlgren, this volume; see also Cronquist, 1981, 1983), Anisophylleaceae seem, on the basis of their embryological features, to represent a different evolutionary line.

In conclusion, we need further information on the embryology of Rosales sensu stricto and particularly of Cunoniales for more critical comparison. Meanwhile, however, considering evidence of various kinds, it seems appropriate to conclude that Anisophylleaceae, like Myrtales, are one of the derivatives from the common ancestor of Rosales–Saxifragales–Cunoniales. Anisophylleaceae may or may not be directly related to Myrtales, but they do appear to be at approximately the same evolutionary level as that order, at least with respect to embryological features. It might be most appropriate, at least for the time being, to regard Anisophylleaceae as constituting a distinct order in this general phylogenetic lineage.

NEW SPECIES AND A NEW COMBINATION FOR PLANTS FROM TRANS-ANDEAN SOUTH AMERICA[1]

Alwyn H. Gentry[2]

ABSTRACT

Eight new species from the trans-Andean parts of Colombia, Ecuador, and Peru are described, each in a different family. The new species are: Bonamia leonii *(Convolvulaceae)*, Prockia pentamera *(Flacourtiaceae)*, Marila parviflora *(Guttiferae)*, Lozania glabrata *(Lacistemataceae)*, Rouchera monsalveae *(Linaceae)*, Carapa megistocarpa *(Meliaceae)*, Desmoncus cirrhifera *(Palmae)*, *and* Allophylus dodsonii *(Sapindaceae). In addition, a new combination for* Albizia paucipinnata—Pithecellobium paucipinnatum—*is proposed.*

In the course of preparing local florulas in western Colombia (*A Checklist of Plants of Chocó Department, Colombia* (Forero & Gentry, in press), *Flora de Bajo Calima* (Gentry & Monsalve, in prep.), and Ecuador (*Flora of Capeira* (Dodson & Gentry, in press), *Flora of the Río Palenque Science Center*, Revised edition (Dodson & Gentry, in prep.)) we have encountered the following eight novelties, each in a different family. In addition, a new combination is needed for one of the species included in the Capeira florula.

CONVOLVULACEAE

Bonamia leonii A. Gentry & Austin, sp. nov. TYPE. Colombia. Chocó: Municipio de Riosucio, Parque Natural Nacional "Los Katyos," Camino Tilupo Alto via Sautatá, desviando por el camino a Tilupo Salto parte baja, 250–100 m, bejuco, flor lila, 25 Feb. 1976, *H. León 525* (holotype, COL; isotype, MO).

Frutex scandens, ramulis tomentosis. Folia ovata, acuminata, dense tomentosa. Cyma densa, axillaris, pedunculo 1–3 cm longo. Sepala 6–7 mm longa, extima elliptica, obtusa, puberula; corolla infundibuliformis, ca. 1.5 cm longa, extra pilosa. Fructus ignotus.

Liana, the stems densely tannish-tomentose, becoming partially glabrescent. Leaves ovate, sharply acuminate, rounded at base, 8–15 cm long, 3–6.5 cm wide; densely tomentose with golden tannish trichomes, these forming a slightly thickened base, erect with curving tips, appearing macroscopically ± sericeous; petiole 0.3–2 cm long, tomentose. Inflorescence a compound axillary cyme, rather dense, ca. 3 cm across, the peduncle 1–3 cm long; bracts and bracteoles narrowly oblanceolate, tannish tomentose, to ca. 8 mm long. Flowers with the sepals 6–7 mm long, subequal (outermost somewhat longer), the outermost elliptic with obtuse tips, the inner sepals ovate with ± acute tips, appressed puberulous; corolla (only 1 seen) infundibuliform, lilac, ca. 1.5 cm long, pilose outside, slightly lobed, the lobes ca. 2 mm long; stamens 5, the anthers 2–2.5 mm long, on slender glabrous 3–4 mm long filaments; styles 2, free to near base, glabrous, the stigmas biglobose. Fruit not seen.

Known only from Parque Natural Nacional "Los Katyos" in northern Chocó Department of Colombia.

This plant was originally identified tentatively as *Tetralocularia pennellii* O'Donell; however, it does

ANN. MISSOURI BOT. GARD. 75: 1429–1439. 1988.

not closely resemble that monotypic genus and clearly belongs to *Bonamia*. In Myint & Ward's key to *Bonamia* (Phytologia 17: 121–239. 1968) this new species will key out with three species that they recognize from Southeastern Brazil—*B. agrostopolis* (Vell.) Hall. f., *B. burchellii* (Choisy) Hall. f., and *B. tomentosa* Hassler. All of these have the upper leaf surface densely pubescent and belong to sect. *Trichantha*. Recently, Austin & Staples (unpubl.) examined the types of these Brazilian names and concluded that they represent a single variable species that should be known as *B. agrostopolis*. This Brazilian species differs from *B. leonii* in having slightly smaller leaves; scalelike, linear, caducous bracts only 2–3 mm long rather than oblanceolate, persistent bracts ca. 8 mm long; corolla 2–3 cm long vs. 1.5 cm long; villous lower filaments; and a reniform to sub-bilobed rather than biglobose stigma.

Bonamia leonii appears to be most closely related to *B. trichantha* H. Hallier of northwestern South America and Mesoamerica and to *B. apurensis* Austin of Amazonian Venezuela. Although *B. trichantha* and *B. leonii* overlap geographically, they appear to be ecologically separated, with *B. trichantha* usually found in drier, more seasonal habitats. *Bonamia trichantha* differs further in having white flowers, more glabrescent leaves with glabrous or very sparsely puberulous upper surfaces, and densely glandular pubescent rather than glabrous filament bases.

Allopatric *B. apurensis* is the only *Bonamia* described (*Flora de Venezuela* 8(3): 40. 1982) since Myint & Ward's monograph. That species differs from *B. leonii* in the more broadly ovate leaf shape, cordate base, obtuse apex, more glabrescent upper leaf surface, simple capitate stigma, and especially the larger, more openly corymbose inflorescence with elongate peduncles (12–14 cm long in the MO isotype vs. 1–3 cm long in *B. leonii*).

It is a pleasure to dedicate this distinctive species to its collector, Henry Léon, who made extensive collections in the Katíos Park area of northern Chocó Department, where it is apparently endemic.

FLACOURTIACEAE

Prockia pentamera A. Gentry, sp. nov. TYPE. Peru. Tumbes: Prov. Contralmirante Villar, Huasimo, Quebrada Ucumares, 550 m, 12 Feb. 1976, *T. Plowman 5443* (holotype, USM; isotype, GH, photocopy MO).

Arbor parva. Folia late ovata, acuta vel breviter acuminata, ad basim truncata vel cordata. Flores 2–2.8 cm diametro, sepalis 5, ovatis, ca. 10 mm longis, petalis 5, dense tomentosis, stigmate 5-lobato.

Small tree 5–6 m tall, the bark rough, dark brown, the branchlets appressed puberulous when very young, soon glabrescent except at nodes, lenticellate, the stipules tiny and apparently (only one seen) very early caducous, linear, less than 1 mm long, with a pair of thick yellow glands in lower half. Leaves ovate to broadly ovate, acute to short-acuminate, the base truncate to broadly and shallowly cordate, with 2–4 basal glands at petiole insertion above, membranaceous, glabrous above except for small appressed trichomes on midvein, below rather sparsely hirtellous to glabrous over surface, persistently pubescent at least in and above axils of lateral nerves, serrate, 2.5–15 cm long, 1.3–12 cm wide, 5-nerved from base; petiole 0.5–3.5 cm long, pubescent with appressed or erect trichomes. Inflorescence of 2–3 flowers at end of lateral branches, the slender peduncle ca. 5 cm long, the pedicels 0.5–1 cm long, puberulous with mostly subappressed trichomes. Flowers green when fresh, the sepals five, densely grayish tomentose, ca. 10 mm long, 3–8 mm wide; the petals 5, narrowly oblong, acute, rather densely tomentose, about as long as sepals; stamens inserted on receptacle, the filaments glabrous; ovary subglobose, glabrous, the style ca. 4 mm long, the stigma distinctly 5-lobed. Fruit not seen.

Endemic to the now mostly destroyed dry forest of southwestern Ecuador and extreme northwestern Peru.

Additional specimens examined. ECUADOR: GUAYAS: Capeira, km 21, Guayaquil to Daule, 20–200 m, tropical dry forest, 17 Feb. 1982 (st), *Dodson & Gentry 12588* (GUA, MO, SEL). PERU. TUMBES: Cerros de Amotape 15–25 km SE of Cherrelique, 600–800m, premontane moist forest along Quebrada Los Conejos, 4°9'S, 80°37'W, 9 June 1987 (st), *Gentry & Díaz 58225* (MO, USM); Cerros de Amotape, Quebrada Los Conejos ca. 25 km SE of Cherrelique, 820 m, premontane moist forest, 4°9'S, 80°37'W, 9 June 1987 (st), *Gentry & Díaz 58245* (MO, USM).

Prockia pentamera, only the third species of *Prockia*, is very distinct from its closest relative, *P. crucis* L. *Prockia crucis* (fide Sleumer, 1980) is extremely polymorphic but always has smaller flowers (8–14 mm in diameter, with sepals and petals 4–7 mm long) with 3 (rarely 4) sepals, 3 petals (sometimes none by abortion), and a 3-lobed stigma, whereas all these parts are in 5s in *P. pentamera*. *Prockia pentamera* is the only pentamerous species of *Prockia*, necessitating changes in Sleumer's (1980) generic circumscription. Further, the leaves of *P. pentamera* are generally larger than in *P. crucis*, although only the largest exceed the largest extremes (to 10(–15) × 5(–10) cm) of the latter species. In *P. crucis*, the stipule is rather foliaceous, 5–8(–17) mm long, and persistent, unlike the minute (less than 1 mm long), early caducous stipule of *P. pentamera*.

This species was first collected as a sterile transect voucher at Capeira, near Guayaquil. During fieldwork for the *Florula of Capeira* (Dodson & Gentry, in press), we were unable to discover it in fertile condition despite repeated visits to the single tree. I tried comparing this sterile material in several herbaria with *Prockia* and related genera of Flacourtiaceae (as well as with *Morus* to which it has a superficial resemblance), but was unable to match it and decided that it must be undescribed.

When first found, there were numerous seedlings under the single capeira tree, but in 1985 both tree and seedlings were burned in one of the fires that devastate the remnants of dry forest in coastal Ecuador during the dry season. It seemed possible that an undescribed species had gone extinct. However, in the Universidad de San Marcos herbarium (USM) in Lima, I came across the fertile Plowman collection, which is here designated the type of *P. pentamera*.

Subsequent fieldwork in Tumbes, Peru, shows that *P. pentamera* can be locally very common in dry forest remnants. Indeed, it turns out to be the tenth-commonest species in a study site in the Cerros de Amotape, where there were eight individual plants of this species at least 2.5 cm dbh in a 0.1-ha sample; the largest tree measured 17 cm dbh (Díaz & Gentry, in prep.).

GUTTIFERAE

Marila parviflora A. Gentry, sp. nov. TYPE. Colombia. Valle: Bajo Calima, ca. 10 km N of Buenaventura, Cartón de Colombia concession, transition between tropical wet and pluvial forest, ca. 50 m, 3°56′N, 77°08′W, *H. Mazuero 47* (holotype, CUVC; isotype, MO, fragment and photocopy, IBE). Figure 1.

Arbor. Folia oblongo-ovata, acuta vel breviter acuminata. Inflorescentia spicato-racemosa, 9–13 cm longa, pedicellis 1–2(–3) mm longis. Flores 2 mm longi, petalis 2 mm longis, caducis, staminibus numerosis, ovario glabro.

Tree. Leaves simple, opposite, rigid-coriaceous, oblong-ovate, acute to short-acuminate at apex, obtuse at base, 14–19 cm long, 6–10 cm wide, drying dark gray-brown above, tan below, densely appressed-puberulous below on main veins, sparsely and ± glabrescently so over surface, the secondary nerves almost at right angle to midvein, 23–25 on a side, 4–8 mm apart, anastomosing with a strong submarginal collection vein; petiole 1.5–2.5 cm long. Inflorescences spicate-racemose, usually 3 per axil, the slender rachis 9–13 cm long, ca. 1 mm diam., puberulous with suberect trichomes, the pedicels 1–2(–3) mm long. Flowers tiny for the genus, 2 mm long, the sepals subappressed puberulous, 2 mm long; petals caducous, thinly membranaceous, strap-shaped, 2 mm long; stamens many, free, about as long as sepals, the minute anthers subglobose with the connective thick and patelliform-glandular; pistil ca. 2.5 cm long, the ovary ovoid, glabrous, the style linear, the stigma truncate, subcapitate.

Known only from the type locality, which appears to be in an area of high species richness for the genus. Cuatrecasas (1949) described five new species and a new variety of *Marila* from the central Pacific coastal region of Colombia. Two of these, *M. micrantha* and *M. geminata*, are closely related to *M. parviflora* by their very small flowers; indeed, *M. parviflora* and *M. micrantha* have the smallest flowers in the genus. Unique among described species of *Marila* is the almost spicate inflorescence of *M. parviflora*. *Marila parviflora* differs from *M. micrantha*, presumably its closest relative, by having shorter pedicels (1–2 mm vs. 3–6 mm long) and consequently spiciform inflorescence, inflorescences several per node (rather than solitary), larger, obtuse-based leaves with over twice as many straight (rather than arcuate-ascending) lateral veins, and subcapitate stigma. The other close relative of *M. parviflora* is *M. geminata*, which has similar multiple inflorescences at each node but distinctly larger flowers (sepals 3.5–4 mm long) and longer pedicels (4–7 mm long). The leaves of *M. geminata* differ in being larger and having acute bases and longer petioles and especially in the lateral nerves averaging almost twice as far (8–10 mm) apart.

An undescribed species of *Marila* from Amazonian Peru has a similarly spicate inflorescence but is amply distinct from *M. parviflora* (McDaniel, pers. comm.).

LACISTEMATACEAE

Lozania glabrata A. Gentry, sp. nov. TYPE. Colombia. Chocó: north ridge of Alto de Buey above Dos Bocas del Río Mutatá, tributary of

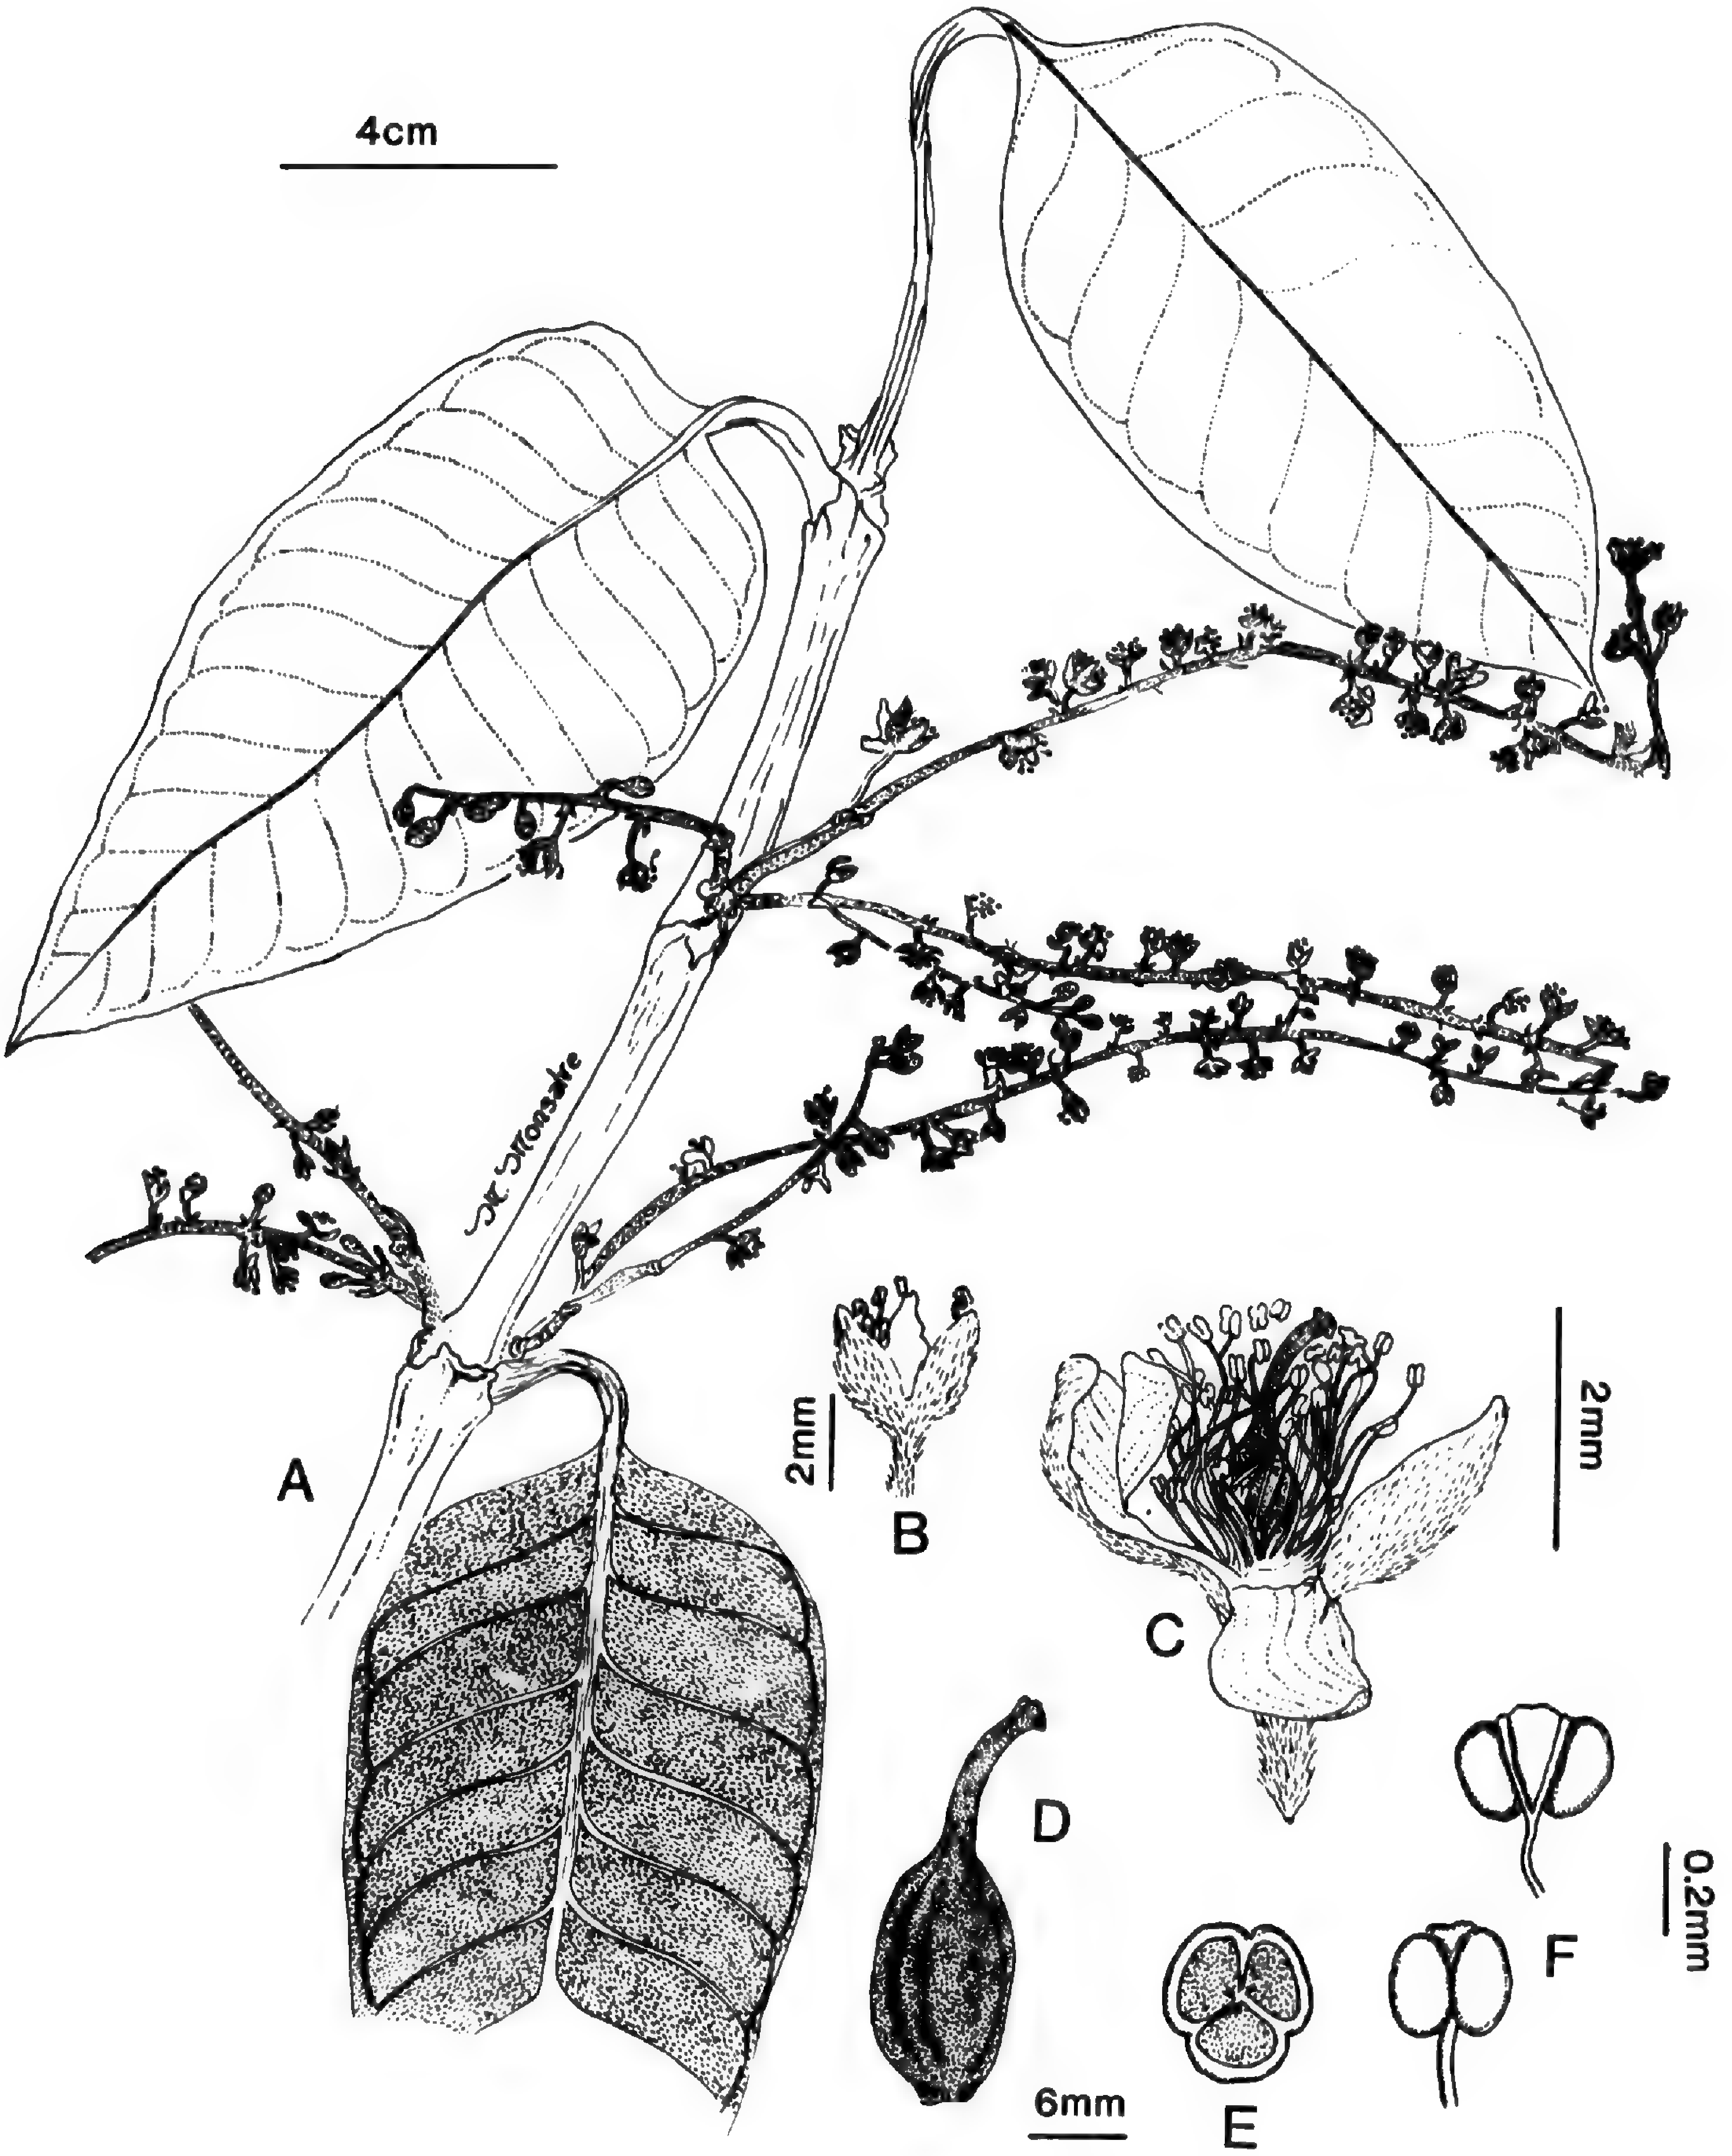

FIGURE 1. Marila parviflora (Mazuero 47).—*A. Habit.—B. Post-anthesis flower with petals fallen.—C. Open flower.—D. Pistil.—E. Ovary, cross section.—F. Anthers.*

Río El Valle, ESE of El Valle, 200–500 m, tropical and premontane wet forest, 8 Aug. 1976, *Gentry & Fallen 17425* (holotype, COL; isotype, F, MO, NY, U, UTD).

Arbor, ramuli glabri. Folia oblongo-elliptica, acuminata, glabra, subintegra. Inflorescentia axillaris, peranguste racemosa, 6–10 cm longa. Flores marronini, sepalis 4, ovatis, filo singulari furcato. Fructus ellipsoideo-trigonus, dehiscens, semine singulari.

Tree 6 m tall. Branchlets glabrous. Leaves oblong-elliptic, acuminate, cuneate at base, membranaceous, completely glabrous above and below, subentire to very inconspicuously serrulate, 9–16 cm long, 3.5–5 cm wide, the tertiary veins perpendicular to the midvein and ± parallel (but not as strikingly so as in other *Lozania* species); petiole 0.7–1.2 cm long, grooved above, glabrous or very inconspicuously puberulous with a few minute scattered trichomes. Inflorescence a long, slender, subspicate, axillary raceme, mostly in fascicles of several per node, 6–10 cm long, sparsely puberulous, the adjacent flowers separated by ca. 5 mm, the pedicels glabrous, ca. 1 mm long, subtended by a bilobed cupule formed by two 0.3-mm-long, sessile, basal bracteoles. Flowers with the sepals 4, ovate, spreading, ca. 1 mm long, maroon when fresh, drying dark brown with a brown-flecked cartilaginous apex and margin; petals absent; stamen 1, the short thick filament ca. 0.3 mm long, deeply forked apically, each side with a subglobose anther ca. 0.3 mm long, the ovary broadly ovoid, ca. 0.5 mm long, glabrous, the blunt apex with 3 slender, reflexed style branches ca. 0.2 mm long; ovary and stamen surrounded by a thick extra-staminal ± 4-lobed disk 1 mm across. Fruit irregularly ellipsoid-trigonous, 6–7 mm long and 4–6 mm wide, splitting incompletely at apex into 3 valves, with a single round orangish 5-mm-long and 4–5-mm-wide seed.

This is easily the most distinctive species of *Lozania*, a small genus traditionally assigned to Lacistemataceae but placed by Sleumer (1980) in Flacourtiaceae. It is closest to *L. mutisiana* J. A. Schultes on account of its very short filament and glabrous pedicels and sepals, although the relatively large fruit is closer to that of Amazonian *L. klugii* (Mansfeld) Mansfeld. *Lozania glabrata* is the only species of *Lozania* with glabrous leaves; the subentire leaf margin is also unusual, being approached only by occasional variants of *L. klugii*. The longest inflorescences are the longest in the genus, although shorter inflorescences are equalled by those of the type specimen of *L. bipinnata* L. B. Smith (a species merged into *L. mutisiana* by Sleumer but perhaps better maintained as distinct). *Lozania glabrata* is unique in the genus in the deeply split filament apex, which gives the illusion of two stamens.

LINACEAE

Rouchera monsalveae A. Gentry, sp. nov. TYPE: Colombia. Valle: Bajo Calima, Pulpapel concession, 100 m, bosque pluvial tropical, 3°55′N, 77°W, 14 Dec. 1984, *M. Monsalve 631* (holotype, CUVC; isotypes, MO, and to be distributed).

Arbor. Folia obovata, obtuse cuspidata vel acuminata, ad basim cuneata, margine subtiliter crenulata. Inflorescentia axillaris, fasciculata vel perbreviter racemosa. Flores lutei, petalis glabris, filis 10, ad basim connatis. Fructus ignotus.

Tree 6(–30?) m tall, mostly glabrous, inconspicuously puberulous on young branches, elenticellate, the stipules tiny, 1 mm long, caducous. Leaves alternate, obovate, oblanceolate when young, 2–8 cm long (–15 cm in juvenile state), 1–3.5 cm wide, obtusely cuspidate to acuminate at apex, the base cuneate, the margin finely and conspicuously crenulate, chartaceous to subcoriaceous, drying dark gray or olive gray above, tannish olive below, the secondary and intersecondary veins indistinguishable, close together, finely parallel, with an inconspicuous collecting vein ca. 0.5 mm from the margin, minutely glandular-punctate below, also with somewhat larger scattered disk-shaped glands, subsessile, the poorly defined petiole 1–3 mm long. Inflorescence a sessile or subsessile axillary fascicle of few flowers, sometimes extended as a contracted raceme or spike to 10 mm long with 2–3(–5)-mm-long peduncle, the flowers subtended by bracteoles 1–2 mm long, these glabrous except the ± ciliate margin. Flowers yellow; sepals 5, oblong, 2–3 mm long, glabrous except for the ± ciliate margin; petals narrowly obovate, contracted at base, to 5 mm long, completely glabrous; stamens 10, the filaments ca. 3 mm long, fused into a ca. 0.5-mm-long basal tube, the anthers flattened-globose, ca. 0.6 mm long; pistil glabrous, the ovary ovoid, ca. 1 mm long, the 3 styles separate, each with a discoid stigma. Fruits unknown.

Known only from Bajo Calima.

Additional specimen examined. COLOMBIA. VALLE: Bajo Calima, ca. 10 km N of Buenaventura, ca. 50 m, 3°56′N, 77°08′W, 13 Dec. 1981, *Gentry 35624* (CUVC, MO).

Common name. Juana se va.

The genus *Rouchera* has been used in a broad sense to include Asian and African lianas with hooked processes for climbing and in a narrow sense to exclude *Hebepetalum*, which differs in having hairy petals with a clawed base. *Rouchera* sensu stricto and *Hebepetalum* (now mostly included in *Rouchera*) are South American. This new species is most closely related to *R. calophylla* Planch., the type of the genus, and to *R. parviflora* (Ducke) Ducke. These are the only other species with reduced inflorescences and sessile or subsessile axillary flowers. *Rouchera calophylla*, which occurs in central and eastern Amazonia, differs in having more membranaceous narrower, narrowly oblong-elliptic leaves with less conspicuously crenate margins, better-defined petioles, and much longer (to 1 cm) petals. *Rouchera parviflora,* which occurs near Manaus in central Amazonian Brazil, has leaves similar to *R. calophylla* but smaller. According to the original description, it differs from *R. monsalveae* by its suborbicular, distinctly gland-margined sepals, completely glabrous young branches, and apparently larger flowers ("floribus dimidio brevioribus" compared with *R. calophyllum*). Although I have seen no material of *R. parvifolia* and the description is incomplete, its habitat (wet forest on sand) and distribution strongly argue against conspecificity with the coastal Colombian plant.

Only two other species of *Rouchera* are known from coastal Colombia. One is the very different *R. humiriifolia* (sometimes segregated as *Hebepetalum*), which has terminal paniculate inflorescences and white flowers with hairy petals. In view of the controversy over generic limits, it is interesting that at Bajo Calima *R. humiriifolia* bears the same common name as *R. monsalveae.* The second coastal Colombian species, *R. colombiana* Hall., differs according to the original description by its chartaceous leaves, petioles 6–8 mm long, collecting vein 2 mm from the leaf margin, flowers in a lax short-pedunculate axillary cyme, and especially by the conspicuous persistent stipule 5 mm long.

MELIACEAE

Carapa megistocarpa A. Gentry & Dodson, sp. nov. TYPE. Ecuador. Pichincha: Centinela, km 12 carretera Patricia Pilar–24 de Mayo, cima de las Montañas de Ila, 650 m, 26 July 1984 (fl, fr), *Dodson, Gentry, Palacios & Zaruma 14492* (holotype, MO; isotypes, MO, QCNE). Figure 2.

Arbor 15–20 m. Folia foliolis 7–multi-jugatis, oblongis, apiculatis vel acuminatis, ad basim rotundatis. Inflorescentia cauliflora, 27–50 cm longa, anguste paniculata. Flores calyce 4-lobato, staminorum tubo cylindrico. Fructus permagnus, ellipsoideus, apiculatus, 17–29 cm longus.

Slender unbranched or few-branched tree 15–20 m tall, to 20 cm diam., the branch apices conspicuously bracteate. Leaves with 7 or more leaflet pairs, the petiole and rachis woody, glabrous, finely longitudinally ridged, the leaflets oblong, apiculate to abruptly acuminate at apex, rounded at base, 17–55 cm long, 8–16 cm wide, coriaceous, completely glabrous. Inflorescence cauliflorous, borne usually several together from short shoots on main trunk, 27–50 cm long, irregularly scaly, otherwise glabrous, very narrowly paniculate, the longest (basal) side branches occasionally to 8 cm long. Flowers slender-pedicellate, white with greenish petals and yellowish nectary, functionally unisexual, the calyx 4-lobed to base, the lobes less than 1 mm long, the petals 4, broadly ovate, 4–5 mm long, glabrous, not ciliate, the staminal tube broadly cylindric, not urceolate, 4–5 mm long, apically split into 8 narrowly triangular acute or acutish lobes, the sessile anthers (or antherodes) alternating with lobes of staminal column, the pistil (or pistillode in male flowers) with a conspicuously discoid style-head, the nectary annular-pulvinate, yellowish when fresh. Fruit very large, ellipsoid, not at all tetragonal nor angled and lacking verrucose ridges, 17–29(–30?) cm long without the 1–3 cm-long apiculus, 13–16 cm diam., the surface uniformly brownish, even when young, covered with dense scalelike papillae.

Additional specimens examined. ECUADOR: LOS RIOS: km 12 road from Patricia Pilar to 24 de Mayo, 540 m, 7 Oct. 1976 (fl), *Dodson & Gentry 6593* (MO, SEL). PICHINCHA: type locality, 30 Jul 1984 (fl), *Dodson, Gentry, Palacios, Zaruma 14676* (MO, QCNE).

Only two species were recognized in *Carapa* in the recent *Flora Neotropica Monograph* of Meliaceae (Pennington & Styles, 1981). One of these, *C. procera* DC., occurs in the Guianas and Central Amazonia, and in Africa; the other, very heterogeneous *C. guianensis* Aubl., is widespread in the Neotropics. One collection of the new species (*Dodson & Gentry 6593*) was cited under *C. guianensis,* although the description of *C. guianensis* disagrees with the plant described above in numerous characters.

Typical *C. guianensis* and *C. megistocarpa* grow sympatrically in our study area in western Ecuador, and we are convinced that they cannot possibly be conspecific. At least in our study area, *Carapa guianensis* is large, freely branching, ramiflorous (never cauliflorous), and lacks conspicuous bracts at the branch apices. Its flowers (Fig. 2) have a subtle but characteristically different, distinctively more urceolate shape, with the apices of the otherwise fused filaments bent inward and more truncate and more closely appressed than in *C. megistocarpa.* The staminal tube of our population of *C. guianensis* has orange suture lines and the nectary is orange, whereas in *C. megistocarpa* the staminal tube is uniformly white and the nectary is yellowish. Moreover, the fruits of the two species are consistently and dramatically different, as indicated in Table 1. This whole suite of consistent differentiating characters (Table 1, Fig. 2) in two

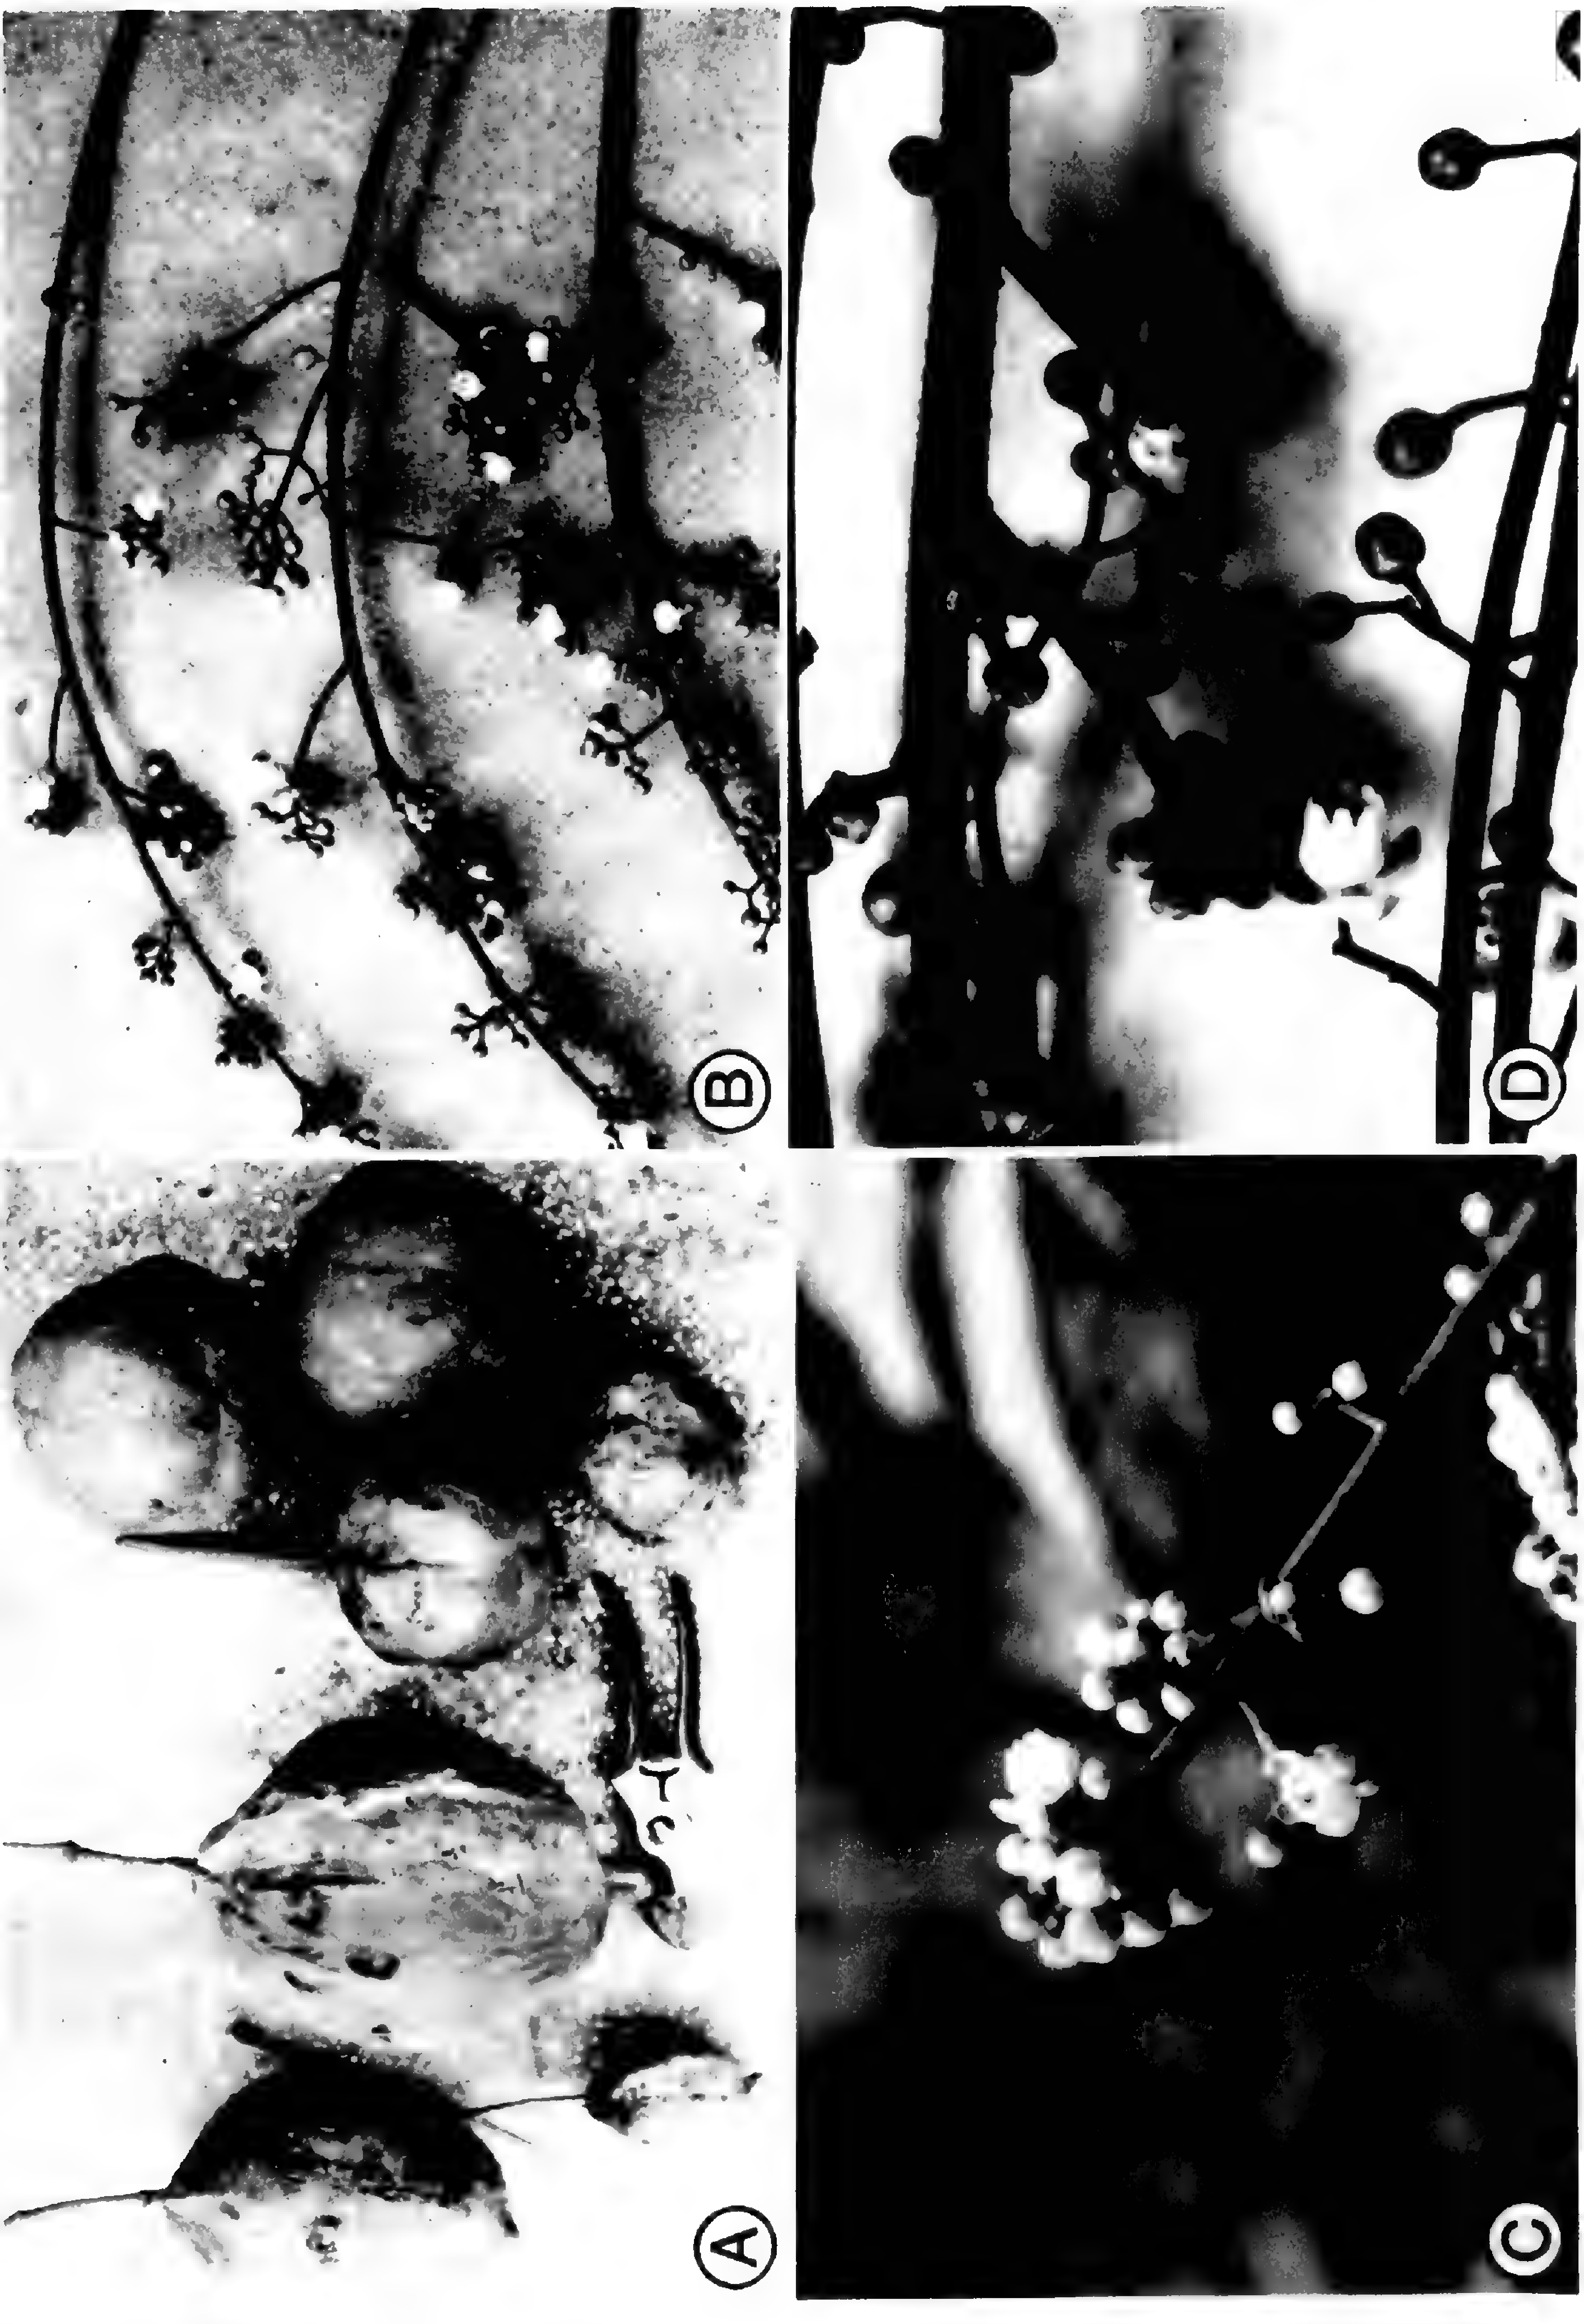

FIGURE 2. Carapa megistocarpa (Dodson et al. 14492) *and* C. guianensis (Dodson et al. 14675).—*A. Fruits (*C. megistocarpa *on left,* C. guianensis *on right; the shears are 20 cm long).—**B. Flowering inflorescences** of* C. megistocarpa.—*C. Flowering inflorescence of* C. guianensis.—*D. Closeup comparison of flowers of* C. guianensis *(top) and* C. megistophylla *(bottom).*

TABLE 1. *Features differentiating* Carapa megistocarpa *from* C. guianensis *at the Centinela study site.*

	C. guianensis	*C. megistocarpa*
Height	mostly 20–40 m	15–20 m
Habit	freely branching	unbranched or few-branched
Bracts at branch apices	lacking or inconspicuous	conspicuous
Inflorescence	ramiflorous on small branchlets	cauliflorous
Corolla	strongly urceolate	urceolate-tubular
Filament apices	truncate, bent strongly inward and closely appressed to adjacent apices	narrow, bent slightly inward and barely or not at all touching
Staminal tube	orange suture lines	uniformly white
Nectary	orange	yellowish
Fruit shape	subglobose to depressed-globose and slightly tetragonal	ellipsoid, not at all tetragonal
Fruit surface	greenish with numerous brown lenticels when young, each valve usually with a verrucose medial ridge	uniformly brownish, even when young, the valves unridged
Fruit size	11–14 cm long and wide[1]	17–30 cm long, 13–16 cm diameter
Fruit apex	truncate or depressed	apiculate (apicule 1–3 cm long)

[1] 5–10(–12) × 6–8(–10) cm fide Styles (in Pennington & Styles, 1981).

sympatric populations clearly mandates specific recognition. Although B. Styles (pers. comm.) maintains that the characters noted above and in Table 1 are variable elsewhere in the range of *Carapa*, they are quite constant in western Ecuador, where *C. megistocarpa* and *C. guianensis* clearly pass the test of sympatry.

In some characteristics *C. megistocarpa* is closer to *C. procera* than to *C. guianensis*, e.g., consistently slender-pedicellate flowers and ellipsoid fruit with valves lacking medial excrescences, but the 4- rather than 5-parted symmetry of its flowers and fruits seemed to relate *C. megistocarpa* definitively to *C. guianensis*. The fruit is the largest in the genus, the minimum length and width both always exceeding the maximum dimensions given for either species in the *Flora Neotropica* monograph, hence the epithet "megistocarpa."

Carapa megistocarpa was the fourth-commonest species in the Centinela forest, with 18 plants at least 2.5 cm dbh in a 1,000-m^2 sample area. Its amazing football-like cauliflorous fruits were one of the most characteristic features of this forest, famous for its high local endemism (Gentry, 1986; Dodson & Gentry, in prep.). Sadly, it may now be extinct, since the last remnants of the Centinela ridgetop have been converted to banana plantations.

PALMAE

Desmoncus cirrhifera Gentry & Zardini, sp. nov. TYPE. Colombia. Valle: Bahía Malaga, steep banks at edge of Mora swamp overlooking tidal stream, 0 m, 4°2′N, 76°15′W, 16 Dec. 1985, *A. Gentry, M. Monsalve, C. Restrepo and J. Gamboa 53392* (holotype, CUVC; isotypes, MO(2), COL, K). Figure 3.

Frutex scandens, sparse spinosus, spinis brevibus curvatis. Folia 25–60 cm longa, foliolis 5–9-jugatis, lanceolato-ellipticis, longicaudatis. Inflorescentia semel ramosa, 15–19 rachillis 1–3 cm longis. Fructus ellipsoideus vel subglobosus, 1.5–2 cm longus, 1–1.5 cm latus.

Spiny climbing palm (± erect when young) with stems (including the enclosing leaf sheath) 1–2 cm thick, the leaf sheath with occasional short thick-based spines < 4 mm long, these mostly ± recurved, glabrous except for small, appressed, irregularly branched reddish scales, extended above the node into an ocrea ca. 5 cm long, this unarmed or with an occasional small spine. Leaves 25–60 or more cm long, with 5–9 pairs of lanceolate-elliptic to narrowly elliptic, subopposite to definitely alternate, caudate-acuminate pinnae, these 6–21 cm long (not counting the acumen), 2–7 cm wide, the tendril-like linear acumen 4–11 cm long, pendent and often somewhat twisted when fresh, the surface glabrous except for minute scattered ± peltate scales, these mostly sessile and reddish, sometimes in part stalked, also with minute whitish scales or scalelike enations, the larger leaflets with somewhat larger, irregularly branching, appressed, reddish trichomes near margin below, the midvein prominent above and below, the other longitudinal veins relatively inconspicuous, the transverse veinlets slightly prominulous above in older leaflets; rachis with irregularly scattered thick-based straight or recurved spines 2–5 mm long; leaf apex linear and unarmed in juvenile state, in mature plants armed with small, strongly recurved spines 2.5–4 mm long, sometimes a few of these thicker and terminated with a reduced, very narrow, vestigial leaflet 4–6 cm long, this always thin and membranaceous; thick, elongate grappling hooks completely lacking at leaf apex. Inflorescence axillary, the peduncular inflorescence bract (spathe) caducous in fruit, the persistent basal part of the prophyll ca. 6–8 cm long, thin, unarmed, fibrous, fragmenting into the individual fibers; peduncle 11–14 cm long, the rachis once-branched with 15–19 rachillae, each 1–3 cm long, the lowermost progressively larger, the flowers not seen, loosely clustered along upper half to two-thirds of rachilla, this flattened and somewhat zigzag or twisted between adjacent flowers. Fruit 1-seeded, red, ellipsoid to subglobose, 1.5–2 cm long, 1–1.5 cm wide, subtended by a sessile 3-lobed cupule formed from the 3 persistent basally fused tepals, this ca. 5 mm across.

Endemic to the wet part of lowland coastal Colombia in Valle, Chocó, and (fide Galeano & Bernal, 1985) extreme northwestern Antioquia departments.

Additional specimens examined. COLOMBIA. VALLE: Bahía Malaga, Quebrada Alegria, trail along proposed route of new road to military base, 50 m, 4°2′N, 77°22′W, 15 Dec. 1985, *Gentry, Monsalve, Restrepo & Gamboa 53319* (CUVC, MO). CHOCÓ: Taparalito, Quebrada Taparal, N of Palestina, primary wet forest, 30 m, 4°15′N, 77°12′W, 30 Mar. 1985, *Gentry, Zardini, Monsalve & Caicedo 53795* (CUVC, MO); Quibdó–Tutunendó road ca. 3 km W of Tutunendó, pluvial forest, 80 m, 5°46′N, 76°35′W, 8 Jan. 1981, *Gentry, Mulampy, Hikes, Libenson, Olson & Cogollo 30363* (COL, MO).

Common name. Matamba.

The outstanding feature of the plant is its exceedingly long tendril-like leaflet apices. It belongs to Burret's (1934) section *Campylacanthium*, as indicated by its short curved spines, and it is the first record of that section in the trans-Andean Neotropics. John Dransfield, who examined a duplicate of one of the sterile collections cited above, identified it as a new species. Subsequently, this species was also recognized as undescribed by Gal-

FIGURE 3. Desmoncus cirrhifera.—*A. Leaf and infructescence (*Gentry et al. 53392*).—B. Cut stems waiting to be made into baskets, Taparalito, Chocó, Colombia (*Gentry et al. 53795*).—C. Basket made from* D. cirrhifera, *Docordó, Colombia.*

eano & Bernal (1985) in their treatment of the palms of Antioquia Department. Again, sterile material prevented its description. Discovery of fruiting material finally makes possible its description.

Desmoncus cirrhifera is one of the most utilized palm species of the Pacific coast region of Colombia. It is used to make nets and shrimp traps (catangas) in the Bahía Malaga and Río San Juan delta areas (sub *Gentry et al. 53392*) and is prized by the Chocó Indians at Taparalito and Docordó who make their strongest baskets from it (Fig. 3C).

SAPINDACEAE

Allophylus dodsonii A. Gentry, sp. nov. TYPE. Ecuador. Los Ríos: Río Palenque Field Station, halfway between Quevedo and Santo Domingo de los Colorados, wet forest, 200 m, 21 Feb. 1974. *Gentry 10098* (holotype, MO; isotype, QCA; additional duplicates distributed as *A.* cf. *amazonicus*).

Arbor. Folia unifoliolata, elliptica vel obovato-elliptica, ad apicem obtusa vel subacuta, ad basim cuneata, margine subintegro. Inflorescentia axillaris, paniculata, ramis floriferis anguste racemosis, ascendentibus. Flores minuti, petalis intra pubescentibus. Fructus ellipsoideus, ca. 1 cm longus.

Tree 15–20 m tall, the branchlets ± glabrescently puberulous with mostly appressed trichomes. Leaves unifoliolate, elliptic or obovate-elliptic, the apex obtuse to acutish, the base cuneate, 6–28 cm long, 3–12 cm wide, membranaceous, the margin entire or inconspicuously crenulate-serrate near apex, almost glabrous, very sparsely and inconspicuously puberulous along midvein above and below, sometimes with few trichomes in axils of lateral nerves, with 10–14 secondary veins on a side, these curved and ascending; petiole 1–2 cm long to petiolule insertion, ± appressed puberulous, at least adaxially, apically jointed with flexed petiolular leaflet base. Inflorescence axillary, paniculate, the usually 3 elongate branches ascending and narrowly racemose, puberulous. Flowers (seen only in female condition) small, ca. 1 mm long and 2 mm across at full anthesis, white, on pedicels 1–2 mm long, the very broadly ovate sepals appressed-puberulous, the petals strongly pubescent inside, slightly pubescent outside, usually also ciliate-margined; stamens ca. 1 mm long, the tiny anthers presumably nonfunctional; pistil almost 2 mm long, the style apically forked to form 2 exserted stigmas almost 0.5 mm long. Fruits broadly ellipsoid, ca. 1 cm long, essentially glabrous.

Known only from the remnant patch of coastal Ecuadorian lowland wet forest at the Río Palenque Field Station.

Additional specimens examined. ECUADOR. LOS RÍOS: Río Palenque Field Station, 16 Feb. 1974 (st), *Gentry 9957* (MO), 7 Oct. 1976 (st), *Dodson & Gentry 6587* (MO, SEL), without date (fl), *Dodson 7343* (MO, SEL), 4 Apr. 1980 (fr), *Dodson & Gentry 10176* (MO, SEL).

This species was treated as *Allophylus* cf. *amazonicus* (Mart.) Radlk. in the *Flora of Río Palenque* (Dodson & Gentry, 1978). However, it differs conspicuously from that Amazonian species in the larger fruits, sparsely appressed puberulous branchlets, entire or subentire leaves, and especially the 3-branched rather than simply racemose inflorescence.

This was one of very few species in the Río Palenque flora interpreted as having a trans-Andean range disjunction, i.e., occurring on both sides of the Andes but not reaching Central America. Thus it is perhaps not surprising that the additional collections now available from both sides of the Andes prove the coastal plant specifically distinct.

LEGUMINOSAE

Pithecellobium paucipinnatum (Schery) Gentry & Dodson, comb. nov. *Albizia paucipinnata* Schery, Ann. Missouri Bot. Gard. 37: 400. 1950. TYPE. Ecuador. El Oro: Portovelo, *Steyermark 54035* (MO) . . . . as "*Albizzia.*"

This is a common tree species of the dry forests of the Guayaquil area of southwest Ecuador, especially in juvenile condition. At Capeira, 20 km N of Guayaquil (Dodson & Gentry, in press), there are about 10 trees at least 2.5 cm dbh per ha in the remnant patch of now highly disturbed dry forest. Although previously unreported from that country, it also occurs in adjacent northwestern Peru. At Capeira its common name is "compoño"; in Peru it is called "angolo."

This species was described as an *Albizia* by Schery, in the absence of fruiting material, and related by him to *Pithecellobium multiflorum* (HBK.) Benth. and *P. coripatense* Rusby of what is now generally known as *Pithecellobium* section *Arthrosamanea* (sometimes segregated as the genus *Cathormion*). These species grow mostly in swampy or riverine habitats and are characterized by a flattened segmented fruit that breaks apart transversely into numerous lomentlike segments, presumably adapted for water dispersal.

Generic delimitation in Mimosoideae is notoriously difficult, and Schery considered section *Arthrosamanea* as related to mostly wind-dispersed *Albizia* rather than mostly animal-dispersed *Pithecellobium*. Sometimes these taxa are accorded generic rank as *Arthrosamanea* (Britton & Rose, 1936) or *Cathormion* (Burkart, 1964). Others

(Brenan & Brummitt, 1965) suggested merging these taxa with *Enterolobium* instead. However, in nearly all neotropical floristic treatments, the indehiscent-fruited species of this alliance are nowadays included in *Pithecellobium* sensu lato (Macbride, 1943; Woodson & Schery, 1950), following Bentham (1875). Although a more recent summary (Nielsen, 1981) returns these plants to *Albizia* (along with some other segregates of *Pithecellobium*), we prefer to retain the indehiscent-fruited non-wind dispersed relatives in *Pithecellobium* following Barbosa (1984 and pers. comm.) and the long-standing tradition.

Vegetatively the taxa of *Pithecellobium* section *Arthrosamanea* are characterized by oblong, sessile, asymmetric leaflets with strongly ascending, almost palmate venation. *Pithecellobium* section *Arthrosamanea* is represented in the Guayaquil area by *P. daulense* Spruce ex Benth., which is vegetatively strikingly similar to *P. paucipinnatum* but has more-elliptic leaflets that are glabrous rather than puberulous as in *P. paucipinnatum*. That species, like other bona fide members of section *Arthrosamanea*, occurs in swampy, poorly drained areas along the Río Daule at Capeira, while *P. paucipinnatum* occurs in the upland dry forest.

We were at first inclined to treat the upland plant at Capeira as a variant of *P. daulense*; however, a collection of its fruits (*Dodson & Gentry 12652*; MO, GUA, SEL) proves that it is only distantly related to *P. multiflorum* and its allies. Indeed, the indehiscent fruits are quite unlike those of any *Pithecellobium* known to us, although probably most closely related to the very different but similarly indehiscent fruits of *Pithecellobium saman*. Superficially, there is a surprising resemblance to the fruits of *Hymenaea*, especially in the texture, color, and composition of their resinous-secreting surface.

The fruits of *P. paucipinnatum* are 12–14 cm long, 1.7–2 cm wide, straight, somewhat compressed, subwoody, reddish brown, glabrous, and pitted on the surface with minute resinous glands. Although obviously indehiscent, these fruits are interesting in that they break transversely rather easily, potentially indicating a shared ancestor with section *Arthrosamanea*. Since the fruits of this species are completely unlike the thin wind-dispersed fruits of *Albizia*, transfer to *Pithecellobium* seems appropriate.

Additional specimens examined. ECUADOR. GUAYAS: Capeira, 22 km N of Guayaquil 2°S, 79°58′W, 20–150 m, *Gentry & Dodson 54812* (MO); same locality, *Dodson & Gentry 12652* (MO). MANABI: base of Montecristi, 180 m, *Dodson & Thien 1716* (MO). EL ORO: Río Amarillo upstream from Portovelo, *Steyermark 54035* (MO). PERU. TUMBES: Zarumilla, Dtto. Matapalo, 550 m, Camino Caucho–Campo Verde km 79, *I. Canales P. 15* (MO, MOL).

STUDIES IN NEOTROPICAL PALEOBOTANY. V. THE LOWER MIOCENE COMMUNITIES OF PANAMA— THE CULEBRA FORMATION[1]

Alan Graham[2]

Abstract

The lower Miocene Culebra Formation of central Panama consists of lignites and lignitic shales in a predominantly estuarian sandstone sequence. Forty-one palynomorphs have been identified from the lignites, and the following ten are most abundant: Monolete fern spore type 2 (20%), Manicaria*-type palm pollen (10%),* Cyathea *(8%),* Cryosophia*-type palm pollen (8%),* Selaginella *(7%),* Synechanthus*-type palm pollen (6%),* Rhizophora *(6%), monolete fern spore type 1 (5%),* Hampea/Hibiscus *(4%), and* Lycopodium *(2%). Ferns constituted 25% of the fossil flora, palms 24%, and lowland vegetation types totaled 71%. The most prominent paleocommunities were the tropical moist forest represented by 30 genera that can occur in this vegetation type (including an only moderately developed mangrove swamp), premontane wet forest (25 genera), tropical wet forest (22 genera), and possibly some form of the premontane moist forest (12 genera). Communities of higher elevations and dry to arid habitats (including savannahs) were poorly represented to absent. Paleoenvironments were similar to those of the present, including annual rainfall estimated at about 275–325 cm (107–128 inches). The rainfall probably decreased slightly with elevation, similar to the pattern shown in a transect from sea level to about 1,172 m from present-day Atlantic Costa Rica (353.6–188.9 cm). Annual temperature probably ranged between about 21°C and 32°C, as on adjacent Barro Colorado Island today. These estimates are consistent with the general paleotemperature curve derived from ^{18}O studies of marine invertebrates, and with emerging paleobotanical data from other Central America Tertiary floras. The geographic affinities of the Culebra flora are distinctly Central and North American, with all of the 41 taxa identified represented in the modern flora of Panama. Pollen of the Gramineae and shrubs of open, drier habitats continue to be rare or absent in Tertiary formations from southern Central America.*

The geologic formations of central Panama provide an opportunity to trace vegetational and paleoenvironmental history through five segments of Tertiary time. The Gatuncillo Formation exposed near Alcalde Díaz is of middle(?) to late Eocene age, and study of this paleoflora has been completed (Graham, 1985). The Culebra, Cucaracha, and La Boca formations are of lower Miocene age, and the Gatun Formation is upper Miocene/Pliocene in age (a recent estimate by Vokes, pers. comm., 1988, is that the Gatun Formation may be as young as middle Pliocene). All are known to contain fossil pollen and spores. These studies, together with those of Bartlett & Barghoorn (1973) on Quaternary vegetation, and information on the modern vegetation (Croat, 1978; D'Arcy, 1987; the recently completed *Flora of Panama*; and the Flora Mesoamericana project) will eventually provide a more complete data base for the vegetation of Panama and its Cenozoic evolution than for any other area in the Neotropics.

Concepts on the history of neotropical vegetation are being developed at a time when important new information is also becoming available on other aspects of the biotas. This allows comparison of the paleobotanical data with global paleotemperature and sea-level curves (Savin, 1977; Savin & Douglas, 1985; Savin et al., 1975; Vail & Hardenbol, 1979; Vail et al., 1977; Haq et al., 1987) and studies on marine invertebrates (Jones & Hasson, 1985) and terrestrial vertebrates (e.g., see papers in Stehli & Webb, 1985). This allows in-

ANN. MISSOURI BOT. GARD. 75: 1440–1466. 1988.

terpretation within an increasingly precise paleophysiographic context (Buskirk, 1985; Coney, 1982; Gose, 1985; Smith, 1985).

Other than a few megafossil studies done earlier in the century (see literature in Graham, 1973, 1979, 1982, 1986), the plant microfossils of the Culebra Formation provide only our second insight into lower Miocene vegetation of northern Latin America. The other is an assemblage from the lower Miocene Uscari sequence of Costa Rica (Graham, 1987a).

THE COLLECTING LOCALITY

The Culebra Formation belongs to a complex of lower Miocene strata in the Canal region of Panama (Graham et al., 1985: 489). Material was obtained from a well (Hole No. GH-9) drilled in January 1958 by the Panama Canal Commission. The site was near Gold Hill on the west side of the Canal at latitude 9°02′N, longitude 79°38′W. Fifty-seven samples were taken from lignites or lignitic shales along the 154-m core between levels 491.6 and 377, and 21 yielded pollen and spores. Eleven were selected for study from the following depths (in feet, following the original log data): 377, 407, 415.5, 425, 456, 469.8, 470.6, 488, 490.6, 491, and 491.6.

The 57 samples totaled approximately 9.5 feet of coalified lignite and lignitic shale (avg. ca. 2 inches/sample), with numerous narrow bands adding another ca. 1.5 feet (9.6%). The rest of the core was mostly sandstone (Graham et al., 1985: 489–491, tables 1, 2), and constituted ca. 103 feet (90.4%). Swift (1977) has studied Holocene sedimentation rates in the Panama Basin, but there have been no studies on the Culebra or other Tertiary formations. In general, near-shore sandstones and lignites deposited in an estuarian environment in tectonically active regions accumulate rapidly. In the absence of more precise data, the time span represented by the section is estimated at a few to several tens of thousands of years. Other details on the geology of the Culebra and related formations are given in Graham et al. (1985).

MATERIALS AND METHODS

Extraction and processing techniques are described in Graham (1985). Slides are labeled Pan Core, Culebra, with depth and slide number cited. Location of specimens on the slides is by England Slide Finder coordinates (e.g., ESF L-39, 1). All materials are deposited in the palynology collections at Kent State University.

SYSTEMATICS

Forty-one palynomorphs were identified from the Culebra Formation, and a number of others were recovered whose biological affinities could not be established. Some of the more distinctive and/or common ones are listed as Unknown types 1–14 in Table 1. Further details of the identification procedures are given in Graham (1985: 507–508).

LYCOPODIACEAE

Lycopodium (Figs. 1–3). Amb oval-triangular, apices rounded; trilete, laesurae straight, narrow, ca. 20 μm long, extending to and occasionally branching at spore margin, inner margin entire; distal surface with numerous circular punctae ca. 1 μm diam., proximal surface laevigate; wall ca. 1.5–2 μm thick; 35–37 μm.

These spores are similar to the modern *L. reflexum* Lam./*L. linifolium* L. type (cf. Tryon & Tryon, 1982: 811, fig. 22), presently growing in moist shaded habitats in Panama. Similar spores have been reported from the lower Miocene Uscari shale sequence in Costa Rica (Graham, 1987a).

SELAGINELLACEAE

Selaginella (Fig. 4). Spherical to nearly bilateral, amb circular to reniform; trilete, laesurae frequently obscured by wall thickness and sculpture elements, straight, narrow, ca. 20–22 μm long, extending nearly to spore margin, inner margin entire; echinate, echinae short (ca. 2 μm), occasionally curved, dense, bases broad; wall ca. 2 μm thick (excluding echinae); 26–30 μm.

Microspores of *Selaginella* vary in size, and specimens from the Culebra Formation are relatively small (26–30 μm) and thick-walled. They are common in the Gulf/Caribbean Tertiary and have been reported from all formations studied in the present project (Eocene Gatuncillo Formation of Panama, Graham, 1985; Oligocene San Sebastian Formation of Puerto Rico, Graham & Jarzen, 1969; lower Miocene Uscari sequence of Costa Rica, Graham, 1987a; lower Miocene Culebra Formation of Panama, present report; and upper Miocene Paraje Solo Formation of Veracruz, Mexico, Graham, 1976). *Selaginella* is widely distributed in tropical regions in shaded, humid habitats.

CYATHEACEAE

Cyathea (Figs. 7–9). Amb oval-triangular, apices rounded; trilete, laesurae straight, narrow, 14–16 μm long, extending to spore margin, inner

TABLE 1. *Identification and numerical representation of fossil palynomorphs from the lower Miocene Culebra Formation, Panama. Figures are percentages based on counts of 200, except levels 377–425, which are based on 100 due to lower concentration and only fair preservation of the specimens; these levels also contain high percentages of fungal spores.*

margin entire, bordered by lip 2–3 μm wide with punctae 1 μm diam.; distal surface finely punctate, proximal surface more laevigate near laesurae; wall 1.5–2 μm thick; 32–36 μm.

The classification of tree ferns differs among various authors, and reference slides with spores similar to the fossil specimens come from herbarium material labeled as *Alsophila* and *Cyathea*. As

10

noted by Tryon & Tryon (1982: 204), "The name *Cyathea* has been variously applied to genera of widely different scope and definition, sometimes including nearly all members of the family." In illustrations of spores of neotropical tree ferns (Gastony & Tryon, 1976; Tryon & Tryon, 1982: 207), the micropunctate forms are referred to *Cyathea.*

The genus consists of 40 species of the American tropics growing primarily in montane forests and cloud forests, and also in low rain forests in Central America, usually at 1,500–2,000 m, but as low as 500 m (Tryon & Tryon, 1982: 204–205). Fossil spores are common in Gulf/Caribbean Tertiary deposits.

PTERIDACEAE

Pteris (Fig. 10). Amb triangular, apices rounded; trilete, laesurae straight, narrow, 18–22 μm long, extending to spore margin, inner margin entire; distal surface with coarse, irregular verrucae, proximal surface more laevigate, flange ca. 5–6 μm wide, hyaline; wall 2 μm thick; 42–48 μm.

Pteris includes about 200 species, with approximately 55 occurring in the American tropics (Tryon & Tryon, 1982: 334). The plants typically grow in wet forests or in openings along stream banks at low elevations (sea level to 2,000 m). Fossil spores are frequent, but in low percentages in Gulf/Caribbean Tertiary deposits.

SCHIZAEACEAE

Lygodium (Figs. 5, 6, 11, 12, 17). Amb triangular to concavo-triangular, apices rounded; trilete, laesurae ± straight, narrow, 34–38 μm long, extending nearly to spore margin, apices frequently branched, inner margin entire; laevigate to faintly verrucate; wall 2–4 μm thick; 80–100 μm.

Lygodium is a genus of about 30 species, with six to eight in the American tropics. According to Tryon & Tryon (1982: 71): "*Lygodium* characteristically occurs in open forest especially along the borders where the climbing leaves can reach well-lighted situations. In tropical America, it sometimes grows in rain forests, but more commonly in gallery forests, shrubby savannahs or along the borders of streams or river banks. It most commonly occurs from sea level to about 350 m, as a characteristic element of the low, humid tropics, and less often grows up to 1,000 m."

The specimens are large (up to 100 μm in diameter) and somewhat diverse in morphology; more than one biological species may be represented. The most notable variation is in the dark coloration that can occur at the apices. This is not found in our modern reference material, but in the fossil specimens it ranges from absent (Figs. 5, 6) to quite prominent (Fig. 17). Spores of *Lygodium,* but of a different morphological type, have been reported from the upper part of the lower Miocene in northern South America (Germeraad et al., 1968) under the artificial generic name *Crassoretitriletes.* Spores similar to the Culebra specimens are also known under the name *Matonisporites* described by Couper (1958; see especially pl. 20, figs. 15, 16) from the Jurassic and Lower Cretaceous of England. Dettmann (1963, pl. 11, figs. 1, 2) emended the description to include the thickened apices and reported the genus from Lower Cretaceous deposits of southeastern Australia. She noted (p. 59) possible affinities with *Dicksonia* (*D. sellowiana* Hook., *D. antarctica* Labill.), but our modern reference material of these species, and others in the genus, is different (see illustrations in Tryon & Tryon, 1982: 148). Recently Jameossanaie (1987, fig. 10, #5) described similar spores (*Matonisporites*) from the Upper Cretaceous of New Mexico. The Culebra specimens are the first of the type illustrated in Figures 5, 6, 11, 12, and 17 for the Gulf/Caribbean region.

VITTARIACEAE

Cf. *Antrophyum* (Figs. 18, 20). Amb triangular, apices rounded; trilete, laesurae relatively small in relation to spore diameter, straight, narrow, 10–14 μm long, extending ca. ⅔ distance to spore margin, inner margin entire; laevigate; wall ca. 1.5 μm thick; 52–65 μm.

Approximately ten of the ca. 40 species of *Antrophyum* occur in the Neotropics from Hidalgo, Mexico, through Central America and the Antilles,

to northern Argentina and southeastern Brazil. The genus grows in rain forests and cloud forests, usually at elevations of 100–1,500 m. The specimens are laevigate, while modern spores often have a delicate sculpture ("echinate rods and surface strands," Tryon & Tryon, 1982: 360–361). Tryon & Tryon believe, however, that a perispore is present, and in fossil specimens this ornamental covering would not be preserved. Similar large, trilete, laevigate spores are known from the Eocene of Panama (Graham, 1985, figs. 13, 16) and the Miocene of Veracruz, Mexico (Graham, 1976, fig. 227).

OTHER TRILETE FERN SPORES

Several trilete fern spores were recovered for which biological affinities could not be determined. Four of the more distinctive ones are described below.

Type 1 (Fig. 13). Amb oval-triangular; trilete, laesurae straight, narrow, ca. 20 μm long, extending to spore margin, inner margin ± entire; finely reticulate to micropunctate (width of muri equals diameter of lumen, ca. 1 μm), sculpture less dense near laesurae; wall ca. 1.5 μm thick; 42 μm.

Type 2 (Fig. 14). Amb oval-triangular to ± circular; trilete, laesurae straight, narrow, 20–22 μm long, extending ca. ⅔ distance to spore margin, inner margin entire; finely reticulate; wall 1.5 μm thick; 45–55 μm.

Type 3 (Figs. 15, 16). Amb oval-triangular to wedge-shaped, apices rounded; trilete, laesurae straight, narrow, 22–26 μm long, extending to spore margin, inner margin entire; punctate, punctae circular (ca. 1 μm) to elongated (2–4 μm) and slitlike and sinuous; wall 2 μm thick; 42 × 36 μm (slightly compressed).

Type 4 (Fig. 19). Amb irregular, ± oval-triangular, apices rounded; trilete, laesurae straight, narrow, 34–36 μm long, extending to spore margin, inner margin entire, conspicuous lip 12 μm wide (maximum, conspicuousness augmented by folds?); low, moundlike verrucae ca. 2–3 μm diam.; wall ca. 3 μm thick; 72 × 64 μm (compressed).

MARATTIACEAE

Danaea (Fig. 21). Amb circular to ± reniform; monolete, laesurae straight, narrow, 18–20 μm long, extending nearly to spore margin, inner margin entire; echinate, echinae ca. 2 μm long, relatively dense; wall 1 μm thick; 28–32 μm (excluding spines).

Danaea is a neotropical genus of about 20 species, which presently grows from southern Mexico, through Central America and the Antilles, into Venezuela, the Guianas, Bolivia, and the Amazon Basin (Tryon & Tryon, 1982: 47). It grows in moist habitats, wet forests, and rain forests from sea level to about 2,300 m. Fossil spores have not been reported previously from Tertiary deposits in the Gulf/Caribbean region.

OTHER MONOLETE FERN SPORES

Type 1 (Fig. 22). Reniform; monolete, laesura straight, narrow, 22–26 μm long, extending ca. ¾ spore length, inner margin entire; laevigate; 41 × 22 μm.

These spores likely represent the Blechnaceae (e.g., *Blechnum*) and Polypodiaceae (e.g., *Asplenium, Thelypteris*) without the delicate ornamented perispore. They are common in fossil deposits, recognized under the artificial generic name *Laevigatisporites*, and range from Paleozoic to Recent.

Type 2 (Fig. 23). Reniform; monolete, laesura straight, narrow, 22–26 μm long, extending ¾ spore length, inner margin entire; verrucate, verrucae moderately low and conspicuous, shape irregular, ca. 2 × 4 μm; wall 2–3 μm thick; 56–58 × 39–41 μm.

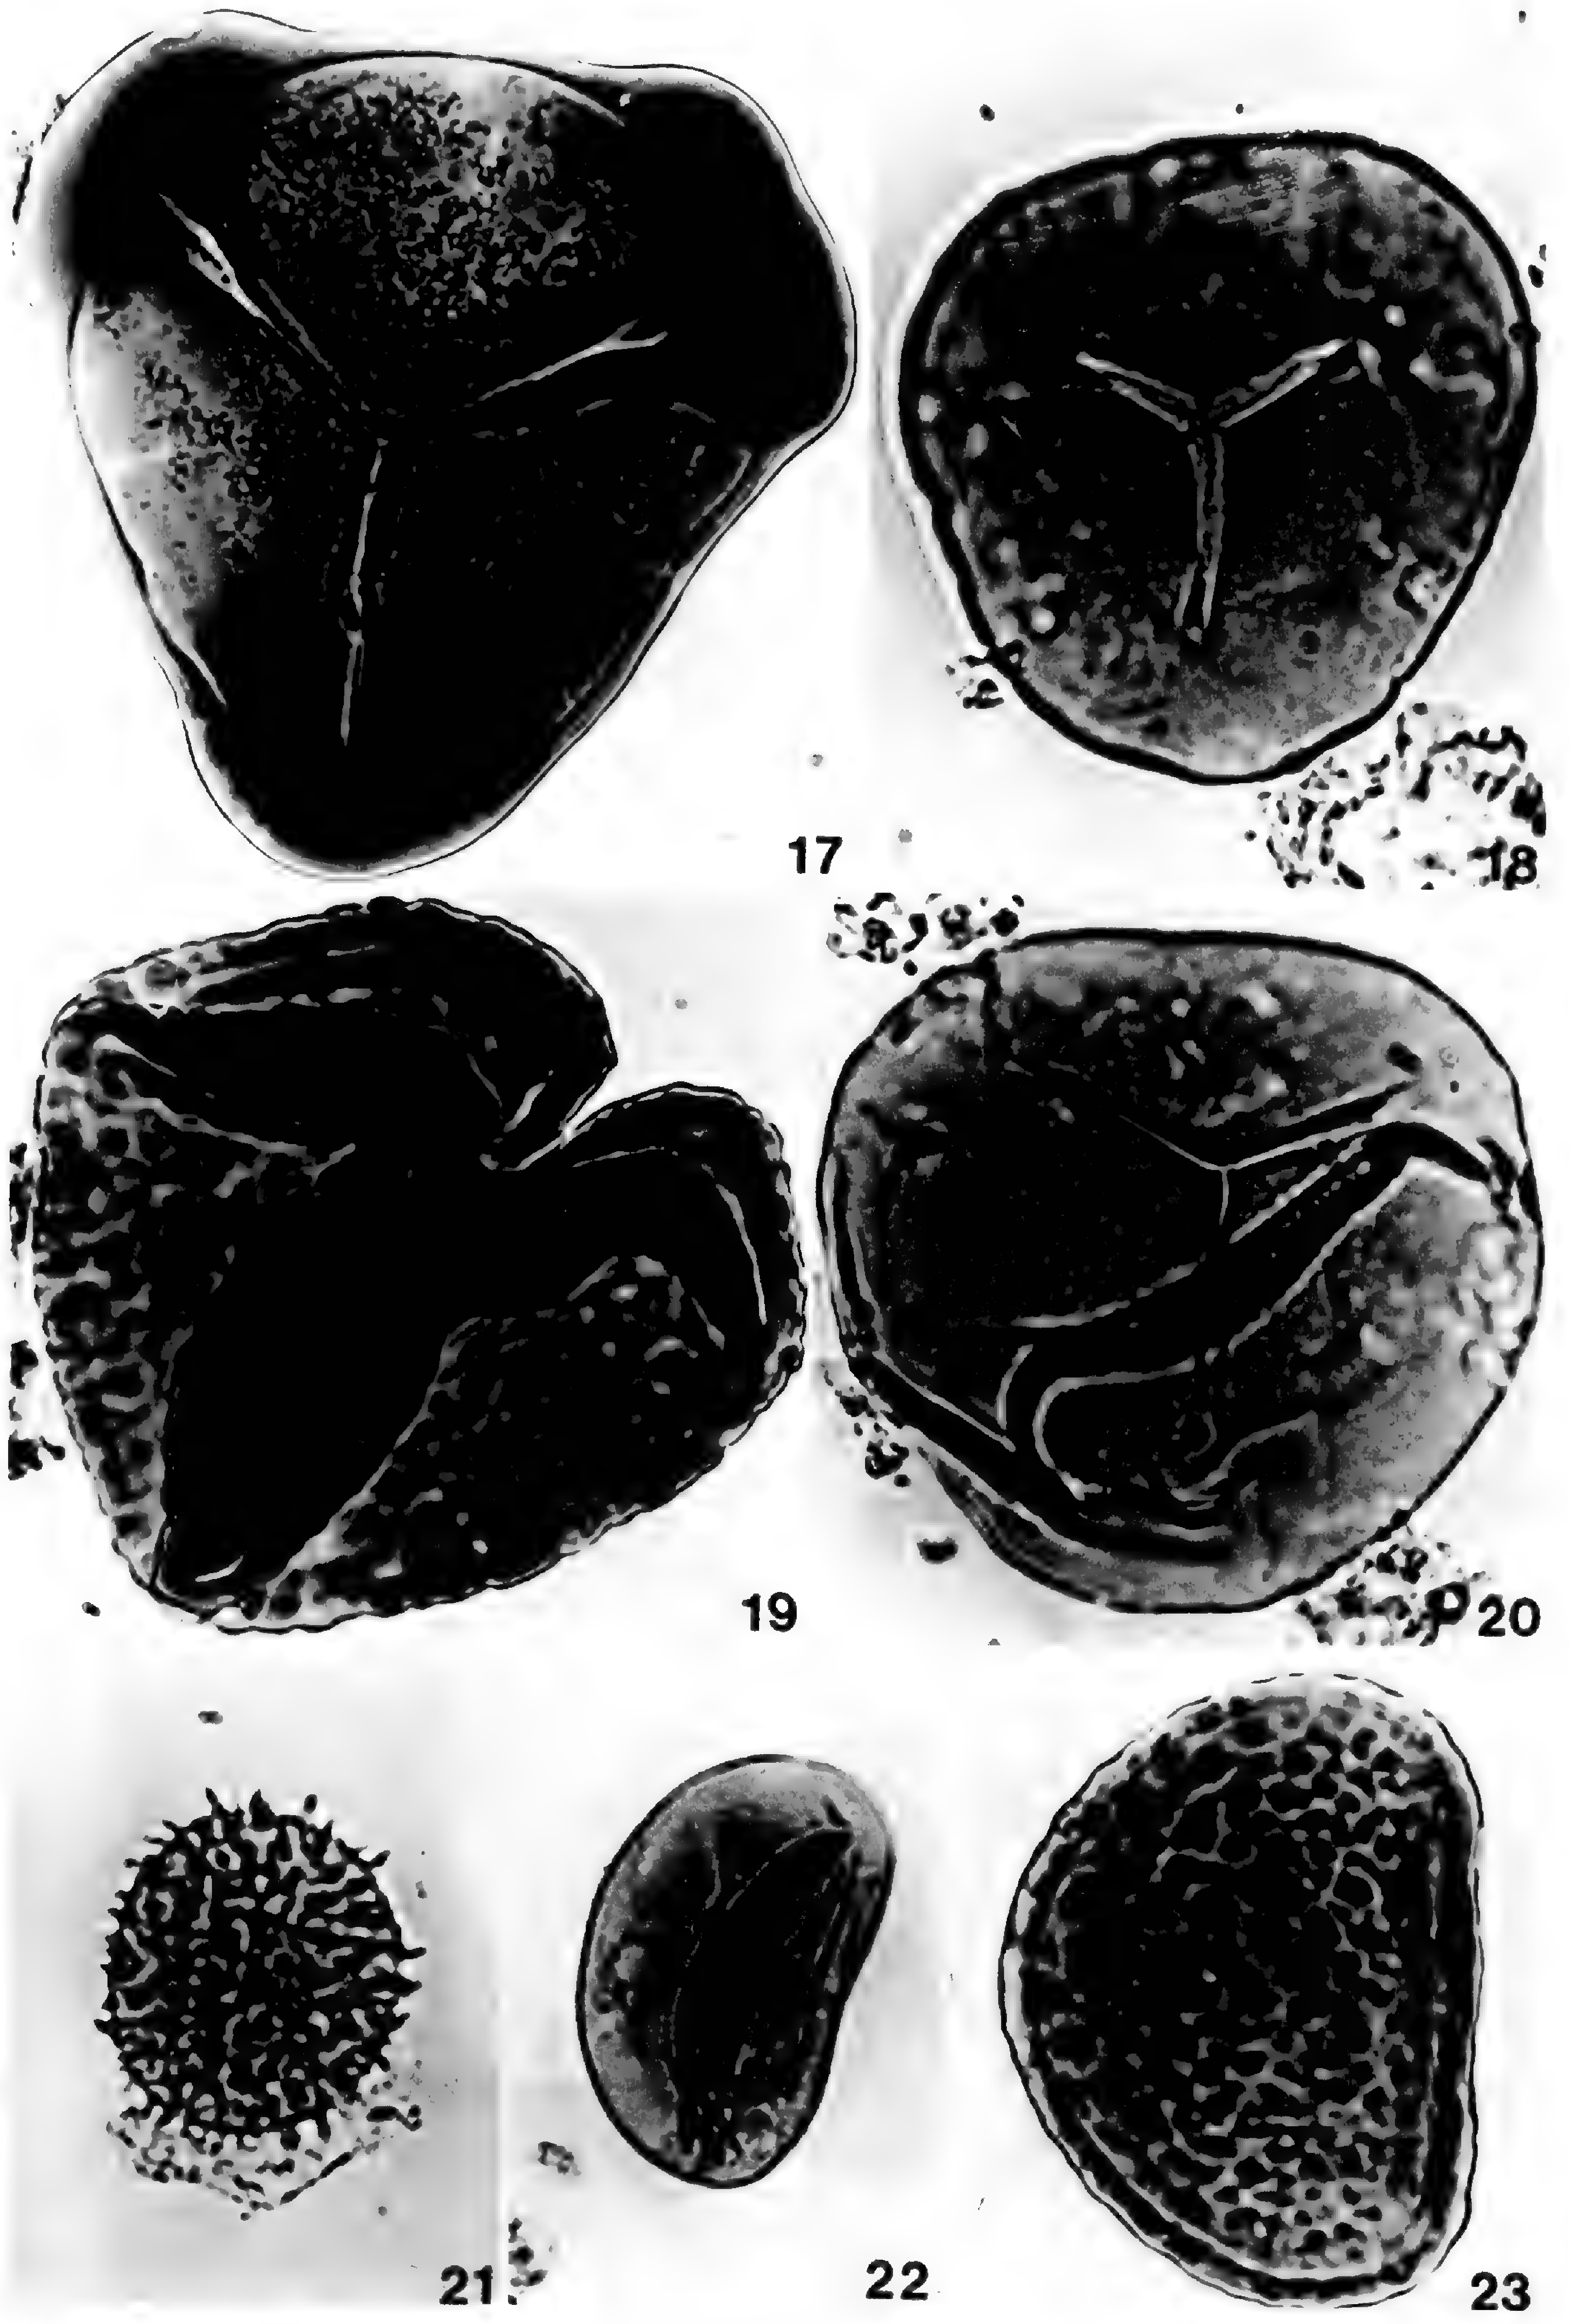
These spores are produced by species of several genera of the Polypodiaceae and Blechnaceae (e.g., *Blechnum, Microgramma*), bear the artificial generic name *Verrucatisporites*, and range from the Paleozoic to Recent.

Type 3 (Figs. 24–26). Reniform; monolete, laesura straight to curved, narrow, 32–36 μm long, extending ca. ½–⅔ spore length, inner margin entire; verrucate, verrucae distinct peglike structures, apices often flat, moderately to sparsely dense, ca. 2–3 μm diam.; 52–65 × 27–51 μm.

GRAMINEAE

(Fig. 27). Spherical, amb circular; monoporate, pore circular, 3 μm diam., inner margin entire, annulus ca. 2 μm wide, outer margin entire; tectate, wall ca. 2 μm thick; scabrate; 36–40 μm.

The Gramineae are stenopalynous, and the specimens cannot be referred to any single genus. Grass pollen has been reported from the Miocene of Veracruz (Graham, 1976) but not from the Eocene Gatuncillo Formation of Panama (Graham, 1985) or the lower Miocene Uscari sequence of Costa Rica (Graham, 1987a). Germeraad et al. (1968) listed its range in the Gulf/Caribbean region as base of the middle Eocene to Recent, but Muller



FIGURES 17–23. *Fossil spores from the Culebra Formation, Panama.—17.* Lygodium. *Pan core 456, slide 4, ESF K-11, 2. 18, 20. Cf.* Antrophyum.—*18. Pan core 456, slide 1, ESF U-14, 3–4.—20. Pan core 456, slide*

(1981) cited reports extending it back into the Paleocene of Brazil.

PALMAE

Palm pollen is one of the most common plant microfossils in the Culebra Formation. Four types are described, and it is likely that more than one genus may be represented by each.

Cryosophila-type (Figs. 29–32). Prolate, amb oval; monocolpate, colpus straight, 24–26 μm long, extending entire length of grain, margin entire; tectate-perforate, wall 2 μm thick; reticulate, muri relatively broad (ca. 1–1.5 μm), flat, lumen ca. 2 μm diam. on distal side, smaller approaching colpus; 34–38 × 24–32 μm.

This is one of the most common types of palm pollen in the Culebra Formation (Table 1). It is very similar to that of *Cryosophila warscewiczii* (H. Wendl.) Bartl., a tree up to 10 m tall distributed from Belize to Panama. In Panama it is known from the "tropical moist forest on both slopes of the Canal Zone and in Panamá and Darién; known also from premontane wet forest in Coclé (El Valle) and Panamá (Cerro Campana) and from tropical wet forest in Darién" (Croat, 1978: 171). Palm pollen is usually abundant in Gulf/Caribbean Tertiary deposits, but this is the first report of the *Cryosophila* type. Bartlett & Barghoorn (1973: 230, figs. 5, 6) reported a more finely reticulate form from the Quaternary of Panama.

Desmoncus-type (Figs. 33, 34). Prolate; monocolpate, colpus straight, broad, boatlike, apices rounded, 26–28 μm long, extending nearly entire length of grain, inner margin entire; tectate-perforate, wall ca. 1.5 μm thick; finely reticulate (diameter of lumen ca. 1 μm or slightly less); 30 × 18 μm.

This kind of pollen is produced by several palms, and *Desmoncus* is used primarily as an example of a morphologically similar type. A climbing palm known from Mexico to South America, it grows in Panama in tropical moist forests in the Canal region, in the provinces of Panamá and Darién, and in the tropical wet forest in Colón (Croat, 1978: 171).

Manicaria-type (Figs. 37, 38). Prolate; monocolpate, colpus straight to occasionally bent, 36–40 μm long, extending nearly entire length of grain, inner margin entire; finely reticulate (diameter of lumen ca. 1 μm or slightly less); tectate-perforate, wall ca. 1 μm thick; 40–45 × 21–27 μm, widest part just off equator of grain.

Manicaria is used as an example of a palm producing pollen morphologically similar to the specimens. It is a tree up to 10 m tall with three species in the Antilles, Central America, and South America (fide Bailey, 1943) and often occurs in dense groves in wet places. Similar pollen of this general palm type has been reported from the Eocene of Panama (Graham, 1985, fig. 26).

Synechanthus-type (Figs. 35, 36). Prolate; monocolpate, colpus straight, 28–30 μm long, extending entire length of grain, inner margin entire; scabrate (to possibly microreticulate); tectate, wall 1.5–2 μm thick; 28–34 × 22–26 μm.

Synechanthus is representative of modern palms producing morphologically similar pollen (cf. also *Aiphanes*, the West Indian *Thrinax*). It is a tree to 6 m tall distributed from Costa Rica to Colombia and Ecuador, usually at low elevations. In Panama it is known from "tropical moist forest on both slopes in the Canal Zone and in San Blas and Darién, from premontane wet forest in Veraguas (Cerro Tute) and Panamá (Lago Cerro Azul), and from premontane rain forest in Panama (Cerro Jefe) and Darién (Cerro Pirre)" (Croat, 1978: 178).

AQUIFOLIACEAE

Ilex (Fig. 28). Oblate-spheroidal, amb circular; tricolporoidate, colpi straight, 9–11 μm long (pole to equator), tapering to acute apex, equatorially arranged, meridionally elongated, equidistant, extending within 7 μm of pole (P.I. 0.33), inner margin diffuse, pores obscure, diam. ca. 2–3 μm, circular, situated at midpoint of colpus; intectate, clavate, wall 3 μm thick; 25–30 μm.

Ilex is one of the most common microfossils in the Gulf/Caribbean Tertiary, and its stratigraphic range and ecology have been discussed previously (e.g., Graham, 1985: 514). Briefly, its geologic range is from Late Cretaceous to Recent (Muller, 1981), and in northern Latin America pollen has been recovered from all formations studied in the

present project (Eocene to Recent). In the modern flora it grows at mid altitudes in moist to slightly drier habitats.

CHENOPODIACEAE/AMARANTHACEAE

(Fig. 39). Spherical, amb circular; periporate, pores circular, evenly distributed, distance between pores ca. 6–8 μm, estimated number ca. 40, diam. 3 μm, inner margin entire; tectate, wall relatively thick (3 μm); psilate; 21–23 μm.

Pollen of genera in these two families cannot be distinguished consistently, and the specimens serve only to record the family (or families) in the lower Miocene vegetation of Panama.

COMBRETACEAE

Combretum/Terminalia (Figs. 40, 41). Prolate to prolate-spheroidal; tricolporate with 3 pseudocolpi, colpi straight, 15 μm long, apices blunt, equatorially arranged, meridionally elongated, equidistant, inner margin entire, pore frequently obscure, circular, diam. 2–3 μm, situated at midpoint of colpus; tectate, wall 1.5–2 μm thick; psilate to faintly scabrate; 14–16 × 18–20 μm.

The occurrence of *Combretum/Terminalia* in Gulf/Caribbean deposits has been discussed recently by Graham (1985). Pollen of the two genera cannot be distinguished consistently (Graham, 1980), and the morphological type ranges from Eocene to Recent in the region. Both genera are found in moist to wet habitats, although individual species may range into drier habitats.

COMPOSITAE

(Figs. 42, 43). Spherical to oblate-spheroidal, amb circular; tricolporate, colpi straight, short (ca. 4–6 μm pole to equator), equatorially arranged, meridionally elongated, equidistant, pore obscure, ca. 2 μm diam., situated at midpoint of colpus; vesiculate (air cavities evident in equatorial mesocolpial region); tectate, outer wall 3–4 μm thick; echinate, spines short (ca. 3 μm), base broad, moderately dense (distance between spines ca. 3–4 μm); 24–26 μm.

These vesiculate Compositae pollen grains are typical of later Cenozoic deposits and have not been reported previously in our studies, although other Compositae pollen types are known from the upper Miocene Paraje Solo Formation of Veracruz, Mexico (Graham, 1976). The Culebra specimens are of the Heliantheae type (e.g., *Ambrosia*, *Franseria*, *Iva*) but cannot be referred to any one genus.

CONNARACEAE

Cf. *Rourea* (Figs. 44, 45). Prolate; tricolpate, colpi straight, 16–18 μm long, equatorially arranged, meridionally elongated, equidistant, inner margin entire to appearing minutely dentate due to overlying sculpture elements; tectate, wall ca. 1 μm thick; finely reticulate; 20–24 × 14–18 μm.

These prolate, tricolpate reticulate grains are a generalized type but compare most closely to members of the Connaraceae, especially *Rourea*. The genus is represented in Panama by three species (fide Woodson & Schery, 1950a), the most common being *R. glabra* Aubl., distributed from southern Mexico, through Central America and the Antilles, to the Guianas and Brazil. In Panama it is "known principally from tropical moist forest in the Canal Zone, San Blas, Veraguas, Los Santos, Panamá, and Darién; known also from tropical dry forest in Coclé and Panamá (Taboga Island), from premontane moist forest in the Canal Zone and Panamá, and from premontane wet forest in Colón and Panamá" (Croat, 1978: 423).

DILLENIACEAE

Cf. *Doliocarpus* (Figs. 46–48). Prolate to prolate-spheroidal; tricolporate, colpi straight, 23–25 μm long, equatorially arranged, meridionally elongated, equidistant, inner margin entire, costae colpi ca. 3 μm wide, pore obscure, circular, ca. 3 μm diam., situated at midpoint of colpus; tectate perforate, wall 2.5–3 μm thick; reticulate, muri smooth, about as wide as lumen; 30–34 × 20–24 μm.

Four species of *Doliocarpus* presently occur in the vicinity of the collecting site: *D. dentatus* (Aubl.) Standley, *D. major* J. F. Gmel., *D. multiflorus* Standley, and *D. olivaceus* Sprague & L. O. Williams ex Standley. The specimens are most similar to *D. dentatus*, but there is some variation in the

modern pollen among individual herbarium collections. In the collection *Lewis et al. 722A* (Chiriquí, Panama, MO) the reticulum is slightly coarser (muri broader) like the specimens, while in the collection *Proctor et al. 27037* (Nicaragua, CR) the reticulum is finer. Consequently the fossil specimens are presently identified only as cf. *Doliocarpus.*

Doliocarpus dentatus occurs from Mexico through Central America to Paraguay and is scattered in the Antilles. In Panama it grows in the tropical moist forest, tropical dry forest, premontane moist forest, and premontane wet forest (Croat, 1978: 599).

DIOSCOREACEAE

Dioscorea/Rajania-type (Fig. 51). Prolate; tricolpate, colpi frequently sinuous, irregular, 21–23 μm long, equatorially arranged, meridionally elongated, equidistant, inner margin entire; tectate-perforate, wall relatively thin (ca. 1.5 μm); finely reticulate; 26–28 × 17–19 μm.

Eleven native species of *Dioscorea* are listed for Panama by Morton (1945), and Croat (1978) listed five native Central American species for Barro Colorado Island. *Dioscorea* is found primarily in the tropical moist, premontane moist, premontane wet, and tropical wet forests. *Rajania* is a West Indian segregate of *Dioscorea.* Similar pollen has been reported from the Miocene of Veracruz, Mexico (Graham, 1976).

EUPHORBIACEAE

Alchornea (Fig. 52). Oblate, amb circular; tricolpate, colpi straight, 6–8 μm long (pole to equator), equatorially arranged, meridionally elongated, equidistant, extending within 5–6 μm of pole, inner margin entire, distinct operculum; tectate, wall 1.5 μm thick; psilate to faintly scabrate; 20 μm.

Pollen of *Alchornea* is frequent in Gulf/Caribbean Tertiary deposits and ranges from the lower and middle Eocene (Colombia; González Guzmán, 1967) to Recent (Muller, 1981). Its distribution and ecology for the region have been summarized by Graham (1987a), based on Croat (1978) and Webster & Burch (1967). Briefly, it grows in the tropical moist, premontane wet, and premontane rain forest, with a wide altitudinal range of 300 to 2,000 m. Pollen of the family has been described by Punt (1962).

Sapium (Figs. 49, 50). Prolate; tricolporate, colpi straight, 62–66 μm long, equatorially arranged, meridionally elongated, equidistant, inner margin entire, costae colpi 4–6 μm wide, margo present (formed by reticulum becoming finer bordering the colpi), pore large (12–14 μm diam.), oval, situated at midpoint of colpus; tectate-perforate, wall 3 μm thick, individual columellae distinct; finely reticulate; 76–80 × 52–56 μm.

Sapium is a genus of about 120 species (fide Willis, 1966) of trees and shrubs widely distributed in tropical and subtropical regions of the New World. Webster & Burch (1967) listed four species for Panama, and Croat (1978) recorded two for Barro Colorado Island. It grows in the tropical moist, premontane wet, and lower montane wet forests. Hartshorn (1983: 143–144) described its occurrence within the Monteverde Reserve in Costa Rica (cove, leeward cloud, windward cloud, and swamp forests).

There is considerable range in size of *Sapium* pollen, and the smaller forms (48 μm) have been described from the Quaternary of Panama (Bartlett & Barghoorn, 1973). Slightly larger specimens (58 μm) occur in the upper Miocene Paraje Solo Formation of Veracruz, Mexico (as cf. *Sapium*; Graham, 1976). The Culebra specimens are exceptionally large (80 μm) and are matched by a collection labeled *S. haematospermum* Muell.-Arg. (*Rocha 3666*, Argentina, TEX). It is not possible to refer the specimen to any one modern species, but pollen identical to the specimens in size and fineness of the reticulum apparently does occur in the genus.

Tetrorchidium (Figs. 55–58). Oblate-spheroidal, amb circular; tricolpate, colpi straight, 12–14 μm long (pole to equator), equatorially arranged, meridionally elongated, equidistant, inner margin finely dentate; intectate, finely baculate to nearly echinate, wall ca. 1.5 μm thick; 26–30 μm.

According to Webster & Burch (1967), there are about ten species of *Tetrorchidium* in the New World (five in Africa), and two are listed for Panama (*T. euryphyllum* Standley, rainforests of Costa Rica and Panama; *T. gorgonae* Croizat). Hartshorn (1983) mentioned *Tetrorchidium* sp. in the swamp forests of the Monteverde Reserve in Costa Rica (associated with *Alchornea* and *Sapium*). Pollen wall thickness varies among the species of *Tetrorchidium*, and the specimens are similar to the thinner-walled forms in our collection (e.g., *T. rotundatum* Standley, Nicaragua). Similar pollen has been reported from the Oligocene of Puerto Rico (Graham & Jarzen, 1969) and the Miocene of Veracruz, Mexico (Graham, 1976).

FLACOURTIACEAE

Casearia (Fig. 53). Prolate; tricolporate, colpi straight, 18–20 μm long, apices acute, equatorially arranged, meridionally elongated, equidistant, inner margin entire, narrow costae colpi, pore equatorially elongated (colpi transversalis), 1.5–2 × 4–5 μm, situated at midpoint of colpus; tectate, wall 1.5 μm thick; sculpture subdued, appearing psilate; 23–25 × 16–18 μm.

Casearia pollen records in the Gulf/Caribbean Tertiary have recently been reviewed by Graham (1985). Briefly, it is known from the middle(?) to late Eocene (Gatuncillo Formation, Panama) to Recent. The modern plants are trees and shrubs widely distributed in tropical and subtropical regions, with eight species listed for Panama (Robyns, 1968). They are most typical of moist forest types but can range into somewhat drier habitats (Croat, 1978). Pollen of the family has been studied by Keating (1973).

LEGUMINOSAE–MIMOSOIDEAE

Acacia (Fig. 54). Solid sphere, 16-celled polyad, amb circular; nonaperturate; individual cells ± cubical, ca. 20 μm; tectate, wall 1.5 μm thick; faintly scabrate; 52–54 μm.

Woodson & Schery (1950b) listed 12 species of *Acacia* for Panama, and Croat (1978) recorded five for Barro Colorado Island. They grow mainly in the tropical moist forest (in contrast to the familiar savannah habitats of African and Australian species) but can range into drier vegetation types. *Acacia* pollen has been reported from the Oligocene San Sebastian Formation of Puerto Rico (Graham & Jarzen, 1969), and a similar grain was recovered from the Quaternary of Panama (as Mimosoideae; Bartlett & Barghoorn, 1973).

MALPIGHIACEAE

(Figs. 61, 62). Spherical, amb circular; periporate, pores circular, 4–5 μm diam., inner margin entire; tectate, wall thick (3–4 μm); scabrate; 38–42 μm.

Only two poorly preserved specimens of the Malpighiaceae were recovered from the Culebra Formation and serve only to record the family in the assemblage.

MALVACEAE

Hampea/Hibiscus (Figs. 59, 60). Spherical, amb circular; periporate, pores circular, 3–4 μm diam., inner margin entire, narrow annulus; tectate, wall 2 μm thick; echinate, spines 4–5 μm long, broadened at base, moderately dense (distance between spines ca. 6–8 μm); 48–70 μm.

Robyns (1964a) and Croat (1978) listed one species of *Hampea*, *H. appendiculata* (Donn. Sm.) Standley, for Panama and Barro Colorado Island. It is a shrub to mid-size tree growing in Honduras, Costa Rica, and Panama in the tropical moist, premontane moist, tropical wet, and premontane rain forests. *Hibiscus* is represented by 14 species in Panama (fide Robyns, 1965), and on Barro Colorado Island by three species (Croat, 1978). *Hibiscus sororius* L.f. is a herb to small suffrutex that is common in marshy areas as a component of floating masses of marshy and swamp vegetation (Croat, 1978: 583). Hartshorn (1983) listed it as a member of the coastal strand vegetation in Costa Rica. Although insect pollinated, with large (to 70 μm) echinate pollen, the plant grows in habitats that would be immediately marginal to the Culebra depositional basin, and fossil specimens are frequent in the deposits.

←
core 470.6, slide 3a, ESF U-31, 3.—65, 66. Eugenia/Myrcia. *Pan core 470.6, slide 3a, ESF Q-22, 4; Pan core 470.6, slide 3a, ESF D-26, 2–4.—67–70.* Rhizophora. *Pan core 456, slide 4, ESF J-17, 1; Pan core 456, slide 4, ESF Q-11, 3–4; Pan core 488, slide 1, ESF V-12, 3.*

The *Hampea/Hibiscus* pollen type is recorded under the artificial generic name *Echiperiporites* and ranges globally from the upper Eocene to Recent. It is known from the upper Eocene of Venezuela (Muller, 1981), upper Miocene of Veracruz, Mexico (Graham, 1976), and the Quaternary of Panama (Bartlett & Barghoorn, 1973).

MYRTACEAE

Eugenia/Myrcia (Figs. 65, 66). Oblate; amb triangular; tricol(poroid)ate; colpi straight, 6–8 μm long (pole to equator), equatorially arranged, meridionally elongated, equidistant, inner margin entire, syncolpate, pores vaguely defined, located at apices of grain at midpoint of colpus; tectate, wall ca. 1.5 μm thick; scabrate; 12–16 μm.

Occurrences of *Eugenia/Myrcia* in the Gulf/Caribbean Tertiary have been discussed recently by Graham (1985, 1987a). It is frequent in the sediments, although not in high percentages, and ranges from the middle Eocene to Recent. Study of the modern pollen (Graham, 1980) indicates that isolated microfossils cannot be referred consistently to any one genus of the family, and the specimens serve only to document the Myrtaceae as a prominent component of the lower Miocene vegetation of Panama.

RHIZOPHORACEAE

Rhizophora (Figs. 67–70). Prolate to prolate-spheroidal; tricolporate, colpi straight, 14–16 μm, equatorially arranged, meridionally elongated, equidistant, inner margin entire, costae colpi ca. 2–3 μm, pores elongated equatorially (colpi transversalis), 1 × 4 μm, constricted at midpoint of colpus; tectate-perforate, wall 2–3 μm thick; finely reticulate; 16–20 × 14–19 μm.

Records of *Rhizophora* pollen in the Gulf/Caribbean Tertiary have been summarized by Graham (1985: 519, 1987a). The Culebra specimens further document its widespread occurrence and often dominant percentages in sediments such as lignites deposited under warm-temperate to subtropical, coastal, brackish-water conditions. It ranges from late Eocene to Recent in tropical American sediments (often reported under the artificial generic name *Zonocostites*), and in older deposits is replaced by its presumed ecological counterpart, *Brevitricolpites* of unknown biological affinity. Other aspects of modern and fossil mangrove pollen have been discussed by Langenheim et al. (1967), Leopold (1969), and Muller & Caratini (1977).

RUBIACEAE

Sabicea (Figs. 63, 64). Oblate, amb oval-triangular to nearly circular; tricolpate/porate (apertures short, slitlike, ca. 2:1 length/width ratio), 4–6 × 2–3 μm, equatorially arranged, meridionally elongated, equidistant, inner margin faintly dentate (due to overlying sculpture elements), faint costae colpi; tectate-perforate, wall 2–3 μm thick; finely reticulate, muri smooth, width about same as diameter of lumen (ca. 0.5–1 μm); 32–36 μm.

The presence of *Sabicea* pollen in the Culebra assemblage has been reported recently by Graham (1988a). Briefly, the genus presently grows from Mexico to northern South America and is represented in Panama by three species and two varieties common in tropical moist and premontane wet forests. *Sabicea* has not been reported previously in the fossil record.

SAPINDACEAE

Allophylus (Figs. 71–75). Oblate to peroblate, amb distinctly triangular; triporate, pore slightly elongated meridionally, ca. 5 × 3 μm, equatorially arranged, equidistant, inner margin entire, faint costae colpi; tectate, wall 2 μm thick; scabrate to microreticulate; 14 × 24 μm.

Allophylus is a mostly South American genus of about 190 species of shrubs or small trees with six species in Mexico and Central America, and three in Panama (fide Croat, 1976). It typically grows at low to moderate elevations (ca. 1,000 m) and ranges through several forest types—tropical dry, tropical moist, tropical wet, premontane moist, and premontane wet forests. It has been reported previously from the upper Miocene Paraje Solo Formation of Veracruz, Mexico (Graham, 1976).

Cupania (Fig. 76). Oblate to peroblate, amb triangular; tricolpor(oid)ate, colpi straight, 7–8 μm long, equatorially arranged, meridionally elongated, equidistant, inner margin entire, syncolpate; tectate, wall 2 μm thick; psilate to faintly scabrate; 12–16 μm.

Cupania is a genus of about 45 tropical American species of trees and shrubs. The nine species listed for Panama (Croat, 1976) grow primarily in the tropical moist, tropical wet, and premontane wet forests. The genus has been reported from the upper Miocene Paraje Solo Formation of Mexico (Graham, 1976) and from the Quaternary of Panama (Bartlett & Barghoorn, 1973).

Matayba (Fig. 77). Oblate, amb triangular;

tricolpor(oid)ate; colpi straight, 12–14 μm long, apices branched with triangular sexine area included at poles, equatorially arranged, meridionally elongated, equidistant, inner margin entire; tectate, wall 2 μm thick; scabrate; 23–27 μm.

Croat (1976: 433) noted that *Matayba* is not always easily separable from *Cupania*. The pollen is also similar. *Matayba* pollen, however, commonly has branched colpi that include a triangular segment of the sexine at the poles, while in *Cupania* the colpi most frequently are unbranched or, when branched, do not usually include the triangular segment of sexine.

Matayba consists of about 45 species of trees and shrubs in tropical America, four of which are recorded for Panama (Croat, 1976), where it is found in the tropical dry, tropical moist, tropical wet, premontane moist, and premontane wet forests. *Matayba* has been reported from the upper Miocene Paraje Solo Formation of Veracruz, Mexico (Graham, 1976).

SAPOTACEAE

Cf. *Pouteria* (Figs. 78, 79). Prolate; tricolporate, colpi straight, equatorially arranged, meridionally elongated, equidistant, inner margin entire, narrow costae colpi, pores elongated equatorially, 2–3 × 4–5 μm, situated at midpoint of colpus, narrow annulus; tectate, wall relatively thick (2–3 μm); faintly scabrate; 26–28 × 20–22 μm.

Pouteria is a genus of about 100 species of trees and shrubs found chiefly in tropical America. Included are a number of segregates that "are probably sound and deserve recognition at least at the subgeneric level. Unfortunately many of the segregate genera themselves are poorly defined, being based on relatively few specimens. As more material is collected, the generic limits may have to be shifted. This is particularly true among American species" (Pilz, 1981: 186).

The pollen is also similar to other members of the family, including *Sideroxylon*, which is a genus of trees and shrubs of the New and Old World tropics growing in Mexico, northern Central America, and Colombia but is not listed for Panama (Blackwell, 1968; Croat, 1978; D'Arcy, 1987). Species previously assigned to *Sideroxylon* from Panama are now mostly referred to *Pouteria* (e.g., *S. sapota* Jacq. = *P. sapota* (Jacq.) Moore & Stearn; *S. uniloculare* Donn. Smith = *P. unilocularis* (Donn. Smith) Baehni; Pilz, 1981). Collections at MO are rare from Mexico (one collection) and South America (two collections) but common from Asia, Africa, and Oceanica (Ricketson, pers. comm., 1987), suggesting a possible Old World origin. It is the only genus in the Culebra assemblage with this pattern of distribution, hence the provisional reference of the fossil specimens to *Pouteria*.

STERCULIACEAE

Cf. *Guazuma* (Fig. 80). Prolate; tricolporate, colpi straight, 16–18 μm long, equatorially arranged, meridionally elongated, equidistant, inner margin entire, narrow costae colpi, pores obscure, slitlike, ca. 1 × 3 μm, situated at midpoint of colpus; tectate-perforate, wall 2 μm thick; finely reticulate; 22–24 × 20–22 μm.

Guazuma is a genus of trees and shrubs consisting of three species with only *G. ulmifolia* Lam. listed for Panama (Robyns, 1964b). The latter species grows from Mexico to Panama and in the West Indies. It is ecologically variable and in Panama grows in the tropical moist, premontane wet, premontane moist, premontane dry, and tropical dry forests (Croat, 1978: 594).

UNKNOWNS

A number of specimens were recovered that could not be identified. Some of the more distinctive and/or abundant ones are illustrated and briefly described below.

Type 1 (Fig. 81). Spherical, amb circular; nonaperturate; intectate, wall thin (ca. 1.5 μm); echinate, spines short (ca. 2–3 μm), dense; 36 μm.

Type 2 (Figs. 82–86). Prolate; tri(?)colpate, colpi sinuous, 28–46 μm long, equatorially arranged, meridionally elongated, equidistant, inner margin entire; tectate, wall 2–3 μm thick, homogeneous and hyaline; psilate to faintly textured (scabrate?); 32–50 × 19–34 μm.

These specimens are characterized by a glass-like, hyaline wall and possibly represent an unknown fungal spore.

Type 3 (Figs. 87–90). Prolate; tricolporate, colpi straight, 40–46 μm long, equatorially arranged, meridionally elongated, equidistant, inner margin entire, costae colpi 5–9 μm wide, pore slightly oval, 3 × 5 μm, situated at midpoint of colpus; tectate-perforate, wall 2 μm thick; finely reticulate; 42–55 × 32–43 μm.

These specimens are similar to pollen of several genera of the Anacardiaceae but also resemble

some Bignoniaceae and Euphorbiaceae. They are common in the Culebra assemblage and in several other Gulf/Caribbean Tertiary formations (e.g., Eocene Gatuncillo Formation, Panama; Graham, 1985, figs. 138–144).

Type 4 (Fig. 107). Oblate-spheroidal, amb circular; tetracolporate, colpi straight, equatorially arranged, meridionally elongated, equidistant, inner margin entire, pores equatorially elongated, ca. 1 × 4 μm, situated at midpoint of colpus; tectate, wall 2 μm thick; psilate to faintly scabrate; 23 μm.

Type 5 (Figs. 94, 95). Oblate to oblate-spheroidal; amb circular; stephanocolpate, colpi 6, straight, 6 μm long, equatorially arranged, meridionally elongated, equidistant, inner margin entire, pores equatorially elongated, ca. 1 × 4 μm, situated at midpoint of colpus; tectate, wall 2 μm thick; psilate; 14–16 μm.

Type 6 (Figs. 105, 106). Oblate-spheroidal, amb circular; tricolpor(oid)ate, colpi straight 15 μm long, equatorially arranged, meridionally elongated, equidistant, margin diffuse; tectate, wall 3 μm thick; scabrate, some sculpture elements more pointed, approaching echinae; 36 μm.

These specimens are generally similar to *Valeriana*, but no exact match could be found among the species examined.

Type 7 (Figs. 99, 100). Prolate-spheroidal; tricolpate, colpi straight, 22–24 μm long, equatorially arranged, meridionally elongated, equidistant, inner margin entire, costae colpi ca. 3 μm wide, pores circular, 3 μm diam., situated at midpoint of colpus; tectate-perforate, wall 3 μm thick; reticulate, muri smooth, slightly narrower than the lumina; 36 μm.

These rare specimens may represent obliquely preserved specimens of *Coccoloba*.

Type 8 (Figs. 96–98). Oblate, amb spherical; tricolporate, colpi straight, short (4–6 μm), equatorially arranged, meridionally elongated, equidistant, inner margin entire, pores elongated equatorially (colpi transversalis), 1 × 5–6 μm, situated at midpoint of colpus; tectate, wall 1.5 μm thick; psilate to faintly scabrate; 14–20 μm.

Type 9 (Fig. 91). Oblate, amb triangular; tricolpate/porate (length/width ratio ca. 2:1), equatorially arranged, meridionally elongated, equidistant, inner margin entire, situated at apices of triangular grain; tectate, wall 2–3 μm thick; scabrate; 45 μm.

Type 10 (Fig. 108). Oblate to peroblate, amb oval-triangular to circular; tricolpate, colpi short (3–4 μm), equatorially arranged, meridionally elongated, equidistant, inner margin entire, costae colpi ca. 3 μm wide; tectate-perforate, wall 2 μm thick; finely reticulate; 24–28 μm.

These specimens are similar to several Bombacaceae and related families (Tiliaceae, Sterculiaceae), but a precise identification could not be made.

Type 11 (Figs. 102–104). Oblate, amb circular; triporate, pores circular, 2–3 μm diam., equatorially to slightly subequatorially arranged (grains heteropolar), equidistant, inner margin entire, annulus 3–4 μm wide; tectate-perforate, wall 2 μm thick; finely reticulate; 43–50 μm.

These distinctive specimens are common in the Culebra Formation and probably represent a plant that was and likely still is common in the tropical American flora. The specimens are similar to *Bocconia arborea* S. Wats., but the modern pollen is periporate with only an occasional triporate grain, while the numerous specimens are all triporate.

Type 12 (Fig. 101). Oblate-spheroidal to spherical, amb circular; tri- to periporate, pores circular, 2 μm diam., conspicuous annulus 2–3 μm wide; tectate-perforate, wall thick (ca. 4 μm); finely reticulate; 35 μm.

Type 13 (Fig. 93). Spherical, amb circular; tricolpate (colpi short, obscure); tectate-perforate, wall thick (4–5 μm); reticulate, muri smooth, fine and slightly sinuous; 25–28 μm.

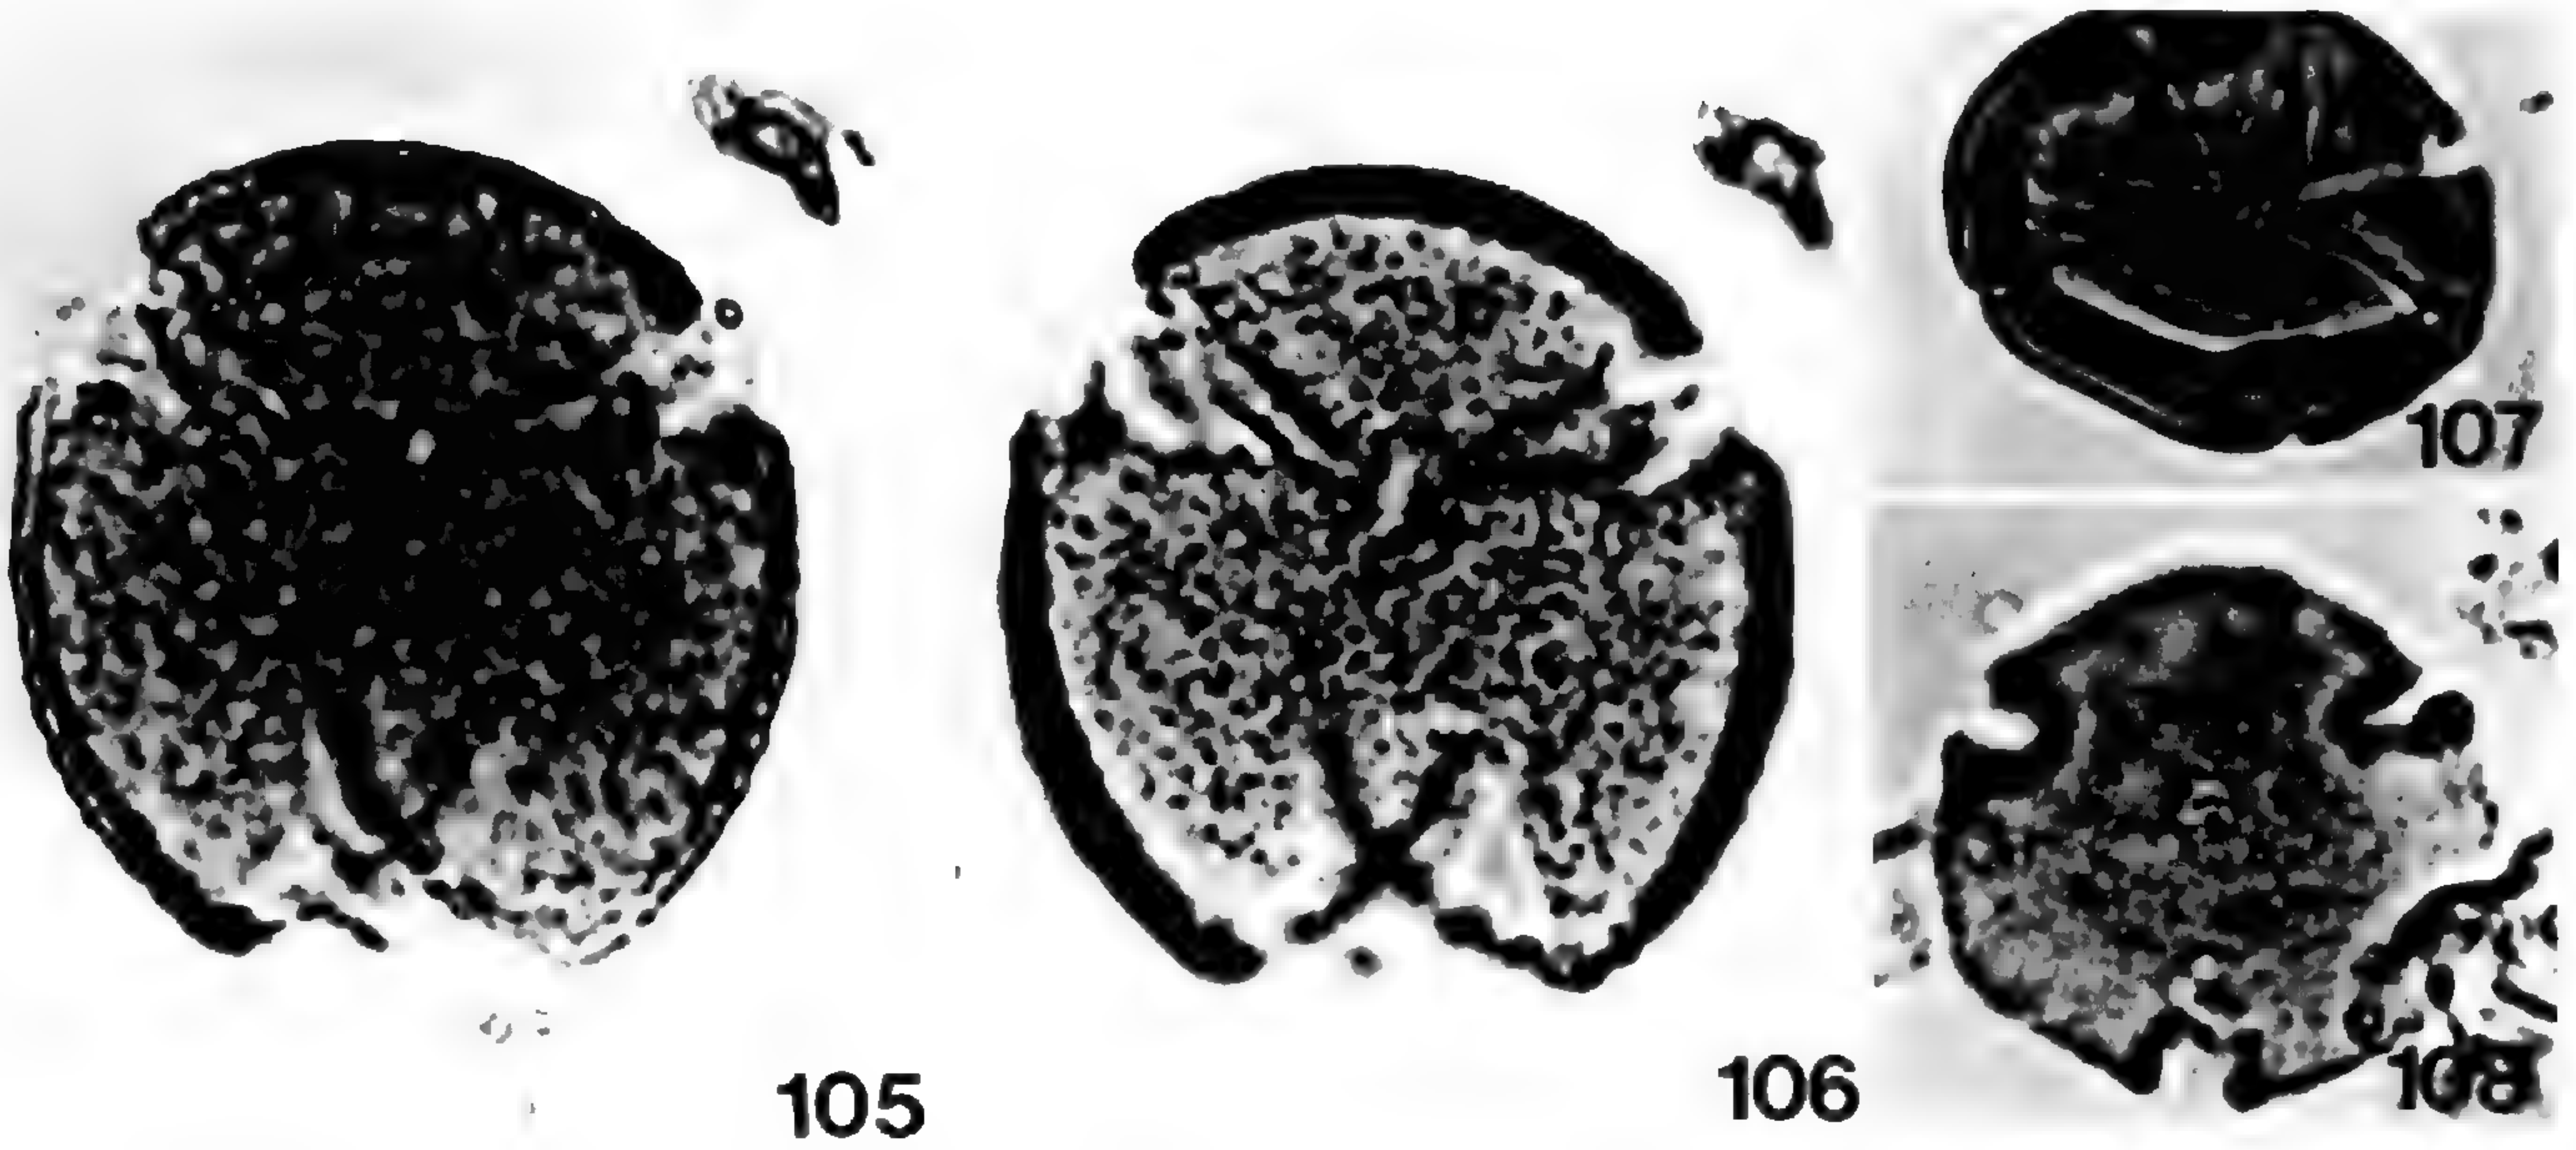
Type 14 (Fig. 92). These specimens are similar to Type 13, but the muri and walls are slightly thicker. Both are similar to pollen in some Rubiaceae (*Chomelia, Terebraria*) but do not match exactly any species in our reference collection.

In addition to these unknowns, there is also present the usual assortment of generalized small, prolate, tricolpate/colporate, finely reticulate forms common in Gulf/Caribbean Tertiary deposits. These are illustrated in Graham (1985, figs. 117–128). It is difficult to distinguish among these similar, intergrading types and they cannot presently be identified.

NUMERICAL REPRESENTATIONS

A total of 1,800 palynomorphs were tabulated from the Culebra material (200 each from levels 491.6–456, and 100 each from levels 425–377; Table 1). The ten most abundant types are as follows:

Monolete fern spore type 2: 367 specimens (20%)



FIGURES 105–108. *Fossil pollen from the Culebra Formation, Panama.—105, 106. Unknown type 6. Pan core 456, slide 3, ESF M-15, 3–4.—107. Unknown type 4. Pan core 488, slide 1, ESF J-13, 4.—108. Unknown type 10. Pan Core 456, slide 3, ESF F-25, 3.*

Manicaria-type palm pollen: 176 (10%)
Cyathea: 140 (8%)
Cryosophila-type palm pollen: 140 (8%)
Selaginella: 128 (7%)
Synechanthus-type palm pollen: 109 (6%)
Rhizophora: 100 (6%)
Monolete fern spore type 1: 84 (5%)
Hampea/Hibiscus: 68 (4%)
Lycopodium: 40 (2%)
Total ferns: 25%
Total cryptogams (ferns, *Lycopodium*, *Selaginella*): 40%
Total palms: 24%
Total lowland vegetation types (ferns, other cryptogams, palms, *Rhizophora*, *Hampea/Hibiscus*): 71%.

The composition of the Culebra flora clearly reflects a lowland tropical vegetation. Since the flora is derived from lignites deposited under lowland, coastal, brackish-water, warm-temperate to tropical conditions, there is a tendency to emphasize, possibly to over-emphasize, the potential bias toward this vegetation type. The actual bias is more in quantitative representation, with lowland communities over-represented and upland communities usually under-represented. Direct comparison of the fossil assemblage with modern vegetation types can be complicated further by differential preservation, insect versus wind pollination, and other factors. Thus attempts to quantify the paleocommunities in terms of relative abundance or aerial extent would be speculative, particularly in the absence of modern studies on pollen rain. Any impression, however, that major components of the vegetation, such as upland communities or savannahs, are *a priori* missing from paleofloras derived from lignites is inconsistent with existing data. The middle to upper Oligocene San Sebastian flora of Puerto Rico (Graham & Jarzen, 1969) and the upper Miocene Paraje Solo of southeastern Mexico (Graham, 1976), both preserved in lignites, contain many representatives of inland and highland communities in the form of pollen and spores blown or washed into the lowland basins of deposition. The data show rather convincingly that virtually any tropical vegetation type can be represented in and recognized from palynofloras such as the Culebra. An exception may be paramo, since the pollen of some important components, such as Gramineae, Compositae, and Cyperaceae, cannot be differentiated from non-paramo species. In general, however, when the characteristic and defining members of a community are missing from a diverse and well-preserved palynoflora, this is likely due to the absence or poor representation of the community in the region rather than to an absolute bias in the depositional process.

Features traditionally examined in core material are the first and last appearances of distinct types, changes in percentages of individual types through the section, and similar data on groups or assemblages of types. The purpose is to assess the possibility of subdividing or zoning the section for more precise comparison with other sections or formations (stratigraphic correlation). Such analysis is difficult for the Culebra section because of the uneven quality of preservation along the core. For example, the lowermost (oldest) samples from 491.6 and 491 feet contain palynomorphs of only fair preservation and of low diversity (14 and 12 types of palynomorphs, respectively; Fig. 109). There

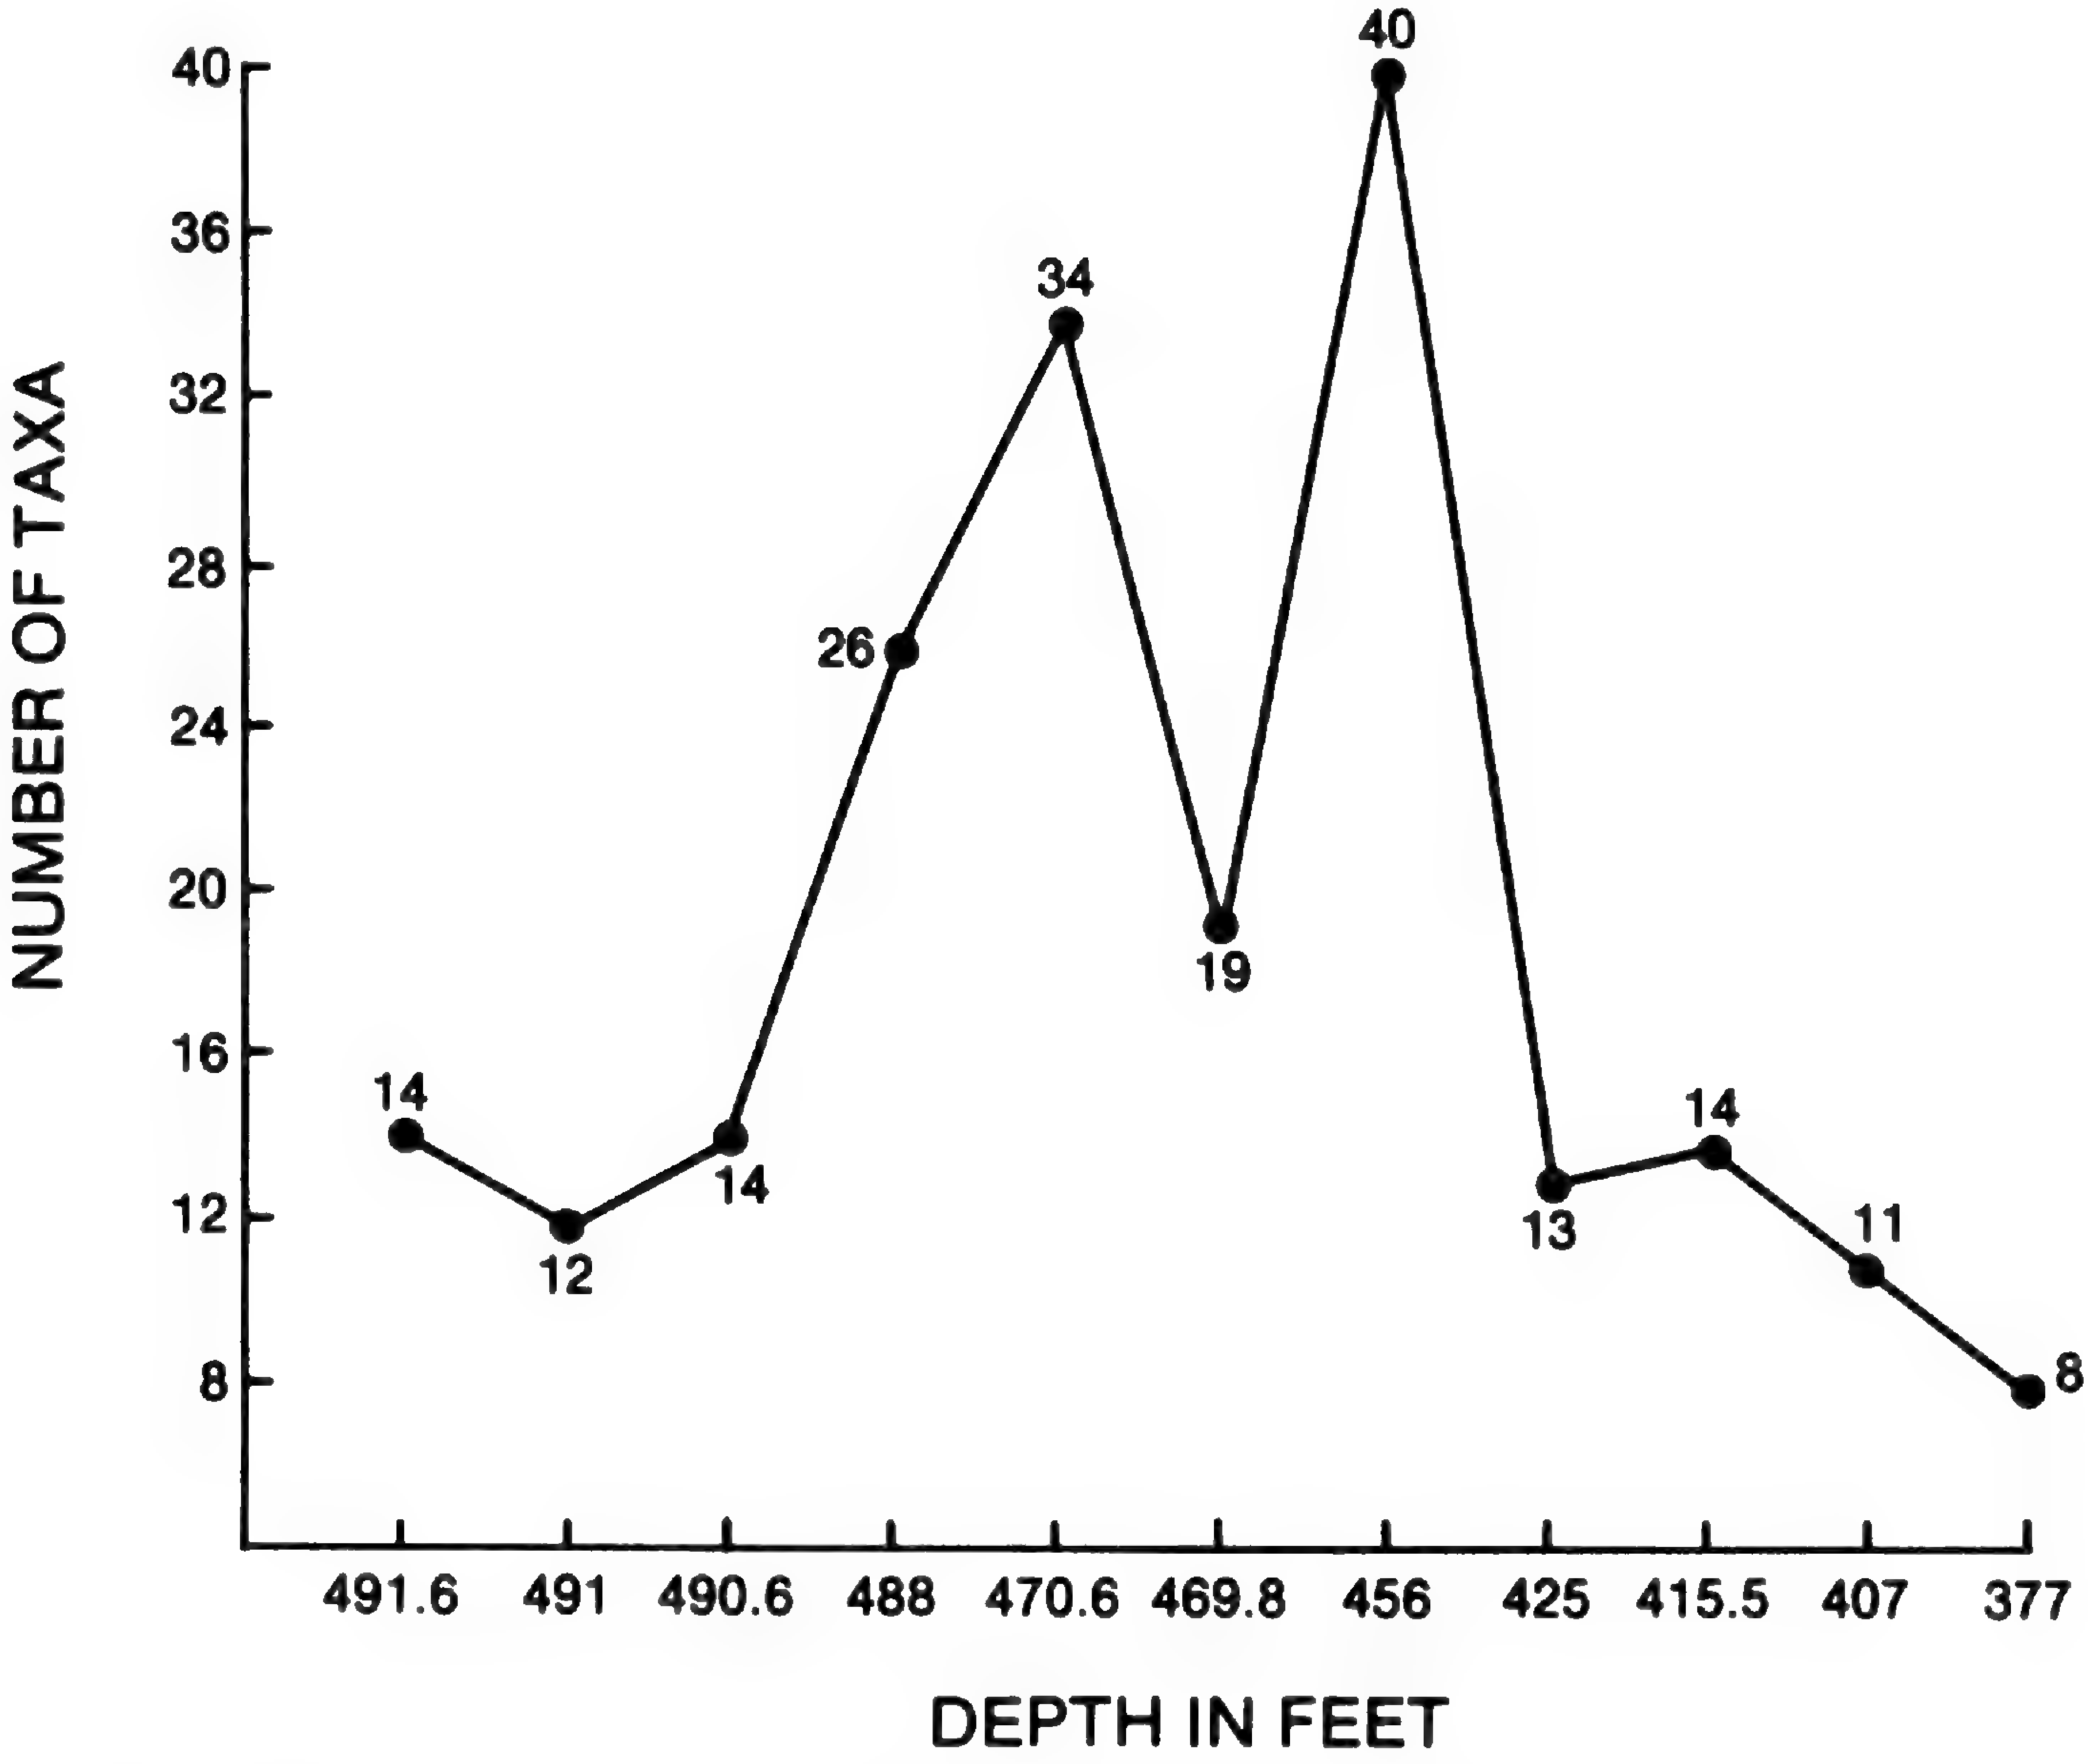


FIGURE 109. *Number of palynomorphs in each of the 11 samples from the Culebra core. Diversity and preservation were lowest at levels 491.6, 491, 490.6, 425, 415.5, 407, and 377, which also contained abundant fungal spores. Levels 470.6 and especially 456 contained the largest number of well-preserved palynomorphs and are probably most representative of the Culebra vegetation.*

are abundant thick-walled fern spores, suggesting possible differential preservation. Beginning with level 490.6, both the quality of preservation and diversity increase, which continue through level 456 (40 types), with the exception of a drop in diversity at level 469.8 (19 types). The remaining four samples (425, 415.5, 407, 377) are poor, with large numbers of thick-walled fern spores and fungal spores. It has been my experience in Gulf/Caribbean Tertiary deposits that abundance of fungal spores usually coincides with a decrease in the quality, abundance, and diversity of pollen.

In light of the differences in preservation along the core, the facts that *Lycopodium* first appears at level 490.6, or *Pteris* and Malpighiaceae at level 488, probably do not carry much stratigraphic or paleoecological significance. In instances where a particular microfossil appears confined to a single level or narrow zone (e.g., *Desmoncus*-type, Chenopodiaceae/Armaranthaceae, Compositae, cf. *Doliocarpus*, *Alchornea*, *Casearia*, *Acacia*, *Eugenia/Myrcia*, *Sabicea*, cf. *Pouteria*, cf. *Guazuma*), the percentages are very low, and the zone is usually between levels 488 and 456, where diversity and preservation are generally high. One quantitative feature of the section that does appear real is the very high percentage of *Synechanthus*-type palm pollen at level 377. Not only are these grains numerically abundant, but many occur in dense, anther-size clusters, indicating that this layer likely was deposited under or immediately adjacent to a dense stand of these palms. Similar clusters of *Rhizophora*, *Pelliceria*, and monolete, verrucate fern spores (Polypodiaceae, Blechnaceae) occur in other Gulf/Caribbean Tertiary deposits.

Other than the unusual, and probably fortuitous, abundance of *Synechanthus*-type palm pollen at level 377, the quantitative features of the assem-

blage do not suggest any distinct zones or significant change in vegetation other than the expected spatial reshuffling of local communities with minor changes in the landscape. The assemblage is best considered as a unit, with levels 488 to 456 most representative of the Culebra vegetation. The tabulations in Tables 1 and 2 provide the most complete listing presently available of plants and paleocommunities occurring on the volcanic islands constituting Central America ca. 20 Ma.

PALEOCOMMUNITIES

Genera identified from the Culebra Formation are arranged according to paleocommunities in Table 2. These are only approximations because the microfossils are mostly identifiable to genus, and many genera range through more than one community. On the other hand, recognition of the paleocommunities is based on the presence of characteristic genera and on the total number of genera indicative of a given assemblage rather than on single "key" members. Thus, the impact of any one assignment is reduced. Also, as data accumulate from other Tertiary fossil floras in northern Latin America, there is increasing consistency, both between floras and between the paleobotanical data and evidence derived from other independent lines of inquiry (see discussions in Graham, 1987a, b, 1988c, d) regarding the kinds of vegetation likely present in the Gulf/Caribbean region. As noted earlier, the prominent representation of wet- to moist-lowland communities, compared with higher-altitude and drier savannah-type vegetation, cannot be ascribed solely to bias in the depositional environment, because the latter communities are recorded in Gulf/Caribbean Cenozoic palynofloras.

Four paleocommunities are prominent in the Culebra flora (Table 2). The tropical moist forest is represented by 30 genera that presently occur in this community. Included is *Rhizophora*, establishing the presence of the mangrove swamp, although pollen was not abundant in this section. The maximum percentage was 10.5% at level 491.6, with an average of 5.8% for the 11 levels. This is in contrast to percentages as high as 96% in one sample from the Paraje Solo Formation of southeastern Mexico (Graham, 1976: 803, table 1). The absence of other mangrove genera such as *Avicennia*, *Conocarpus*, *Laguncularia*, and *Pelliceria* suggests: 1) the community was present but not dominant in the vicinity of the depositional basin at this time, and 2) that these sediments accumulated in an estuarian fern/palm marsh environment behind the mangrove zone. The record of *Rhizophora* can be quite variable through a section, however, reflecting changes in land/sea relationships in this tectonically active region. In January 1984, core material was received from another well drilled on the east bank of the Panama Canal just north of Gold Hill. The base of the core penetrated into the uppermost part of the Culebra Formation. The microfossils were similar to those from the core used in this study, but at level 171.65–171.9, near the transition between the Culebra and the overlying Cucaracha formations (slightly higher in the Culebra section than the material reported here), the assemblage was virtually 100% *Rhizophora*. These rapid changes in the abundance of mangrove pollen are useful in defining the position of former shorelines, and were used by Bartlett & Barghoorn (1973) to trace the history of Quaternary fluctuations in sea level in Panama. Mangrove vegetation was likely common throughout the Gulf/Caribbean region from the late Eocene onwards, even though its representation at a given locality varied with physiographic conditions.

The premontane wet forest potentially includes 25 genera, and the tropical wet forest 22 genera. Some form of the premontane moist forest (12 genera) was probably present, although the evidence is not as strong as for other lowland forests. Representation of vegetation types characteristic of higher altitudes and drier habitats (including savannahs) drops off significantly, and there is no palynological evidence for their presence. This is also true for the middle(?) to late Eocene Gatuncillo flora (Graham, 1985), and the Cucaracha (Graham, 1988b) and La Boca floras of Panama (Graham, in prep.).

Thus, the vegetation of the low-lying volcanic islands constituting present-day southern Central America ca. 20 Ma consisted of a fringing zone of mangrove vegetation, with fern and palm swamps occupying the estuaries where fresh water diluted the brackish-water habitat of the mangroves. On adjacent, better-drained slopes were versions of the tropical wet, tropical moist, premontane wet, and premontane moist forests. Very local, edaphically controlled, temporal habitats supporting drier vegetation may have been present, but there is no paleobotanical evidence for these communities in the Culebra flora.

PALEOENVIRONMENTS

Of the 41 taxa recognized for the Culebra flora, all grow in southern Central America at present. The vegetation clearly grew under climatic conditions comparable to those presently prevailing in the coastal, lowland, and moderate-altitude habitats. It is not possible to quantify precisely the lower Miocene climates of the region, but the data from Barro Colorado Island cited by Croat (1978: 3–5) and from Costa Rica cited by Coen (1983) and Fleming (1986) provide approximations of the rainfall and temperature. For Barro Colorado Island, "Under the Köppen system of climatic classifications, BCI's climate is Am, or tropical Monsoon Climate. Annual rainfall on BCI ranges from 190 to 360 cm (76 to 143 inches); between 1924 and 1962 it averaged 275 cm (107.3 inches). This compares with an average 328 cm (128 inches) at Colón, on the Atlantic coast of the Canal Zone, and 177 cm (68 inches) at Balboa on the Pacific coast, during the same period" (Croat, 1978: 3; data from Rubinoff, 1974). The vegetation of the Culebra Formation is most similar to that of the present Atlantic coast of Panama. It is obvious that the existing climatic differentiation between a moist Atlantic side and a drier Pacific side did not prevail, at least to the same degree, in the lower Miocene when the present-day isthmus consisted of a series of islands. Regarding temperature, "The atmospheric temperature may vary from as low as 16.5°C (61.7°F) to as high as 35.5°C (95.9°F), with the lowest temperature being recorded within the forest during the rainy season and the highest at the Laboratory Clearing in the dry season. With rare exceptions the temperature ranges between 21 and 32°C (70° and 90°F) throughout the year, and the average ambient temperature in the Laboratory Clearing is 27°C (77°F). The seasonal variation in monthly averages is just 2.2°C" (Croat, 1978: 3).

Fleming (1986) presented similar rainfall data for ten sites in Costa Rica. Three of these form a transect from the Atlantic coast (site 10, Limón, elevation 5 m) up the Cordillera Central (site 8, Turrialba, elevation 602 m) to the Central Valley (site 6, San José, elevation 1,172 m). The mean annual rainfall is 353.6, 264.1, and 188.9 cm for the respective sites. These elevations and climatic conditions are considered similar to those prevailing on the islands of southern Central America during the lower Miocene. A generalized illustration of my concept of the spatial distribution of lower Miocene communities in southern Central America is shown in Wake (1987: 255, fig. 14), truncated at about 1,000–1,500 m elevation.

Estimates of general climate can be evaluated to some extent by comparison with ocean surface-water temperature curves derived from ^{18}O analysis of foraminifera and other marine invertebrates (Savin, 1977; Savin & Douglas, 1985; Savin et al., 1975). The curves have been discussed recently by Graham (1987b) in relation to emerging paleobotanical data for northern Latin America. The curve shows that during the lower Miocene temperatures were generally high, consistent with the tropical conditions suggested by the Culebra (Panama) and Uscari (Costa Rica) floras. A sharp drop occurred at the end of the Miocene, and this is clearly reflected in the composition and paleoecology of the late Miocene Paraje Solo flora of southeastern Mexico (Graham, 1976).

The affinities of the Culebra flora are distinctly Central and North American. There are no exclusively South American elements present, and those growing in South America are plants widespread throughout the neotropics (e.g., *Rhizophora*). This is the expected pattern of geographic affinity because the latest connection between the North and South American continents formed only in late Pliocene times, about 3 Ma (Stehli & Webb, 1985).

These data illustrate the consistency beginning to emerge between results from paleobotanical studies in the Neotropics and data derived from other independent sources. The paleoenvironmental reconstructions and biogeographic patterns, presently based on the Uscari and Culebra palynofloras, can be further evaluated and refined when studies on two additional lower Miocene floras are completed. These are the Cucaracha and La Boca floras from the Canal region of central Panama.

STUDIES IN NEOTROPICAL PALEOBOTANY. VI. THE LOWER MIOCENE COMMUNITIES OF PANAMA—THE CUCARACHA FORMATION[1]

Alan Graham[2]

ABSTRACT

*The Cucaracha microfossil flora is the third in a series of four lower Miocene assemblages studied from southern Central America (Uscari—Costa Rica; Culebra, Cucaracha, La Boca—Panama). Nineteen palynomorphs have been identified (*Selaginella, *monolete fern spores types 1–3,* Cyathea, Ceratopteris, Pteris, *cf.* Antrophyum, *trilete fern spores types 1–2,* Crysophila *and* Manicaria*-type palm pollen,* Ilex, *Compositae,* Alchornia, Alfaroa/Engelhardia, Crudia, Eugenia/Myrcia, *and* Rhizophora*). The paleocommunities include a fern marsh, with associated palms, fringed seaward by mangroves, and bordered on the surrounding uplands by versions of the tropical wet, tropical moist, and premontane forests. Evidence for higher-altitude vegetation and communities of drier to arid aspect (open forests, savannahs) continues to be meager for Tertiary floras in the region. Affinities of the flora are distinctly Central and North American, consistent with other paleontological and biogeographic data, as well as paleophysiographic reconstructions for southern Central America. Paleoclimatic conditions were similar to those presently prevailing in coastal, lowland, and mid-altitude (1,200–1,500 m) habitats. Frequent and extensive volcanic activity documented for the region likely disrupted the vegetation, resulting in a shifting mosaic of short-term, more open communities. This may account for a paleobotanical record reflecting primarily dense forests on the slopes, while the few fossil mammalian faunas contain remains of browsers and grazers, suggesting more open forests and savannahs.*

The Cucaracha Formation is lower Miocene in age and outcrops along both sides of the Panama Canal between Hodges Hill and the Pedro Miguel Locks (Stewart & Stewart, 1980). It belongs to a complex of three Tertiary formations similar in age and lithology known to contain plant microfossils. The lowermost is the Culebra, and study of these palynomorphs has been completed (Graham, 1988). The Cucaracha Formation lies directly on the Culebra in local areas, and thus stratigraphic relationships are relatively clear, even though the region is considerably faulted. The position of the La Boca Formation is more difficult to determine because nowhere does it lie directly on the Cucaracha. However, the Pedro Miguel does overlie the Cucaracha, and in other areas it interfingers with the La Boca. Thus the three formations are presently considered sequential in age, with the Cucaracha being intermediate between the slightly older Culebra and slightly younger La Boca formations. For more detailed discussion of the geology of the pollen-bearing strata see Graham et al. (1985).

The Cucaracha Formation consists mainly of bentonitic clay shales, tuffaceous siltstones, and sandstones with lenses of conglomerates, carbonaceous shales, and lignite. A well was drilled through the formation in 1958 (Hole No. PA-33, latitude 9°01′N, longitude 79°38′W, Cucaracha Reach Widening Studies, Panama Canal Commission), and the log shows the above sequence repeated many times through the 40.8-m section. Near the base is a conglomerate containing abundant oyster shells. The sequence is typical of a tectonically active, coastal, estuarine environment, and the lignites

---

[1] *The author gratefully acknowledges R. H. Stewart, J. L. Stewart, Pastoria Franceschi S., and Numan Vasquez, Panama Canal Commission, for many useful discussions and for facilitating fieldwork in Panama in 1963–1964, 1968, 1980, 1983, and 1986. David Lellinger, Smithsonian Institution, provided spore reference material, and David Dilcher, Indiana University, J. L. Stewart, and Ralph Taggart, Michigan State University, made helpful editorial suggestions. The research was supported by NSF grants GB-11862, DEB-8007312, DEB-8205926, BSR-8500850, and BSR-8619203.*

TABLE 1. *Identification and numerical representation of fossil palynomorphs from the lower Miocene Cucaracha Formation, Panama. Figures are percentages based on counts of 100. Samples 57–59 are from the lower lignite in the section, and samples 62–66 are from the upper lignite. Samples 57 and 66 contained abundant fungal spores, and preservation of pollen and other spores was fair to poor.*

indicate warm-temperate to tropical conditions. Extensive vulcanism is indicated by the tuffs (waterlain volcanic ash) and the basalt that caps the section.

THE COLLECTING LOCALITY

Samples were obtained from a roadside exposure along road K-2, about 0.8 km northwest of the intersection with K-15 in the Gaillard Cut section of the Canal. At this site there is a small utility building, and about 4 m above and to the left is a conspicuous conglomerate layer about 1 m thick (see figs. 7, 8 in Graham et al., 1985). This layer terminates abruptly and continues on the other side of the building about four meters lower in the section. This is one of the many minor faults in the region and is a convenient marker for the locality. Ten samples were collected (our locality C, samples 57a–66) and seven contained plant microfossils. Three of these (57–59) came from a 0.6-m layer of lignitic shale about six meters below the conglomerate and to the right (facing the slope) of the utility building. Four (62, 63, 65, 66) came from a similar lignitic shale about four meters above the conglomerate; all samples were spaced horizontally about two meters apart. About 0.7 km further to the right (NW) is the site from which Whitmore & Stewart (1965) reported a mammalian fauna from the Cucaracha Formation, all with distinct North American affinities.

MATERIALS AND METHODS

Extraction and processing techniques are described in Graham (1985). Slides are labeled Pan C, Cucaracha, sample, and slide number (e.g., Pan C, Cucaracha, 66, 1). Location of specimens on the slides is by England Slide Finder coordinates (e.g., ESF R-34, 3–4). All materials are deposited in the palynology collections at Kent State University.

SYSTEMATICS

Nineteen palynomorphs have been identified from the Cucaracha assemblage (Table 1), and two others were recovered whose biological affinities could not be established (unknowns types 1 and 2). Illustrations, descriptions, and other data are provided for each pollen/spore type, but since all have been recovered from other Gulf/Caribbean Tertiary formations, the information is synoptic, and references are provided to more detailed discussions. These formations, with references, are as follows: Gatuncillo (middle(?) to late Eocene, Panama; Graham, 1985), San Sebastian (middle to late Oligocene, Puerto Rico; Graham & Jarzen, 1969), Uscari (early Miocene, Costa Rica; Graham, 1987a), Culebra (early Miocene, Panama; Graham, 1988), and Paraje Solo (late Miocene, southeastern Veracruz, Mexico; Graham, 1976). A map of the geographic distribution and a chart summarizing the age of the formations are given in Graham (1987b; for other aspects of the identification procedures see Graham 1985: 507–508). Present ranges of the modern analogs within the Neotropics and ecological data are summarized after each description, with more detailed summaries provided in the paleobotanical publications previously cited. These data are based on field observations, personal communication with specialists in the various plant groups, and the literature, especially Croat (1978), D'Arcy (1987), Hartshorn (1983), Tryon & Tryon (1982), and Woodson & Schery (1943–1980). Terminology for vegetation types follows Holdridge (1947; Holdridge et al., 1971), used by Croat (1978) and Hartshorn (1983) for describing the plant communities of Panama and Costa Rica.

SELAGINELLACEAE

Selaginella (Figs. 1, 2). Spherical, amb circular to oval-triangular; trilete, laesurae frequently obscured by dense sculpture and appearing monolete, straight, narrow, ca. 20–24 μm long, extending nearly to spore margin; echinate, echinae short (ca. 2–3 μm), occasionally curved, dense, bases broad; wall ca. 2 μm thick (excluding echinae); 26–30 μm.

Other occurrences. Gatuncillo, San Sebastian, Uscari, Culebra, Paraje Solo formations.

Distribution. Widespread; usually moist, shaded habitats; typically low to mid altitudes but widespread altitudinally.

MONOLETE FERN SPORES

These spore types are produced by many members of the Blechnaceae and Polypodiaceae and cannot be referred to any one modern genus, especially in the absence of the ornamented exospore or perine. They are often assigned to the artificial genera *Laevigatosporites* (smooth forms) or *Verrucatosporites* (verrucate forms), and these range from Paleozoic to Recent. They occur in all of our Gulf/Caribbean Tertiary deposits studied to date, and multiple biological species are likely represented by each of the spore types described below.

Type 1 (Figs. 3, 4). Reniform; monolete, laesurae straight, narrow, 24–28 μm long, extending ca. ¾ spore length, inner margin entire; laevigate; 40–50 × 30–40 μm.

This is one of the most abundant spores in the Cucaracha Formation, although percentages vary widely among the samples (Table 1). Figure 4 is a low-magnification view of part of a single field (negative-size portion) typical of samples where the spore is dominant. Ten specimens are evident in this field, and a thousand or more may occur on a slide.

Type 2 (Figs. 5, 6). This spore differs from Type 1 in having a slightly thicker wall and, therefore, is more consistently reniform in shape. The specimens range in size from 35 × 20 μm (Fig. 5) to 42 × 32 μm (Fig. 6).

Type 3 (Figs. 7–11). Reniform; monolete, laesura straight, narrow, 30–45 μm long, extending ¾ spore length, inner margin entire; verrucate, verrucae moderately low, conspicuous and dense, grading into less dense, widely spaced verrucae, shape irregular, ca. 3 × 6 μm; wall 2–3 μm thick; 35–55 × 25–35 μm.

This is another spore that is dominant in several samples, almost to the exclusion of other microfossils (Table 1). In addition to individual specimens, many clusters of 5–20 loosely aggregated spores were evident on the slides (Fig. 7). This indicates that the Cucaracha sediments at this locality were accumulating directly under or immediately adjacent to a fern marsh, with little transport of the specimens.

The spores vary in size and density of the verrucae. Figure 8 illustrates a small specimen (ca. 37 μm), and Figure 9 a larger one (ca. 54 μm), while comparison of Figure 8 with Figure 11 shows the variation in the number of verrucae. Similar spore variation occurs within species as well as among species and genera of modern Blechnaceae and Polypodiaceae. As noted previously, more than one biological species, or genus, is likely represented by this spore type.

TRILETE FERN SPORES

Cyatheaceae

Cyathea. Amb oval-triangular, apices rounded; trilete, laesurae straight, narrow, 14–16 μm long, extending to spore margin, inner margin entire, bordered by lip 2–3 μm wide with punctae 1 μm diam.; distal surface finely punctate, proximal surface more laevigate near laesurae; wall 1.5–2 μm thick; 30–35 μm.

6

7

8

A few poorly oriented specimens of *Cyathea* were recovered from sample 66, but the genus is frequent in other Caribbean Tertiary deposits. According to Gastony & Tryon (1976) and Tryon & Tryon (1982: 207), the micropunctate forms represent *Cyathea*, while similar but smooth (laevigate) types are referred to the closely related *Alsophila*.

Other occurrences. San Sebastian, Culebra, Paraje Solo formations.

Distribution. Widespread, primarily montane forests and cloud forests; in Central America low rain forests usually at 1,500–2,000 m, but as low as 500 m.

Pteridaceae

Ceratopteris (Figs. 14, 15). Amb oval-triangular, spore margin undulating due to projecting sculpture elements; trilete, laesurae straight, narrow, 28–32 μm long, extending to spore margin, inner margin entire; wall coarsely and conspicuously striate, striae psilate, 3–4 μm wide, prominently developed on distal surface, less distinct approaching laesurae; wall 2–3 μm thick; 75–90 μm.

Other occurrences. Gatuncillo, Paraje Solo formations.

Distribution. Widespread, southeastern U.S. (Texas to Florida), southern Mexico, Central America, Antilles, South America; frequently aquatic, ditches, lagoons, river/lake margins, brackish waters; sea level to ca. 300 m.

Pteris (Fig. 13). Amb triangular, apices rounded; trilete, laesurae straight, narrow, 15–18 μm long, extending to spore margin, inner margin entire; distal surface with coarse, irregular verrucae, proximal surface more laevigate, flange ca. 6 μm wide, hyaline; wall 2 μm thick; 42–48 μm.

Other occurrences. Gatuncillo, San Sebastian, Uscari, Culebra, Paraje Solo formations.

Distribution. Mexico, Central America, the Antilles, and South America; openings or along margins of wet or cloud forests; sea level to ca. 2,000 m.

Vittariaceae

Cf. *Antrophyum* (Fig. 12). Amb triangular, apices rounded; trilete, laesurae relatively small in relation to spore diameter, straight, narrow, 12–15 μm long, extending ca. ⅔ distance to spore margin, inner margin entire; laevigate; wall ca. 1.5 μm thick; 47–54 μm.

Other occurrences. San Sebastian (not figured in Graham & Jarzen, 1969), Culebra, and Paraje Solo formations.

Distribution. Hidalgo, Mexico, Central America, and the Antilles, to northern Argentina and southeastern Brazil; rain and cloud forests; elevations usually 100–1,500 m.

OTHER TRILETE FERN SPORES

Type 1 (Fig. 16). Amb oval-triangular; trilete, laesurae straight, narrow, 14–16 μm long, extending to or nearly to spore margin, inner margin entire; finely reticulate, reticulum becoming more irregular near laesurae; wall ca. 1.5 μm thick; 27–30 μm.

Other occurrences. Possibly Culebra Formation (larger specimen).

Type 2 (Figs. 17, 18). Amb oval-triangular; trilete, laesurae straight, narrow, 15–17 μm long, extending to or nearly to spore margin, inner margin entire; punctate, punctae circular (ca. 1 μm) to elongated (2–3 μm), slitlike and sinuous; wall 2 μm thick; 33–36 μm.

Other occurrences. Possibly Culebra Formation (larger specimen with more conspicuous slitlike punctae).

PALMAE

Crysophila-type (Fig. 19). Prolate, amb oval; monocolpate, colpus straight, 22–24 μm long, extending entire length of grain, margin entire; tectate-perforate, wall 2 μm thick; reticulate, muri relatively broad (ca. 1–1.5 μm), flat, lumen ca. 2 μm in diameter on distal side, smaller approaching colpus; 31–33 × 18–20 μm.

Other occurrences. Culebra Formation.

Distribution. Belize to Panama; tropical wet, tropical moist, premontane wet forests; low altitudes.

Manicaria-type (Figs. 20–22). Prolate; monocolpate, colpus straight, 30–36 μm long, extending nearly entire length of grain, inner margin entire; scabrate (to possibly microreticulate); trilete, wall 1.5 μm thick; 36–45 × 20–24 μm.

Other occurrences. Gatuncillo, Culebra formations.

Distribution. Antilles, Central and South America; wet places; low altitudes.

Another palm pollen of the *Manicaria*-type was recovered but differs in size (25 vs. 36–45 μm; Figs. 23, 24).

AQUIFOLIACEAE

Ilex (Fig. 25). Oblate-spheroidal, amb circular; tricolporoidate, colpi straight, 18 μm long, equatorially arranged, meridionally elongated, equidistant, inner margin diffuse, pores obscure, situated at midpoint of colpus; intectate; clavate, wall ca. 3 μm thick (length of clavae); 27 × 22 μm.

Other occurrences. Gatuncillo, San Sebastian, Uscari, Culebra, Paraje Solo formations.

Distribution. Widespread; mesic to slightly drier habitats; low to mid altitudes; Costa Rica—tropical and premontane wet lowlands, montane rain forest.

COMPOSITAE

(Figs. 26–28). Spherical, amb circular; tricolporate, colpi straight, short (ca. 10 μm), equatorially arranged, meridionally elongated, equidistant, pore oval, ca. 4 × 2 μm, situated at midpoint of colpus; tectate, wall 2–3 μm thick; echinate, echinae short (ca. 2–3 μm), base broad, moderately dense (distance between spines ca. 3–4 μm); 23–27 μm.

Other occurrences. Uscari (rare), Culebra (rare), and Paraje Solo (relatively common) formations.

EUPHORBIACEAE

Alchornea (Fig. 29). Oblate, amb circular; tricolpate, colpi straight, 8–10 μm long (pole to equator), equatorially arranged, meridionally elongated, equidistant, extending within 6–7 μm of pole, inner margin entire, distinct operculum; tectate, wall 2 μm thick; psilate to faintly scabrate; 15–21 μm.

Other occurrences. San Sebastian, Uscari, Culebra, Paraje Solo formations.

Distribution. Widespread; Panama—tropical moist, premontane wet, premontane rain forests; Costa Rica—alluvial soil in tropical wet lowlands, mid-altitude wet and rain forests, altitude range 300–2,000 m.

JUGLANDACEAE

Alfaroa/Engelhardia (Fig. 30). Oblate, amb oval-triangular; triporate, pores circular, ca. 2 μm, inner margin entire, equatorially arranged, equidistant; tectate, wall 1.5 μm thick; psilate; 21 μm.

Other occurrences. Gatuncillo, San Sebastian, Paraje Solo formations.

Distribution. Mexico, Central America; typically associated with lower to mid-altitude temperate forests.

LEGUMINOSAE

Caesalpinioideae

Crudia (Fig. 31). Prolate; tricolporoidate, colpi narrow, straight, 25 μm long, extending nearly entire length of grain, equatorially arranged, meridionally elongated, equidistant, pore area faint, circular, situated at midpoint of colpus; tectate but with occasional separation between sculpture elements, wall 1.5 μm thick; distinctly and coarsely striate, striae generally oriented parallel to long axis of grain, surface psilate, margins entire, occasionally appearing beaded from underlying pores in foot layer/endexine; 32 × 20 μm.

Other occurrences. Gatuncillo Formation.

Distribution. Mainly Amazonian, often riverine; low altitude.

MYRTACEAE

Eugenia/Myrcia (Fig. 32). Oblate to peroblate, amb triangular; tricolporate, colpi narrow, straight, 9 μm long, equatorially arranged, meridionally elongated, equidistant, syncolpate, pore ca. 1 μm diam., situated on equator at midpoint of colpus; tectate, wall thin (ca. 1.5 μm); faintly scabrate; 18 μm.

Other occurrences. Gatuncillo, San Sebastian, Uscari, Culebra, Paraje Solo formations.

RHIZOPHORACEAE

Rhizophora (Figs. 33, 34). Prolate to prolate-spheroidal; tricolporate, colpi narrow, straight, 14-16 µm, apices acute, equatorially arranged, meridionally elongated, equidistant, costae colpi ca. 3 µm, pores elongated equatorially (colpi transversalis), 1 × 4 µm, constricted at midpoint of colpus, inner margin entire; tectate-perforate, wall 2-3 µm thick; finely reticulate; 18-25 × 16-20 µm.

Other occurrences. Gatuncillo, San Sebastian, Uscari, Culebra, and Paraje Solo formations.

Distribution. Widespread, southeastern U.S. to South America; warm-temperate to tropical habitats, coastal brackish waters; sea level.

UNKNOWNS

Type 1 (Figs. 35, 36). Oblate, amb circular; tricolporate, colpi narrow, straight, 6-8 µm long, equatorially arranged, meridionally elongated, equidistant, syncolpate, pores circular to slightly elongated equatorially, costae pori, situated on equator at midpoint of colpus; tectate-perforate, wall ca. 2 µm thick; finely reticulate; 16-20 µm.

Type 2 (Figs. 37-39). Prolate; tricolporate, colpi straight, 40-48 µm long, equatorially arranged, meridionally elongated, equidistant, inner margin entire, costae colpi 5-7 µm wide, pore slightly oval, 3 × 5 µm, situated at midpoint of colpus; tectate-perforate, wall 2 µm thick; finely reticulate; 43-55 × 30-42 µm.

Other occurrences. Gatuncillo, Culebra, and Paraje Solo formations.

NUMERICAL REPRESENTATIONS

A total of 700 palynomorphs were tabulated from the Cucaracha material (100 from each of the seven samples; Table 1). Normally 200 pollen grains and spores are counted, but in the Cucaracha assemblage each sample was dominated by a single type, with all other forms collectively constituting only a small percentage of the flora. The most abundant microfossils were monolete fern spore type 3, monolete fern spore type 1, *Rhizophora*, and *Manicaria*-type palm pollen. Vascular cryptogams (ferns and *Selaginella*) totaled 71% of the flora, *Rhizophora* 17%, palms 9%, and all other angiosperm pollen 3%. Clearly, the sediments accumulated in a fern marsh with palms surrounding

and possibly intermingling with the ferns and with mangrove (*Rhizophora*) growing along the seaward margin of the depositional basin. It was a simple ecosystem in terms of community types, with little pollen of other associations being blown or washed into the basin from the surrounding landscape.

Another quantitative feature of the Cucaracha flora is the rapid change in this coastal vegetation over very short periods of time. Samples 57, 58, and 59 were from a lower lignite bed about 0.6 m thick. All samples were taken from about the middle of the seam and horizontally were about two meters apart. Yet sample 57 contained about 60% *Rhizophora* pollen, sample 58 had 65% type 3 monolete fern spores (with only 13% *Rhizophora*), and sample 59 had 62% type 1 monolete fern spore (with only 7% *Rhizophora* and 16% type 3 fern spore). The vertical difference between the samples was, at maximum, only a few centimeters, and in a rapidly accumulating, estuarine sedimentary basin this likely represents only a few to several hundred years. Within this brief time span, three different taxa dominated the site. The upper lignite layer was more uniform in composition, with monolete fern spore type 3 dominant in all samples (Table 1). Among the seven samples from the two lignite layers, *Rhizophora* ranged from absent (sample 63) to 60% (sample 57); monolete fern spore type 1 from 62% (sample 59) to 1% (sample 65); and monolete fern spore type 3 from 77% (samples 63, 65) to 6% (sample 57). There were apparently some habitat differences within and between the lignite layers, as well as differences in ecological preference between the ferns, because the percentages of monolete fern spore types 1 and 3 were reciprocal. These fluctuations evident in the pollen and spore assemblage are typical of estuarine habitats in tectonically unstable regions. Slight elevation of the land surface (or lowering of sea level) drains the lowlands marginal to the coast of salt water, and ferns dominate the freshwater habitats provided by inflowing rivers. With land subsidence marshes are inundated, the waters rendered brackish, and mangroves dominate the site. This sequence is repeated many times through the Culebra Formation, as evidenced by the alternating layers of lignites and lignitic shales; mud-, silt-, and sandstones; water-lain volcanic ash (tuffs); and the basal oyster-rich conglomerate.

PALEOCOMMUNITIES AND PALEOENVIRONMENTS

A limited number of paleocommunities are revealed by the Cucaracha flora. A fern marsh, with associated palms and the floating fern *Ceratopteris*, are well represented. This freshwater assemblage was fringed seaward by mangroves (*Rhizophora*). Some indication of the inland vegetation is provided by a few spores of the tree ferns *Cyathea* and *Pteris*, and small amounts of pollen of *Alchornea*, *Alfaroa/Engelhardia*, Compositae, *Crudia*, *Eugenia/Myrcia*, and *Ilex*. These suggest tropical wet, tropical moist, and premontane forests on the adjacent slopes. It is likely that higher-altitude vegetation was meager, and its absence to poor representation in the microfossil record not just the result of exclusion from the sedimentary process. In other palynofloras (e.g., the San Sebastian flora of Puerto Rico and the Paraje Solo flora of Mexico), representatives from mid- to higher-altitude communities are common. Their poor representation in the Cucaracha flora is probably an accurate reflection of the kinds of communities occupying the low, insular landscape in the region at the time.

Pollen grains of the Gramineae, other species associated with savannah habitats, and dry to arid vegetation were not recovered, consistent with results from other Tertiary floras in Central America.

The paleoenvironment can only be characterized generally as tropical and probably similar to that presently prevailing at lower altitudes in the region (see Graham, 1985: 531–532). All palynomorphs recovered from the Cucaracha Formation occur in the modern vegetation of Panama.

TERTIARY FLORAS, FAUNAS, AND VOLCANISM IN SOUTHERN CENTRAL AMERICA

As data accumulate on the Tertiary floras of northern Latin America, it is becoming evident that little *paleobotanical* evidence is emerging for extensive savannah or open-forest habitats. The limited data do not preclude, however, more local, shifting, temporal stands of these communities in the Central American landscape. Such accommodation is necessary because of a seemingly anomalous situation developing between the kind of vegetation reflected in the Tertiary floras of Central America and the kind of habitats required by the few mammalian faunas known from the area. The palynofloras suggest that tall, dense tropical forests were prevalent on adjacent upland slopes, while the vertebrate faunas contain significant numbers of browsers (low open forests) and grazers (savannahs).

Tertiary palynofloras from Central America (see chart in Graham, 1987b) contain little or no grass pollen, or pollen of trees or shrubs characteristically associated with open forests or savannahs. An exception may be the few grains of *Acacia* pollen found in the Paraje Solo and Culebra floras. Bartlett & Barghoorn (1973) found little evidence for savannah or drier open forests in Quaternary sediments from Gatun Lake, Panama, but Leyden (1984) reported the presence of more arid vegetation from Pleistocene deposits in Guatemala. The latter report, and the very small amounts of grass and *Acacia* pollen in Tertiary sediments, indicate that the list of Cenozoic paleocommunities for the region is still being developed. Nonetheless, the principal communities in the Cucaracha flora were likely the tropical moist, tropical wet, and premontane forests, with mangroves and fern and palm marshes occupying coastal and swamp habitats.

In contrast, browsers and grazers are the prominent components in the two principal Tertiary vertebrate faunas reported from Central America. Olson & McGrew (1941) described a fauna from the Pliocene Gracias Formation, in the Mejocote Valley of Honduras. In addition to *Amphicyon*, *Procamelus* (camel), and *Blickotherium* (mastodon), the most common remains were of the horses *Pliohippus* and *Neohipparion*. Whitmore & Stewart (1965) described a fauna from the Cucaracha Formation, ca. 0.7 km from the plant microfossil locality. In addition to the marsh- and swamp-inhabiting turtle and alligator remains, they reported five browsing ungulates: Equidae (*Anchitherium*, *Archaeohippus*), Rhinocerotidae (*Diceratherium*), Merycoidodontidae (*Merycochoerus*), and Protoceratidae (a selenodont artiodacytyl).

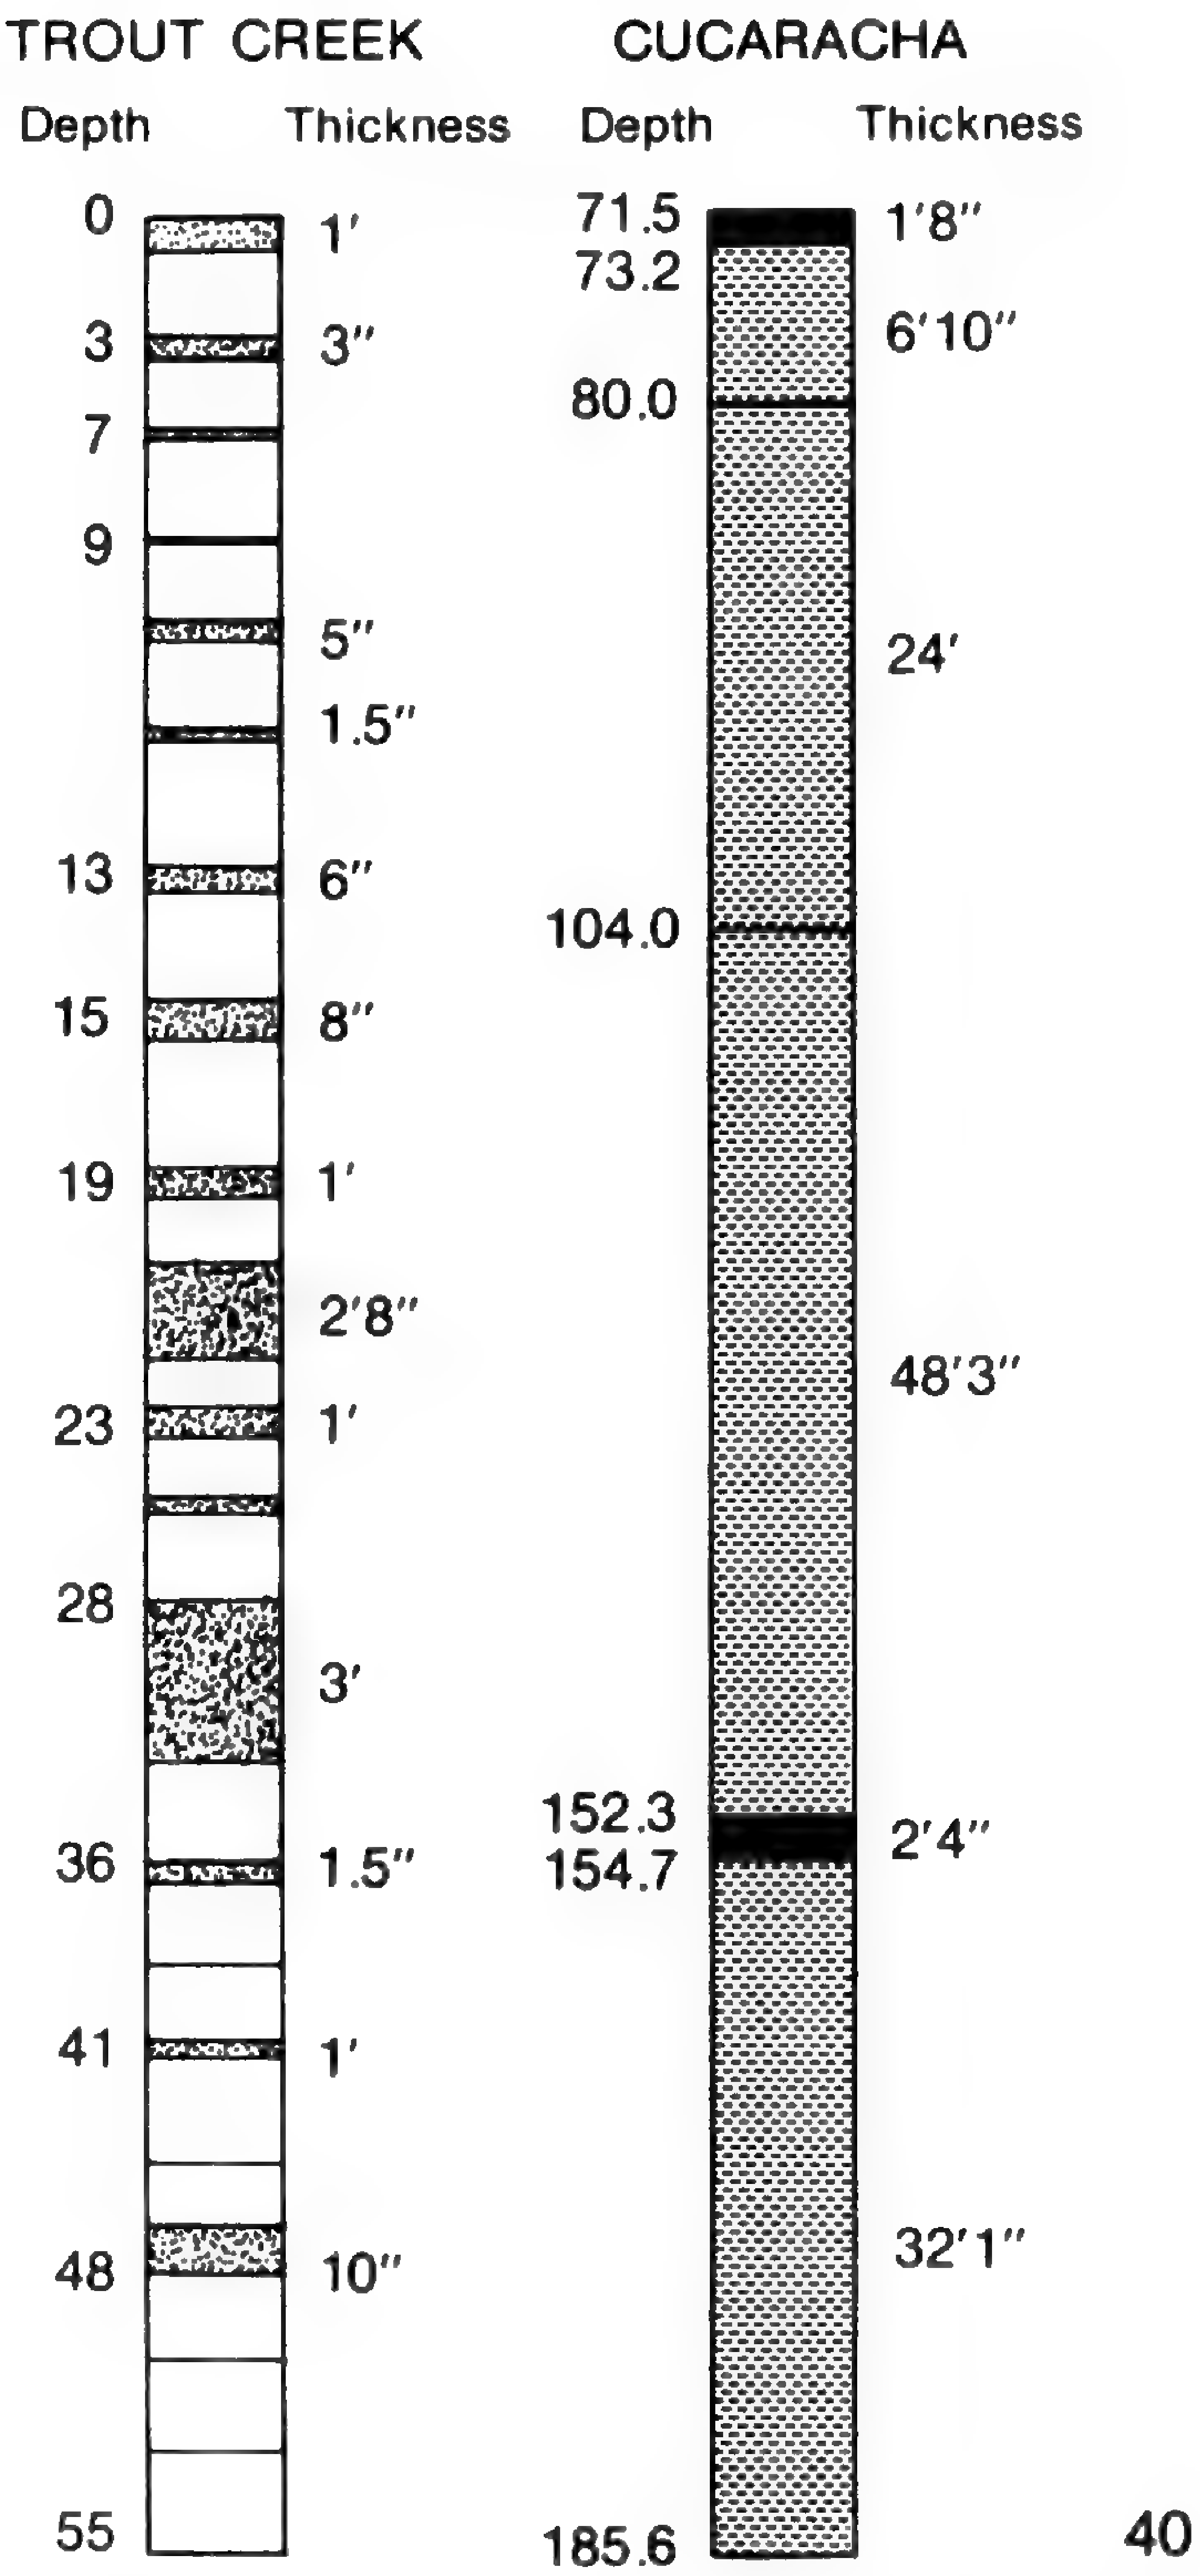

FIGURE 40. *Stratigraphic sections from the Trout Creek (late Miocene, Oregon) and Culebra (early Miocene, Panama) formations. White = diatomite; stippled = sandstone and sandy volcanic ash; black = lignite, lignitic shale, or highly carbonaceous clay-siltstone; dashed = tuffs (water-lain volcanic ash) or clay-siltstones derived from erosion of tuffs. In both sections the plant megafossils (Trout Creek) and microfossils (Culebra) are associated with sediments indicative of frequent and extensive volcanic activity.*

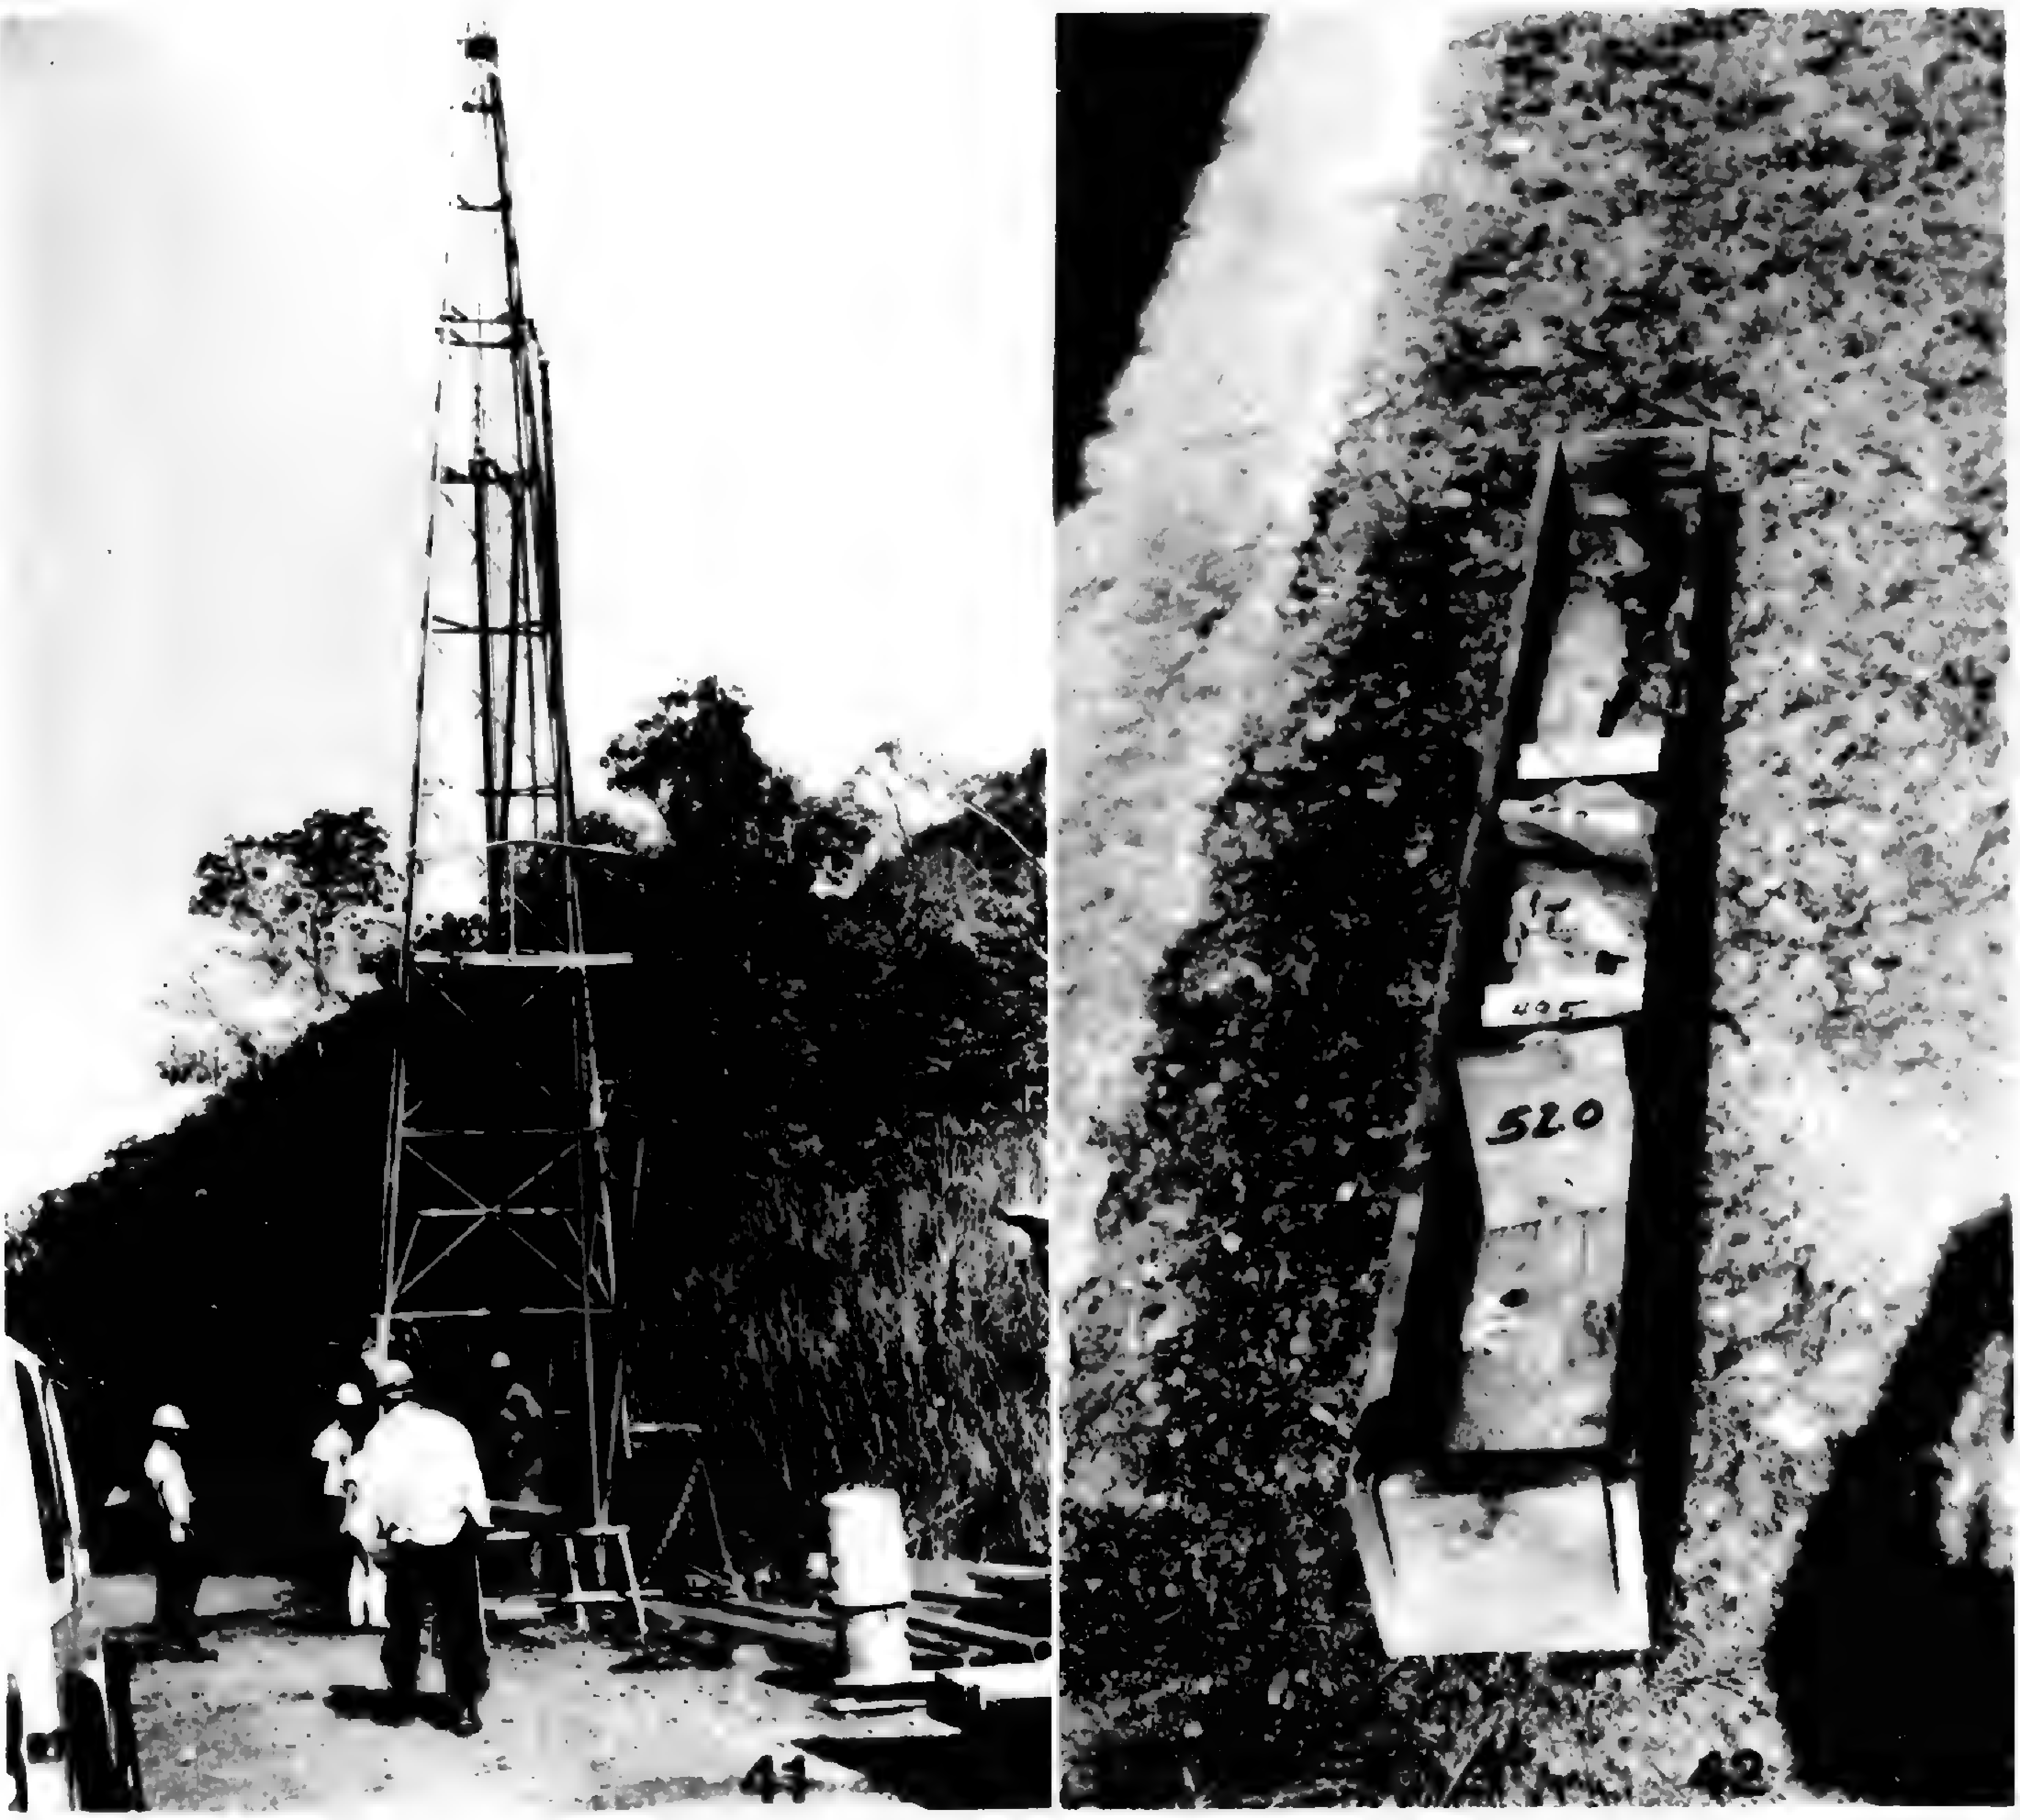
The situation wherein fossil floras suggest forest while faunas, including the near-contemporaneous and adjacent Cucaracha fauna, reflect open forest and savannah on the uplands, is similar to that in the Tertiary biota of the western United States. A tentative explanation suggested for that region may apply to southern Central America. In a study of the Miocene Trout Creek flora of southeastern Oregon (Graham, 1963, 1965), representative megafossil species were not uniformly distributed through the 17-m section. In the middle part of the section there were numerous layers of sand and volcanic ash. Toward the top and bottom, the number and thickness of the ash layers decreased (Fig. 40). Megafossils were abundant in the upper and lower portions and were much less common in the middle part, where volcanic activity was greatest. Clearly the plant communities were disrupted by ejection of quantities of volcanic ash, the deforestation allowing sands to wash into the depositional basin from the surrounding landscape. Taggart et al. (1982; Taggart, pers. comm., 1987) suggested that the browsing and grazing faunas that characterize the middle and late Tertiary of western North America were exploitive, flourishing during recovery periods when open habitats were more extensive. The reduced vegetation, unfavorable preservation conditions in the accumulating sandy ash layers, and the relatively brief time spans involved minimized the representation of this recovery vegetation in the plant fossil record. During intervening times when volcanic activity was less,



FIGURES 41, 42. *Drilling operations and resulting core from the Cucaracha Formation, Canal region, Panama.—41. Portable drill from truck bed.—42. Core from the Cucaracha Formation. Logs from these cores provide the descriptive lithologies (e.g., Fig. 40) used to characterize the general depositional environments of the microfossil assemblages. Photographs taken January 1986.*

forests became more extensive and contributed the abundant plant remains preserved in the diatomite. Another factor is the resistant nature of the faunal remains favoring preservation, transport, and accumulation in the depositional basin.

Figures 41 and 42 illustrate the coring device and the cores derived from the Cucaracha and other Tertiary formations in the Canal region of Panama. A description of the lithologies along these cores is kept by the Panama Canal Commission in the form of drill logs. A portion of one log from the Cucaracha Formation is presented by Graham et al. (1985: 495, table 3) and is summarized in Figure 40. It is clear that volcanic tuffs (water-lain volcanic ash) are common throughout the section (e.g., at levels 154.7′, 104.0′, 80′, and 73.2′), and the same is true for other Tertiary formations in Panama. Basalt also caps many of the sections. If the pattern of Tertiary faunas with significant numbers of browsing and grazing elements, and Tertiary floras reflecting forested vegetation, persists in future studies, a shifting mosaic of brief, open, recovery vegetation in this volcanically active region may afford a reasonable explanation for the apparent differences in habitats suggested by the floral and faunal evidence.

CUPULAR STRUCTURE IN PALEOTROPICAL *CASTANOPSIS* (FAGACEAE)[1]

Robert B. Kaul[2]

ABSTRACT

The structure and some developmental aspects of the cupules of 22 species of paleotropical Castanopsis *are discussed and illustrated. Some species have cupules massively invested with strong, sharp spines, but others are less spiny, and some are nearly smooth. Most cupular armament results from spines produced axillary to the valvular scales and basally adnate to them. Columns of scales straddling the sutures between the cupular valves do not become spines, but the numerous scales elsewhere on the valves become somewhat spiny with age. Dehiscence in the spiny-valved species is mostly along the sutures. The smooth cupules of some species have scales in their early stages, but cupular expansion separates and tears them; such species are often indehiscent or only irregularly dehiscent and usually show nearly complete adnation of the cupule to the nut.*

Castanopsis is the third largest genus in the Fagaceae, after *Quercus* and *Lithocarpus* in their broad sense. Most of the approximately 120 species recognized by Camus (1929) and Barnett (1944) are paleotropical, but a few occur as far north as northeastern China, Korea, and Japan, and some ascend the Himalayas. For Malesia (the Malay Peninsula and all the islands from Sumatra to New Guinea and the Philippines) Soepadmo (1968, 1972) recognized 34 species and mapped species density. In Malesia, Borneo has the most species (21) and the most endemics (10); Sumatra and Java have 11 and 4 species, respectively, none endemic; and the Philippines have 4, including one endemic. Only two—*C. buruana* and *C. acuminatissima*—occur east of Wallace's Line between Bali and Lombok. Barnett (1942) found only one endemic species among the 16 she recognized for Thailand. About 25 are known from China, mostly from the southern provinces. The eight or nine mostly endemic Taiwanese species are taxonomically well studied (Li, 1963; Lin & Liu, 1965; Liao, 1971; Liu & Liao, 1976). One species (*C. cuspidata*), represented by two varieties, occurs in Japan (Ohwi, 1965). The one or two species outside Asia and nearby islands occur in western North America and are sometimes given their own genus, *Chrysolepis*, based largely upon cupular structure; palynologically they are indistinguishable from *Castanopsis* (Erdtman, 1943; Crepet & Daghlian, 1980), and foliar distinctions are weak (Jones, 1986). *Lithocarpus*, closely related and with perhaps 300 species, has a remarkably similar geographic distribution, including a single species in western North America.

Castanopsis in Malesia is characteristic of forests without strongly seasonal climates, but in Java and Thailand some species occur in seasonal climates (Hjelmqvist, 1968; Soepadmo, 1972). Twelve of the 34 Malesian species are restricted to lowland forests, and the others are in lowland and montane forests. Barnett (1942) and Hjelmqvist (1968) noted that the species of Thailand are found mostly in the uplands. Most paleotropical species of *Castanopsis* grow in mixed forests that often include *Lithocarpus* and *Quercus*, but *C. acuminatissima* forms nearly pure stands in New Guinea (Soepadmo, 1972; Whitmore, 1975; Paijmans, 1976). The genus is prominent in subtropical forests of China (Wang, 1961). The northeastern Asiatic and western North American species are sometimes abundant in the forests and are, of course, subjected to more seasonal climates than are most paleotropical species.

Pollination by small insects is suggested by their abundance around the rather strong-smelling, conspicuous staminate flowers, but some pollen might be wind-transported. It is not clear how the incon-

spicuous, presumably odorless pistillate flowers attract insects; perhaps they are pollinated only incidentally to insect movements among the far more numerous staminate flowers around them.

The published infrageneric classifications of *Castanopsis* are based mostly upon fruit characters, as is the case for other fagaceous genera. Camus (1929) recognized three sections in *Castanopsis*: *Eucastanopsis* (cupule spiny, dehiscent or indehiscent, the nuts not fused to it); *Callaeocarpus* (cupule with or without spines, the nuts fused to it for most of their length); and *Pseudopasania* (cupule thin, dehiscent, containing a single free nut). The last group includes *C. acuminatissima.*

Barnett (1944) saw the genus as comprising 11 groups in Asia and nearby islands, but she did not give them formal taxonomic rank. She defined them by degree of adnation of the cupule to the nuts, ornamentation of the cupule, size of the scar of the nuts, size of the fruits, and foliar characters. She included the small "*fissa*-group" in *Castanopsis,* noting that it forms a connecting link to *Lithocarpus*; Forman (1966a, b) also aligned the *fissa*-group with *Castanopsis,* noting its strong alliance with *C. acuminatissima,* but Camus (1929) placed those species in *Lithocarpus* subg. *Pseudocastanopsis.* Thus these authors recognized the close affinity of *Castanopsis* to *Lithocarpus,* and Barnett (1940) suggested that recognition of two genera is perhaps more artificial than natural. Jones (1986) supported the placement of the *fissa*-group in *Castanopsis,* based upon his detailed study of foliar characteristics in the family.

Camus (1929) suggested that *Castanopsis* is closer to *Lithocarpus* than *Lithocarpus* is to *Quercus,* and recent foliar and palynological evidence supports her interpretation (Jones, 1986; Zavada & Dilcher, 1986). (*Lithocarpus* and *Quercus* are usually interpreted as distinct from each other, but exhibit many parallel traits.) The affinity of *Castanopsis* to *Castanea* is undoubtedly close.

Hjelmqvist (1948, 1968) and Forman (1966a, b) saw *Castanopsis* and *Lithocarpus* as distinct, noting the differences between the dichasium-cupule, which encloses all the flowers of a cymule in *Castanopsis,* and the flower-cupule enclosing individual flowers of a cymule in *Lithocarpus.* They interpreted the dichasium-cupule as a product of phylogenetic fusion of flower-cupules, and the dichasium-cupule of the one-flowered cymules of the *fissa*-group and other species thus as indistinguishable from a flower-cupule. The valveless cupules of *Lithocarpus* and *Quercus* are apparently morphologically identical also, but Forman (1966a) suggested that they are convergently derived, the cupule of *Lithocarpus* being a true flower-cupule and that of *Quercus* being a one-flowered dichasium-cupule whose lateral flowers have disappeared. However, there is no direct evidence for that in *Quercus*; rather, it was based upon comparative study of other genera, especially *Trigonobalanus daichangensis.* Some species of *Lithocarpus* show partial to nearly complete fusion of flower-cupules in the cymules, resulting in partial dichasium-cupules (examples illustrated in Kaul, 1987), which Forman (1966a) interpreted as phylogenetically parallel to the dichasium-cupules of *Castanopsis.*

In *Castanopsis* the cupular primordia are rather well developed by anthesis (but less so than in *Castanea*). The mature cupule encloses the one to seven nuts and often has distinct vertical sutures that define the cupular "valves," at the edges of which dehiscence often occurs (such features are not found in *Lithocarpus* and *Quercus*). However, variations in these and other characteristics occur within and between species.

The origin and structure of the fagaceous cupule have had various interpretations; Abbe (1974), Okamoto (1982), and Fey & Endress (1983) reviewed the literature, in which it is implied that the cupule has arisen but once. Most workers interpret it as derived from pre-existing structures, not as a structure *de novo.* Whatever the origin of the cupule, it now has some qualities and functions unlike those of its ancestral parts. Fey & Endress (1983) found that ontogenetic observations in *Castanea, Fagus,* and *Quercus* revealed more orderly arrangement of cupular appendages than is evident at maturity. This is true for *Castanopsis* too, in which the mature cupule is often massively invested with rigid spines and other structures that obscure positional relationships. *Castanopsis* is largely unstudied developmentally, but floral development in *C. cuspidata* var. *sieboldii* of northeastern Asia and Japan has been shown in detail (Okamoto, 1983). *Castanea* has been the subject of several developmental studies, most recently by Fey & Endress (1983).

Many species of *Castanopsis* have spiny cupules, but in others spines are barely evident or absent, and the cupule is then smooth and figlike. Forman (1966a) interpreted the spines as emergences, not foliar homologues. Barnett (1940) noted that they do not appear to be the first cupular appendages to form, but develop later, often in the axils of the "scales." Fey & Endress (1983) interpreted spines of *Castanea* as axillary branch systems.

The patterns of distribution and elaboration of

cupular scales, spines, and sutures vary among the species, and the functional and phylogenetic significance of the various patterns is not known. Forman (1966a) interpreted as primitive in *Castanopsis* the three- or more-flowered cymule; the four-valved cupule dehiscing between the valves; the spines branched, well developed, and in definite rows; and the cupule not adnate to the nut(s). Those characteristics are most common in paleotropical species. He saw derived conditions in the one-flowered cymule, the two-valved cupules, irregular dehiscence not along valve sutures, the spines absent or reduced and not in obvious rows, and the cupule fused to the nut(s). Those attributes occur in paleotropical and palearctic species. He also interpreted the American species as primitive because the valves are free, and some occur between the flowers of a cymule—characteristics used to distinguish *Chrysolepis* from *Castanopsis.* Hjelmqvist (1948) reported remnants of walls between the nuts in the cupules of *Castanopsis hullettii* and *C. fabri.*

Hjelmqvist (1948) interpreted one-flowered, three-parted cupules as originating by the union of three flower cupules, one middle and two lateral cupules. He suggested that in four-parted cupules the middle cupule is reduced and the remaining common (dichasium) cupule is four-parted, the parts corresponding to two bipartite, lateral cupules. Dehiscence then occurs along the longitudinal fissures through the middle of the part-cupules and at the border between the two anterior cupules.

MATERIALS AND METHODS

My colleagues and I collected *Castanopsis* and other Fagaceae from India to New Guinea and Japan, gathering developmental reproductive material wherever possible. We preserved specimens originally in various liquid fixatives and later transferred them to glycerine-alcohol for permanent storage. For three species from the lowlands of Borneo (*C. foxworthyi, C. motleyana,* and *C. oviformis*) we took samples at intervals from marked trees through most of a year. The species reported upon in this paper are listed in Table 1.

The study of reproductive structures of *Castanopsis* presents unusual technical difficulties. Sectioning and clearing, even of young flowers, do not produce photogenic results because of the hard spines and cupules, the numerous hairs, and the heavy sclerification of tissues. Specimens were examined with light and scanning electron microscopy (often following removal of obscuring structures), drawings were produced with the camera lucida, and photographs were taken with incident light.

The dense vestiture obscures many details, and so the line drawings are shown without hairs.

Various sets of herbarium voucher specimens were distributed to A, BH, BKF, E, L, MIN, SAN, SAR, SING, and US (Table 1). The fruits illustrated here are in my research collection, and not all the distributed vouchers have fruits at all stages illustrated in this paper.

Nomenclature for paleotropical species follows Soepadmo (1972), who identified most of my paleotropical specimens. I considered the *fissa*-group with *Lithocarpus* (Kaul, 1987), following Camus's system, but a good case can be made for including it in *Castanopsis* if the two genera are recognized as distinct (Forman, 1966a, b).

OBSERVATIONS

PISTILLATE CYMULES

The pistillate cymules (often called dichasia) are borne on androgynous, pistillate, or androgynecandrous spikes (Kaul & Abbe, 1984; Kaul, 1986). They contain one, two, three, or sometimes more flowers (Figs. 1, 4–6, 10, 11, 13, 14, 17, 20, 25, 29–31, 38–40, 47, 52, 55, 56, 66, 70–77). The number of flowers per cymule is more stable in some species than others. Often there are fewer flowers in more distal cymules, and in some species that ordinarily bear one-flowered cymules, occasional two-flowered cymules appear. When three or more flowers occur in a cymule, the central flower often develops slightly earlier than the others (Fig. 10).

Each cymule is subtended by a primary bract (shown in black in Figs. 1, 5, 14, 20, 25, 29, 30, 38, 47, 52, 55, 56, 60, and evident in Figs. 70, 72, 76) and secondary, tertiary, and sometimes quaternary or even higher-order bracteoles (Figs. 72–77). Distinctions between these bracteoles and those of the cupule (hereinafter called scales) are not always obvious. The pattern of bracteolation in *Castanopsis* is closely similar to that shown for *Lithocarpus* (Kaul, 1987 and in press).

The apparent pedicel of a flower in anthesis (Figs. 1–3, 12, 21, 22) is actually the very undeveloped inferior ovary, and the flower is thus sessile in the cupule.

All species examined at anthesis have prominent staminodia (e.g., Figs. 30, 31, 77), which are sometimes basally adnate to the perianth (Fig. 12).

FRUITS

The fagaceous nut develops from an inferior ovary, and the cupule is an accessory part. If all nuts of a cymule are abortive (probably due to lack of pollination or fertilization, or to competition for resources from other fruits on the rachis), cupular growth stops at about the stages shown in Figures 5, 7, 14, 18, 25, 31, 33, 35, 36, 39, 40, 48, and 53. But if one or more nuts mature, the cupule matures. The mature cupule is not fused to the nuts in some species; it is partially or completely fused in others. Some species have notably scaly and/or spiny cupules, others have rudimentary spines, and some are spineless or scaleless.

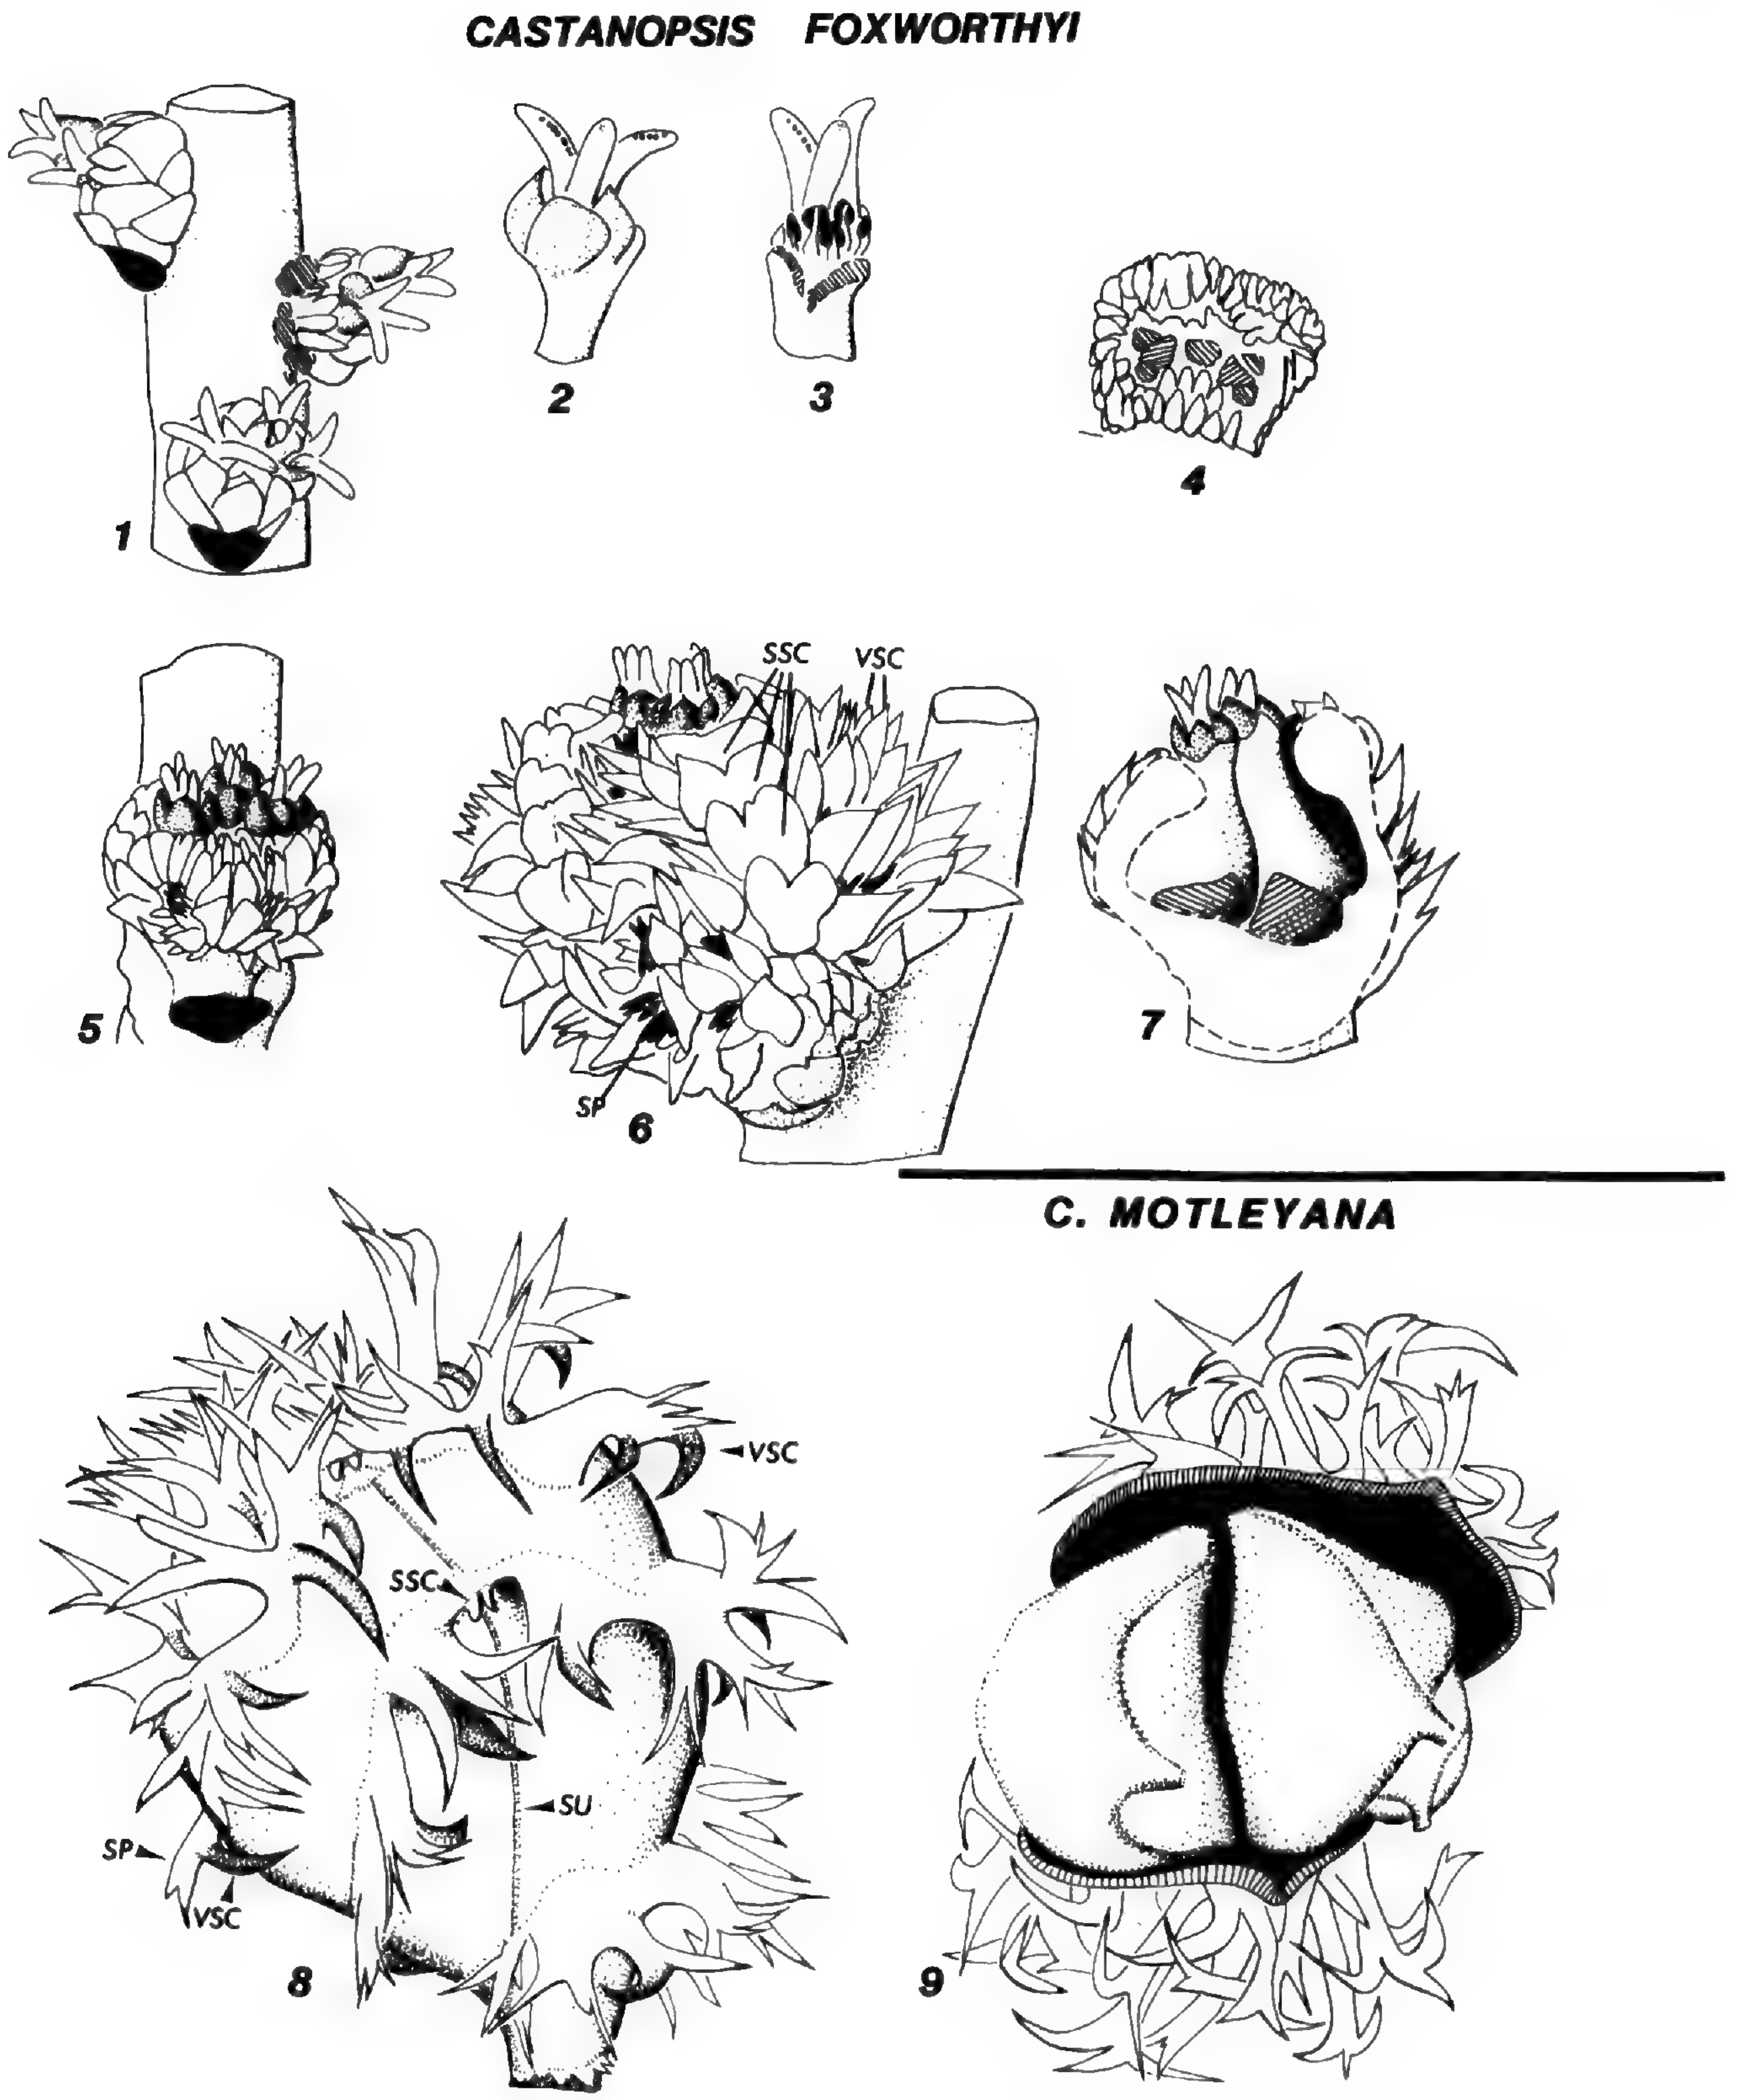
A cupule surrounds all flowers of a cymule, and there are no well-developed valves (segments of cupules) between the flowers except in the American species. Rudimentary interfloral valves were reported by Hjelmqvist (1948) in *C. hullettii* and *C. fabri*, but I have not studied those species and have not seen such valves in others.

Spiny cupules with one nut typically have two valves and dehisce along lines between them ("sutures" in the anatomical sense). In indehiscent fruits with one nut, the valves and sutures are evident at maturity in some species but not others. Fruits with three nuts typically have four valves, dehiscence occurring along the sutures between them (e.g., *C. hystrix*, Fig. 79; *C. schefferiana*, Fig. 82), but variations occur in both valve number and location of dehiscence lines. The mature cupule of *C. motleyana* shown in Figure 9, for example, has three fruits (one apparently abortive), but only two valves are evident. In *C. tribuloides* some cupules are one-flowered and have two valves (Figs. 41, 80), but other cupules, even on the same rachis, are three-flowered and have four valves (Figs. 42, 43). In the latter, some sutures between valves may not rupture.

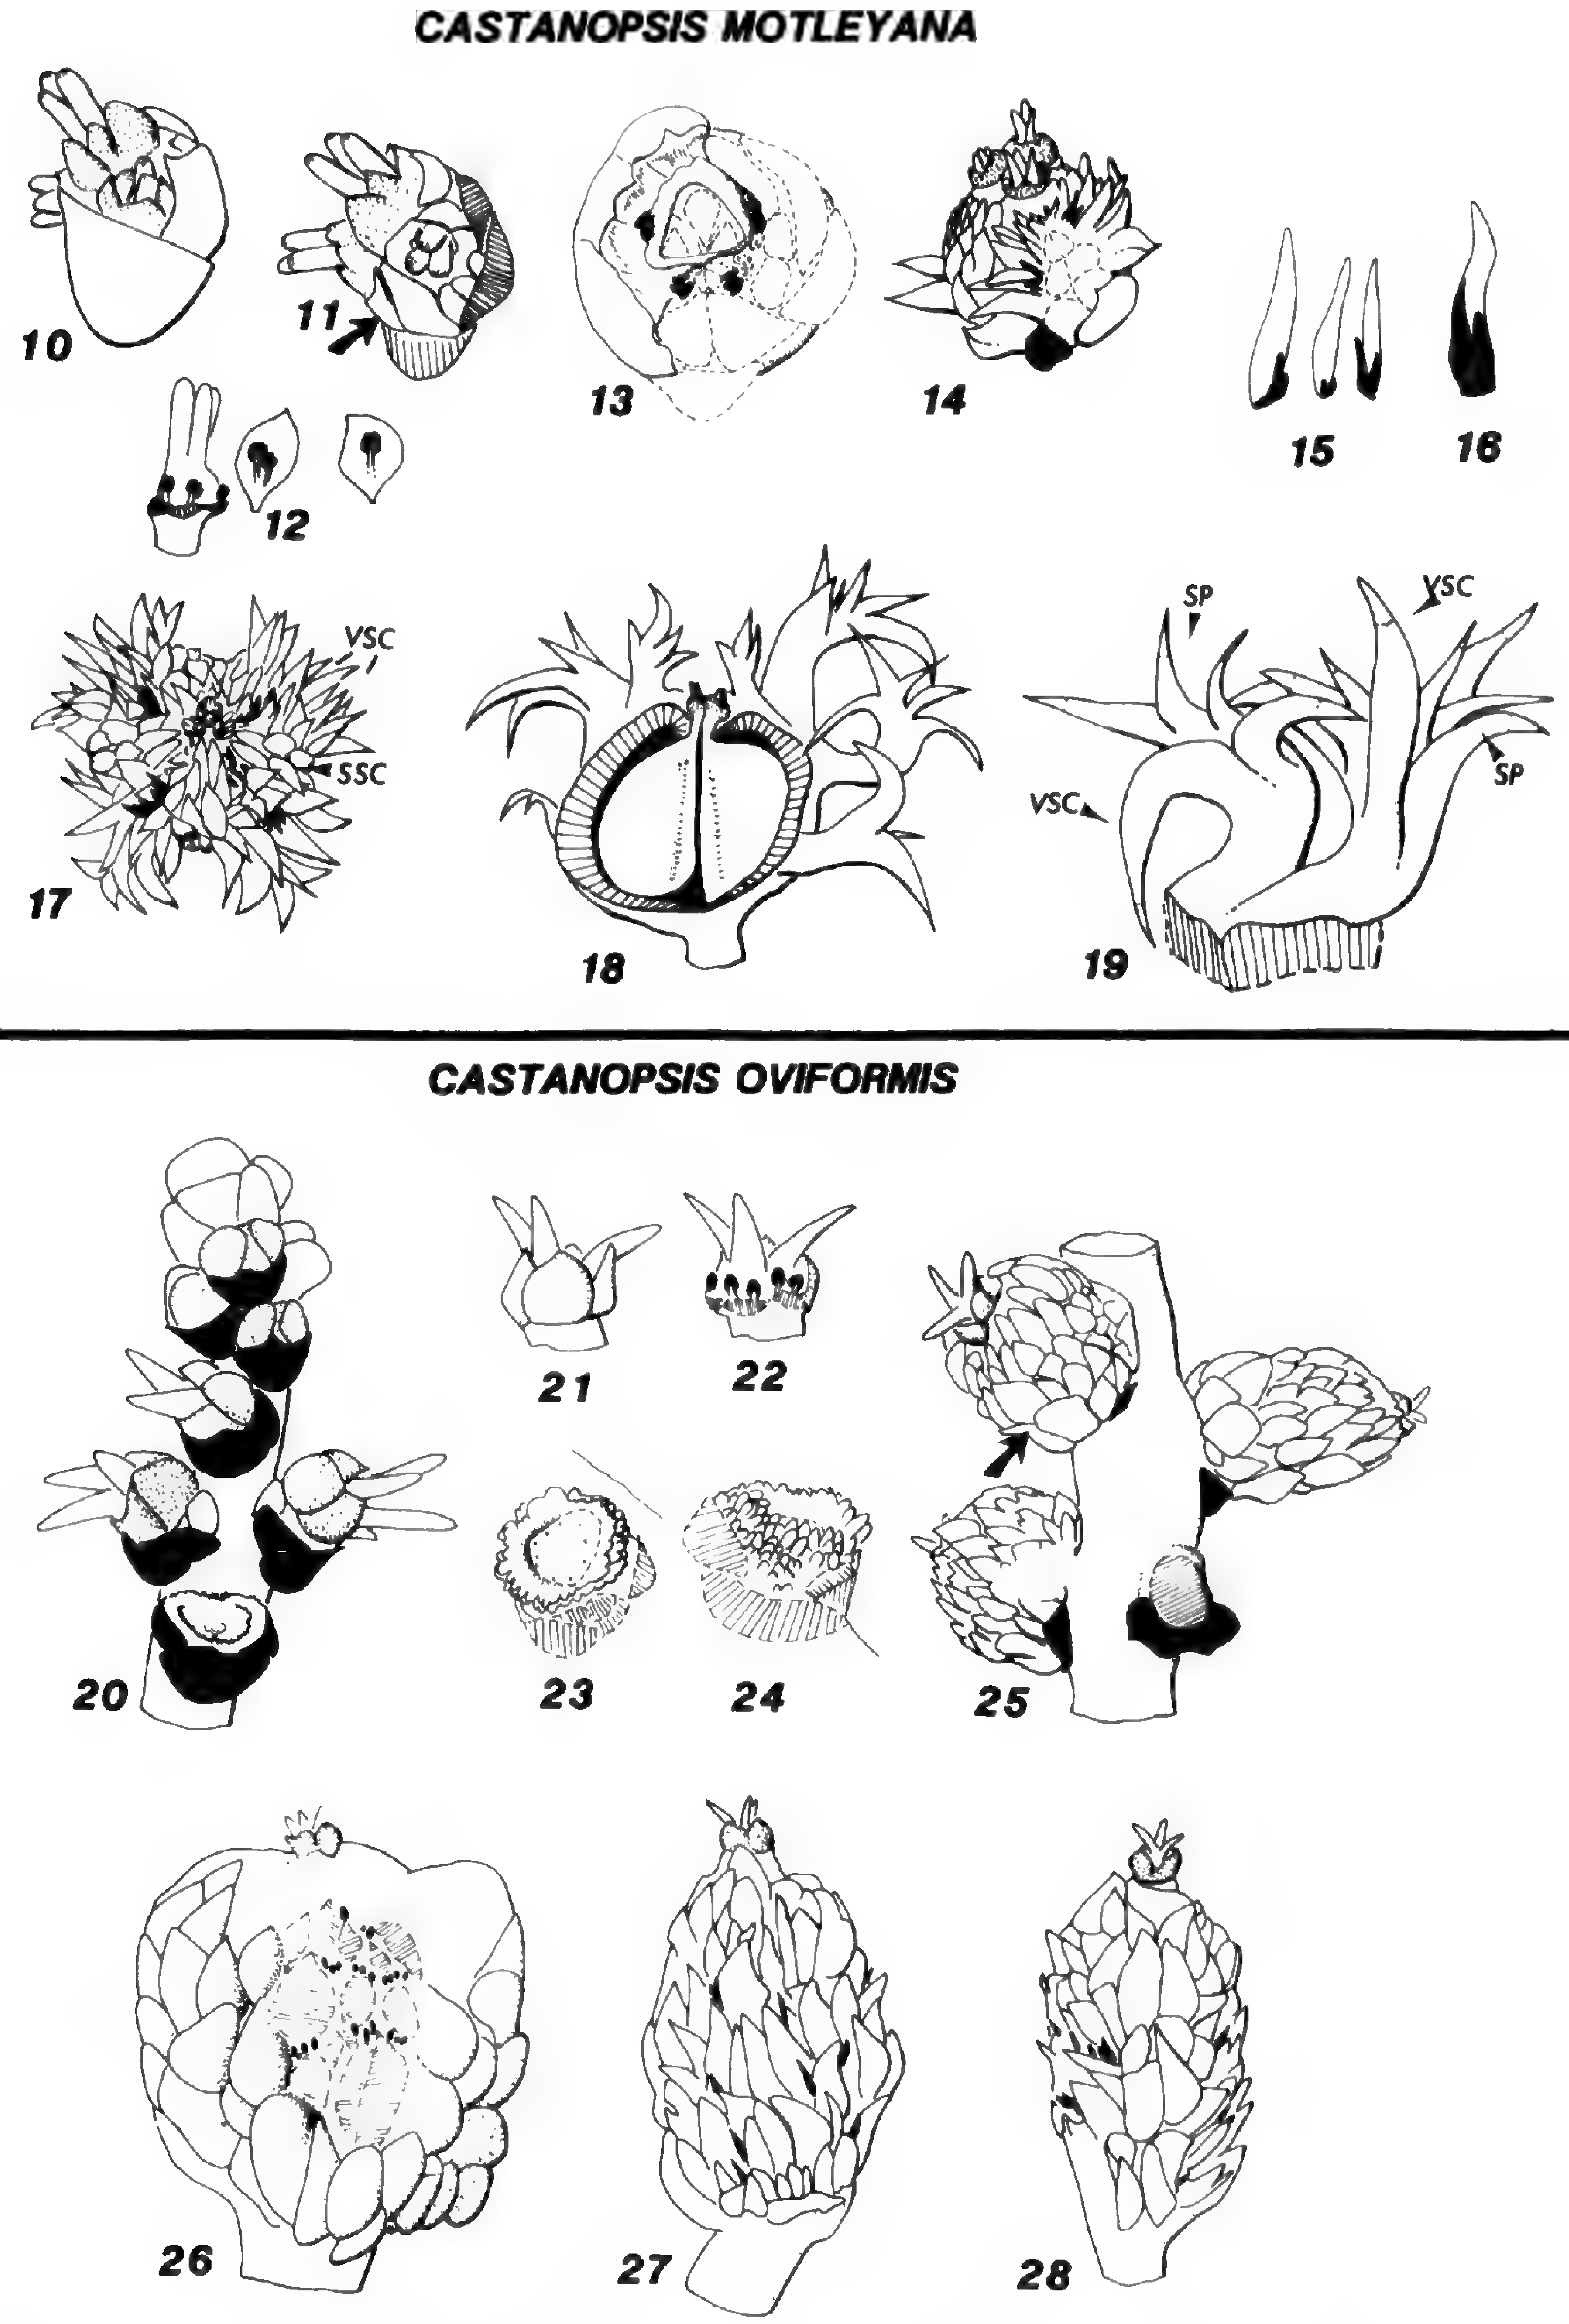
Species with one and three nuts per cupule occur at all elevations in southeastern Asia and southwestern Pacific islands, but in Taiwan they are only at middle and higher elevations. The size ranges (1–6 cm) and averages (ca. 4 cm) of maximum cupular diameters in all the species are about the same in the two areas, except that in southeastern Asia and southwestern Pacific islands there are two lower-elevation species with very large cupules (to 10 cm in diameter). Average maximum cupular diameter in the species with one-nut cupules is about that of those with three-nut cupules, again excepting the extremely large cupules of two southeastern Asiatic species, both of which have one nut per cupule.

SPECIES WITH SPINY CUPULES

In early anthesis the cupule is little developed and is hidden by the bracteoles (Figs. 10, 11, 29, 38, 47, 55, 72–76), but the cupular scales quickly



FIGURES 1–9. *1–8.* Castanopsis foxworthyi.—*1. Segment of pistillate portion of a spike showing three cymules in anthesis, the primary bract black. Primary bract and the bracteoles are removed in the middle cymule, revealing early cupular scales, 3.8×.—2, 3. Flower in anthesis; inferior ovary poorly developed, but staminodia well developed, 7.5×.—4. Polar view of cupule soon after anthesis, revealing scars of seven flowers, the outer four abortive, 3.8×.—5. Cymule after anthesis, with three functional flowers. Cupular scales are differentiating into sutural scales (center) and valvular scales, 3.8×.—6. Still later stage, the sutural scales (SSC) and valvular scales (VSC) now clearly differentiated, the axillary spines (black, SP) now showing, 3.8×.—7. Immature cupule longitudinally halved, with two nuts and their basal scar revealed, 3.8×.—8. Nearly mature cupule with the spines now in bands and somewhat confluent. The sutural scales (SSC) have not enlarged as much as the valvular scales (VSC), but the axillary spine clusters (SP) are now mostly much larger than the VSC. The future line of dehiscence between the two valves shown is indicated by SU, 1.9×.—9.* C. motleyana. *Mature, dehisced cupule in polar view, revealing one abortive and two functional nuts. The cupule has split on only two of its four sutures, 1.9×.*



FIGURES 10–28. *10–19.* Castanopsis motleyana.—*10, 11. Three-flowered cymule in anthesis, the primary bract and the bracteoles removed in Figure 11 to reveal early cupular scales, the lower two (arrow) being the first sutural scale pairs, 7.5×.—12. A single flower with perianth removed, revealing staminodia basally adnate to the tepals and showing the very undeveloped inferior ovary, 7.5×.—13. Three-flowered cupule in late anthesis, the primary bract (lowermost), the bracteoles on the right half, and some of the early cupular scales removed to reveal the four valvular primordia with their young scales (black). The second pair of abaxial sutural scales has formed between the lower two valvular primordia, 7.5×.—14. Lateral view of cymule in early postanthesis, the sutural scales (dashed lines) of the right lateral suture removed to reveal the valvular scales and their immature, axillary spines; primary bract black, 3.8×.—15, 16. Valvular scales (white) and early stages of the axillary spines (black), 15×.—17. Cupule about one-third mature, the sutural scales (SSC) and valvular scales (VSC) clearly differentiated, and the axillary spines (black) just emerging from among the scales, 7.5×.—18. Longitudinally halved immature cupule revealing two of the three nuts, 1.9×.—19. Two mature*

become evident and soon exceed the bracteoles (Figs. 5, 14, 25, 30, 39, 40, 52, 56, 77–83). In the species examined for preanthesis developmental detail (*Castanopsis foxworthyi, C. motleyana, C. oviformis*), the cupule primordium arises as an undulate ring at the base of the flowers, well within the bracteoles (Figs. 13, 23). In the three-flowered cymules of *C. motleyana*, four growth centers (valve primordia) of cupular scales are evident in the early stages (Fig. 13, scale primordia shown in black), but growth centers in *C. foxworthyi* and *C. oviformis* are less obvious, although there are differences in development among various parts of the early cupule (Figs. 4, 23, 24).

Distinctions develop among the cupular scales during and after anthesis, especially in cupules that will be spiny at maturity. Columns of shorter, broader, sometimes connate or paired scales alternate with masses of apparently random, pointed scales (Figs. 5, 6, 14, 17, 28, 31–33, 48, 49, 51, 58). The columns mark the sutures between valves and are potential sites of dehiscence, at which time sutural scales become separated onto adjacent valves (Figs. 34, 41–43, 54). In the three-flowered cupules of *Castanopsis foxworthyi, C. motleyana*, and *C. inermis* there are four such columns: one adaxial, one abaxial, and two lateral (Figs. 6, 13, 51). The columns define the four valves. The first pair of sutural scales is clearly evident in Figure 11, in which the primary bract has been removed to reveal them and the earliest valvular scales. Forman (1966a) found that dehiscence of the cupule of *C. inermis* (Figs. 48–51) does not occur along the sutures between the valves.

The valvular scales between the columns of sutural scales elongate, becoming indurate and spine-tipped with age. They do not comprise the majority of spines of the cupule; instead, most of the spines develop later, in groups axillary to the valvular scales; such spines are shown in black in Figures 6, 14–17, 26–28, 31, 32, 35, and 36, and are evident in Figures 72, 77–83. Figures 15 and 16 show that the spines in each group arise nonsynchronously and free, but they become basally connate and ultimately adnate with the subtending scale. By maturity, each subtending scale becomes spine-tipped, and the axillary spines are as large as or larger than it (Figs. 8, 19). Thus, in these spiny-cupuled species, the armament of the cupule is provided mostly by the axillary spines, with some contribution by the original valvular scales (Figs. 8, 37).

In some species with less cupular armament (e.g., *Castanopsis tribuloides*, Figs. 38–43, 80; *C. ferox*, Figs. 44–46; *C. psilophylla*, Figs. 52–54) the sutural scales are less obviously paired but instead occur in irregular groups. Such groups are evident in Figures 41–44 and 54, which show dehiscence of the cupule through them. In these species, the cupular scales become indurate and spine-tipped, forming much of the cupular armament; the mature axillary valvular spines are of similar size to the scales.

In *Castanopsis curtisii* (Figs. 55–59, 87) the asymmetric cupule is totally fused to the nut, the surface of which is therefore entirely scarred (Fig. 87) except for a tiny portion near the perianth. The flower and young cupule are rather symmetrical at anthesis (Fig. 55), but asymmetry is established soon thereafter (Fig. 56); massive abaxial growth of the cupule turns the fruit upward about 90°, and it becomes anatropous. Thus at maturity all the sutures appear to be on the adaxial side (Fig. 59). Sutural scales are evident only in the early stages of cupular development, when they can be seen to be entirely adnate to the body of the young cupule (Fig. 56, left cupule). The cupular scales in this species are also largely adnate, and are irregularly disposed at maturity (Fig. 59). In dry fruits, rupturing begins in the adaxial suture, but other ruptures radiate from the cupular pore (Fig. 59); those lines apparently do not represent

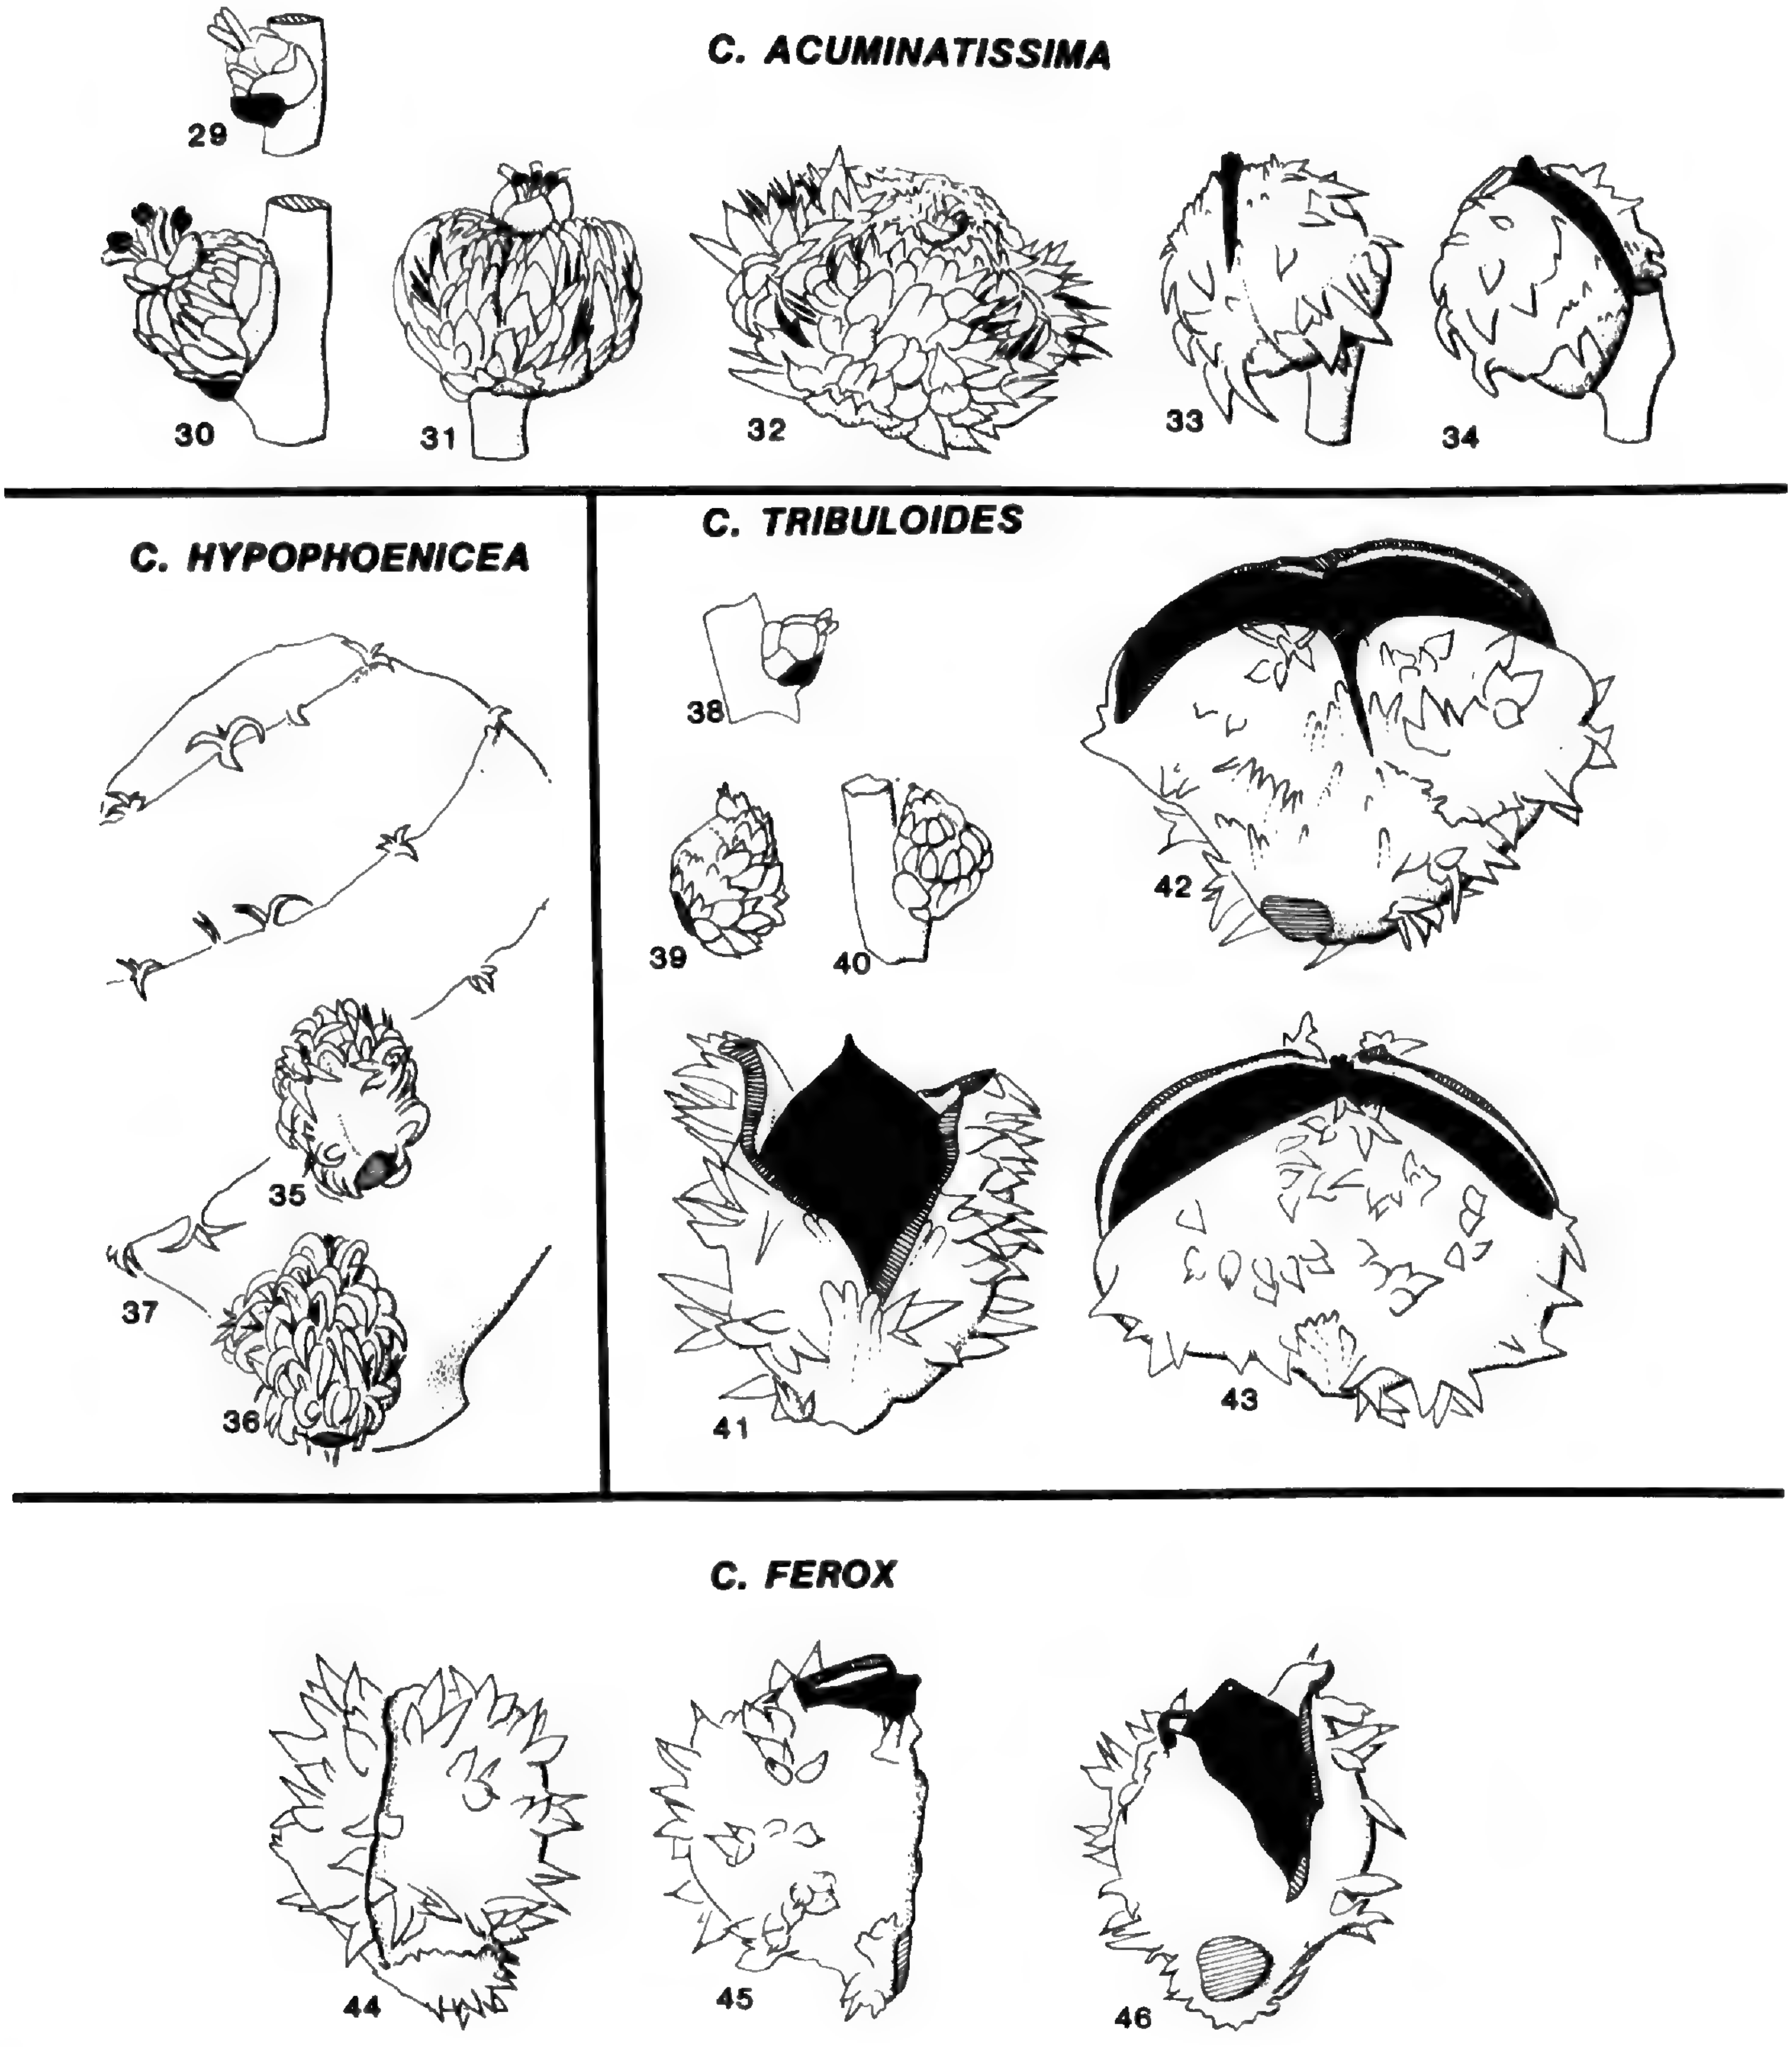
spine clusters, each consisting of one spine-tipped valvular scale (VSC) with its axillary cluster of spines (SP), 3.8×. 20–28. C. oviformis.—*20. Tip of spike in anthesis. Four one-flowered pistillate cymules are shown in anthesis, the lower with the flower removed to reveal the weakly developed cupule. Unopened distal flowers are staminate, 7.5×.—21, 22. Pistillate flower in anthesis, the tepals removed in Figure 22; inferior ovary very undeveloped, but staminodia prominent, 7.5×.—23, 24. Cymule in later anthesis, the primary bract and bracteoles removed to reveal the young cupule, 15×.—25. Segment of pistillate portion of spike well after anthesis, the cupule now emergent from the bracteoles; two pairs of large, sutural scales (arrow) are evident on the abaxial side of the uppermost cymule; cymule on lower right removed to reveal persistent bracteole (black), 3.8×.—26. Still older cupule with 12 valvular scales removed to reveal tiny primordia (black) of the axillary spines, 7.5×.—27, 28. Immature fruit in lateral (Fig. 27) and abaxial (Fig. 28) view, the axillary spines (black) now appearing among the valvular scales; Figure 28 also shows the abaxial column of large sutural scales, 2.8×.*



FIGURES 29–46. 29–34. Castanopsis acuminatissima.—*29. One-flowered cymule in anthesis, the primary bract in black and a few cupular scales evident, 2×.—30. Late anthesis, the cupular scales evident and overtopping the basal bracteoles; perianth and staminodia obvious, 4×.—31. Still later stage in abaxial view, the axillary spines (black) emerging from among the cupular scales, the abaxial suture indicated by the central, vertical depression abutted by sutural scales, 4×.—32. Still later stage of a specimen showing three sutures defined by appressed scales; between the sutures are groups of axillary spines (black) and valvular scales, 4×.—33, 34. Mature, dehiscing cupule showing few spines and dehiscence along two sutures, 2×. 35–37.* C. hypophoenicea.—*35. Adaxial view of one-flowered cupule soon after anthesis, the naked adaxial surface distinct, 2×.—36. Abaxial view of the same cupule showing the prominent recurved cupular scales and the emerging axillary spines (black), 2×.—37. Mature cupule, the scales and spines now widely separated and equally spiny, 0.4×. 38–43.* C. tribuloides.—*38. One-flowered cymule in early anthesis, the primary bract in black, 2×.—39, 40. Somewhat after anthesis, the relatively unadorned adaxial side evident in Figure 39, the neat rows of scales obvious in Figure 40, 2×.—41. Mature, dehiscing cupule in abaxial view, the rounded sutural scales evident adjacent to the suture, but the rows of valvular scales are no longer orderly, 2×.—42, 43. Adaxial (Fig. 42) and abaxial (Fig. 43) views of dehiscing cupule containing three nuts. Rounded scales of the partially opened adaxial*

intervalvular sutures, or at least such sutures are not evident in earlier stages (Figs. 57, 58). These fruits are possibly indehiscent in the wild, where they perhaps never dry, but my dry specimens show regular patterns of splitting.

Four related species reveal comparative details of reproductive structure: *Castanopsis armata, C. inermis, C. lucida,* and *C. pierrei.* The cupule is almost entirely fused to the nut in *C. pierrei* (Figs. 65, 86). Figure 65 shows the massive scar (hatched) and two small abortive nuts near the distal end of the single mature nut. The small free portion of each nut is indicated in black. The relationship of the mature and immature nuts to the cupule is evident in Figure 86, a polar view wherein the partially open cupule reveals two abortive nuts on the right. In this species the cupular scale–spine complexes are massively thickened (Figs. 65, 86). The spine-tips are not much elongated, but they are very sharp. The scale–spine complexes are arranged in slanting rows on the cupule, but that is not evident in Figures 65 and 86.

Castanopsis armata is similar to *C. pierrei* in that the cupule is entirely fused to the nut, but my specimens have no abortive nuts, and the single mature nut has about 20% of its distal end free (nonscarred) (Fig. 88). The mature cupule is massively thickened, and the cupule scale–spine complexes are not aligned in evident rows at maturity but are even more massive than those of *C. pierrei.* Each spine has a short, indurate, subulate tip, and the cupule is therefore formidably armed. Immature fruits display cupular sutures (cf. Fig. 51), along which dehiscence probably occurs eventually.

In *Castanopsis inermis* the cupule contains one to three nuts and is largely free from them (Fig. 89). Forman (1966a) noted a tendency toward reduction of the central flower of each cupule in this species, but I cannot confirm or deny that from observations of specimens from the Malay Peninsula, which show no regular pattern of reduction. The mature cupule displays horizontal rows of groups of low spines (Fig. 89, center). Such regular arrangement is more obvious on immature cupules, where the sutural scales are also readily distinguished (Figs. 48–51). The latter are permanently adnate to the cupule and do not become spiny. The cupular armament is largely made of spine-tipped cupular scales; axillary spines, if present, contribute little. Usually four sutures form on three-flowered cupules, and two form on one-flowered cupules. Variation occurs; some one-flowered cupules have four sutures (Fig. 51), for example. Dehiscence does not follow the sutures entirely and is therefore rather irregular.

The large fruits of *Castanopsis lucida* (Fig. 85) resemble those of *C. inermis,* but the cupular scale groups are proportionally larger and, at least in my specimens, the cupules seldom contain fewer than three nuts. The four sutures of a three-nut cupule are clearly evident in Figure 85 (upper photograph). Dehiscence usually begins with the opening of the adaxial and abaxial sutures, which are the shorter ones; later the longer lateral sutures open and reveal the free nuts within (Fig. 85). Mature spikes sometimes bear as many as ten fruits that collectively weigh 70 g when dry.

SPECIES WITH SMOOTH CUPULES

Some species of *Castanopsis* have nearly smooth, figlike cupules. Examples are shown of *C. piriformis, C. guineri,* and *C. longipetiolata* (Figs. 60–64, 66–69, 84, 89–91), all placed in section *Callaeocarpus* by Camus (1929). In these the indehiscent cupule is fused to the single nut and is unadorned except for low ridges and small, mostly adnate scales. No axillary spine complexes form.

The cupular scale-bearing ridges are widely separated and not concentric. In *Castanopsis piriformis* and *C. guineri* they converge distally on the cupule and there form a continuous spiral around the aperture (Figs. 62, 63, 84, 90). The ridges of *C. longipetiolata* are vertical in places (Figs. 67–69, 91) and converge near the aperture, but do not form a spiral (Fig. 67).

In adaxial view (Figs. 61, 64, 68), the adaxial suture is barely evidenced by a broad longitudinal depression. A few sutural scales show in Figures 61 and 64, but there are none in Figure 68. The cupular scales enlarge little as the cupule swells, and thus they become somewhat remote. In *Cas-*

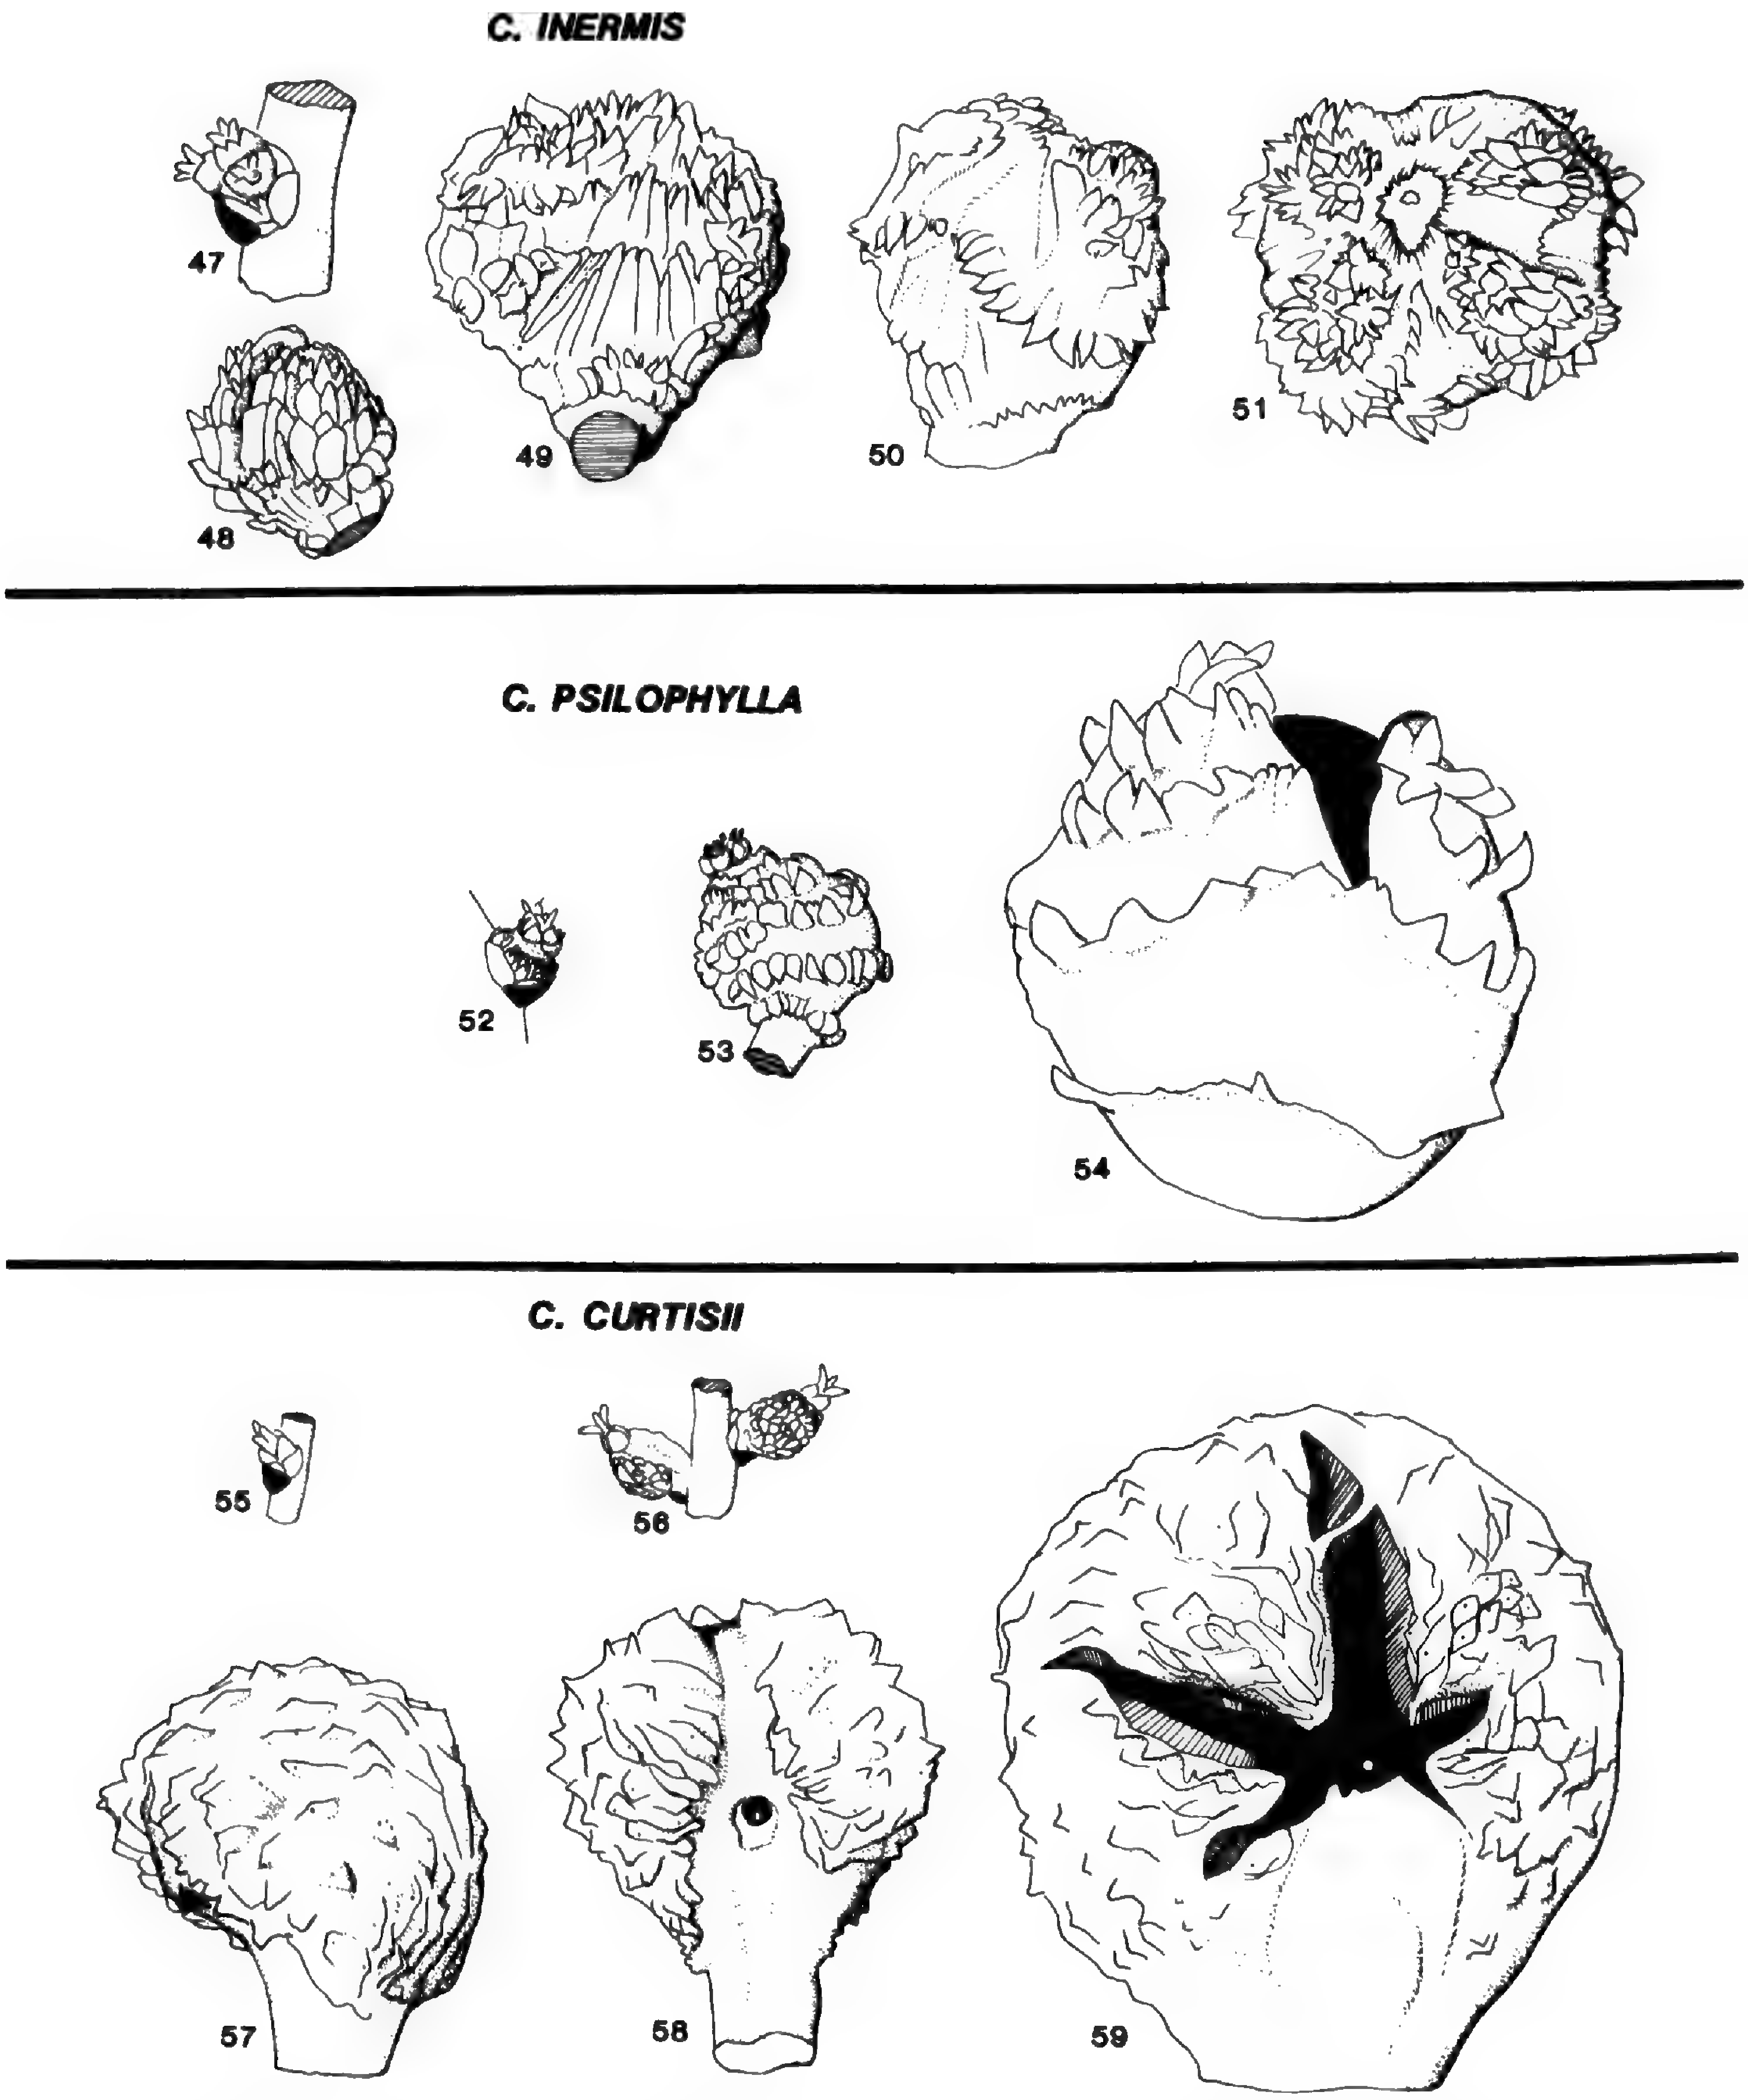
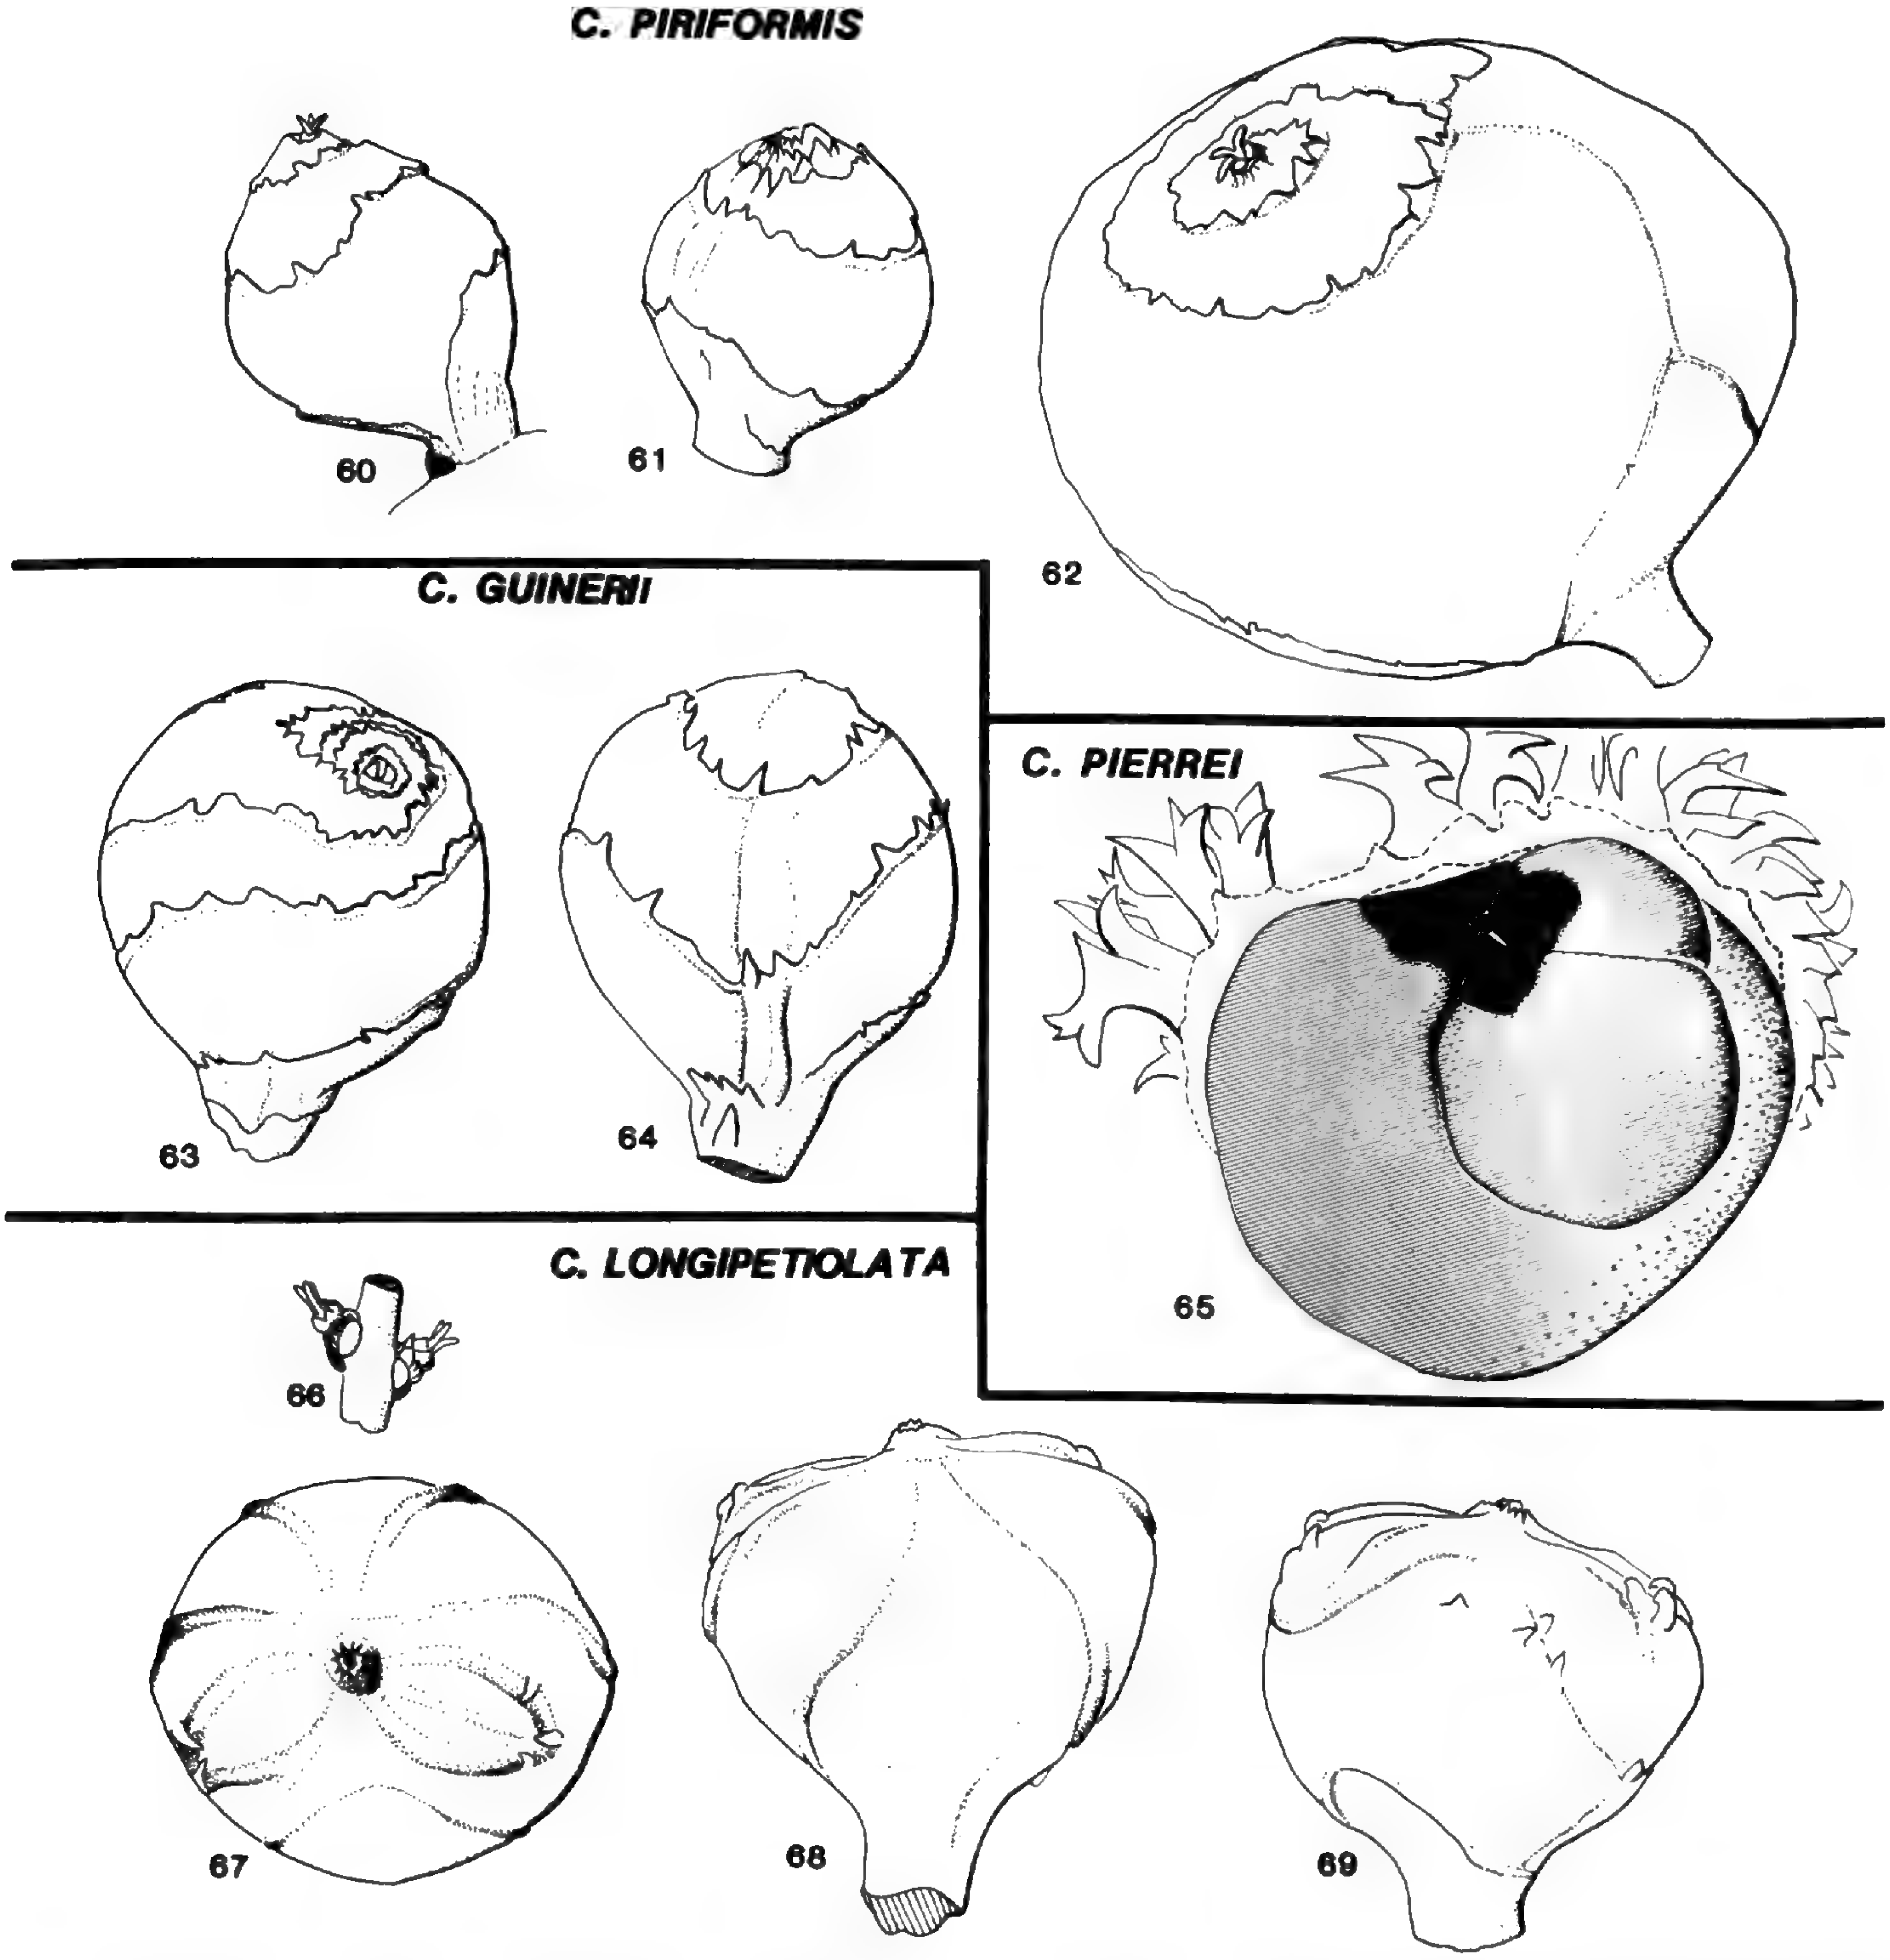
suture are seen to intergrade with the pointed valvular scales in Figure 42, but sutural scales on the abaxial side are confined to the base of the cupule (Fig. 43), 2×.—44–46. C. ferox *showing mature, dehiscing cupule in abaxial, lateral, and adaxial views, respectively. The adaxial side is essentially naked, and the suture there is without adjacent scales; the abaxial suture (Fig. 44) has a few scales, and the valvular scales are irregularly disposed at maturity, 2×.*



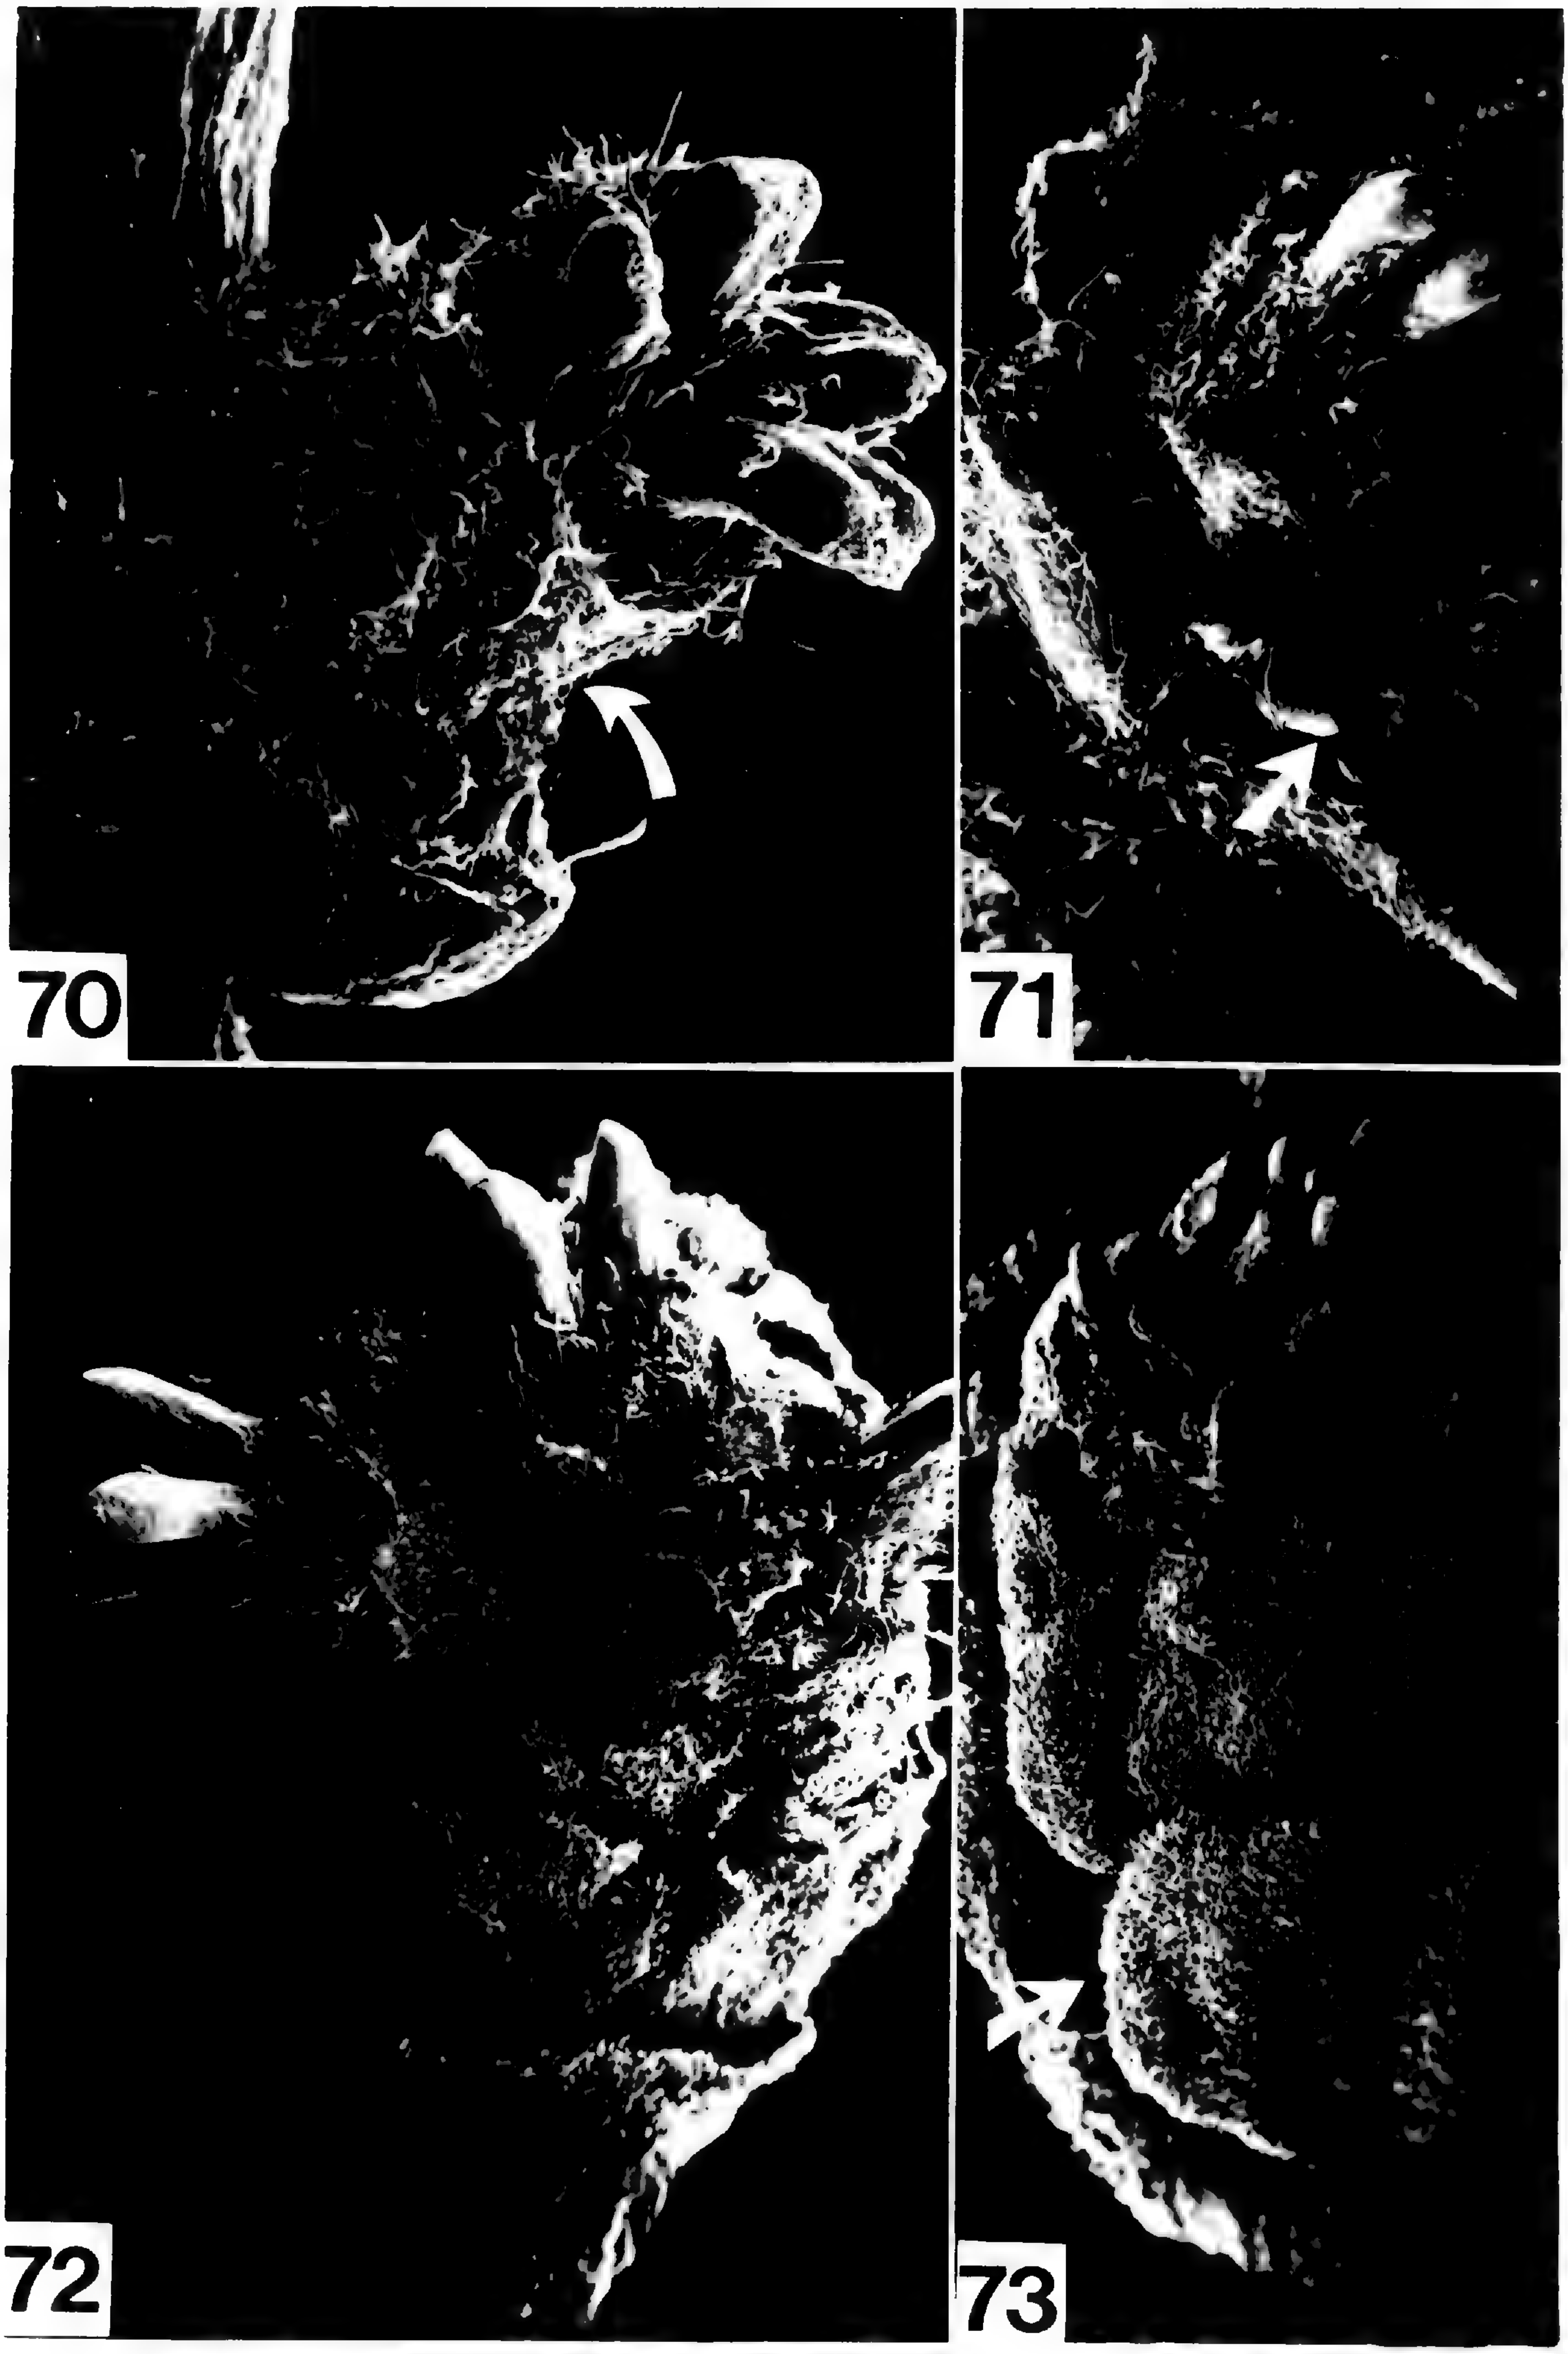
FIGURES 47–59. *47–51.* Castanopsis inermis.—*47. Three-flowered cymule in early anthesis, the primary bract shown in black, and only two cupular scales visible between the basal bracteoles, 2×.—48. Immature cupule in lateral view, the abaxial suture on the left shaded, the valvular scales still in rows, 2×.—49. Nearly mature cupule in adaxial view, the rounded sutural scales of the adaxial suture in tiers, the valvular scales less orderly than in Figure 48, 2×.—50. Lateral view of nearly mature cupule, showing rows of valvular scales, 2×.—51. Oblique polar view of nearly mature cupule, the four sutural areas evident and defined by appressed, more or less rounded sutural scales, and the valvular scales fully enlarged and pointed; there are no evident axillary spines, 2×. 52–54.* C. psilophylla.—*52. Three-flowered cymule in anthesis, the primary bract in black and the large basal bracteoles in white; numerous cupular scales are evident in rows above the bracteoles, 2×.—53. Postanthesis, the cupule and its scales enlarging, the latter yet in evident rows; perianths and staminodia of the three flowers persisting, 2×.—54. Mature, dehiscing cupule in abaxial view, showing a few elongate, appressed sutural scales to the left of the suture; valvular scales yet in rows but somewhat separated by diametric growth of the cupule, 2×. 55–59.* C. curtisii.—*55. One-flowered cupule in early anthesis, the primary bract shown in black, the cupular scales present under the basal bracteoles but not evident in this figure, 2×.—56. Two cymules soon after anthesis, the cupule already prominent above the primary bract and basal bracteoles,*



FIGURES 60–69. *60–62.* Castanopsis piriformis.—*60, 61. Half-mature one-flowered cupule in abaxial (Fig. 60) and semiadaxial (Fig. 61) views. The primary bract is shown in black in Figure 60. Cupular scales are already torn and widely spaced by this stage. The potential adaxial suture is seen on the left in Figure 61, although the fruit is probably indehiscent, 2×.—62. Mature cupule in oblique view, the adaxial side to the right. Upper rows of scales becoming spiral, 2×.—63, 64.* C. guineri, *nearly mature fruits in abaxial (Fig.63) and adaxial (Fig. 64) views. The strong spiral formation of cupular ridges is evident in Figure 63, and Figure 64 shows the adaxial vertical depression marking a potential suture, although the fruit is indehiscent, 2×.—65.* C. pierrei. *Mature fruit with foreground part of cupule removed to expose the massive scars (white) of the three nuts, two of which developed only partially; free portion of the nuts shown in black. The nuts are not fused to each other, 2×. 66–69.* C. longipetiolata.—*66. Two one-flowered cupules in anthesis, the primary bract of each shown in black; the first row of cupular scales is apparent above the basal bracteoles, 2×.—67–69. Nearly mature cupule in polar, adaxial, and lateral views, respectively. The few surviving cupular scales are mostly adjacent to the curving cupular ridges, and there is no obvious indication of potential sutures on this indehiscent cupule, 2×.*

←

the scales more or less in orderly rows; the rather smooth, unadorned adaxial face of the left cupule is easily seen, 2×.—57, 58. Fruit about half grown, in lateral (Fig. 57) and adaxial (Fig. 58) views. Massive adaxial growth has produced strong asymmetry, and the pore through which the tip of the nut can be seen is now more than 90° from the vertical. Scales are no longer in rows, and some slight differentiation is beginning directly to the right and left of the pore, 2×.—59. Mature dehiscing cupule in adaxial view. Five lines of dehiscence are shown on this specimen, the vertical one through the upper, unadorned area visible in Figure 58 and the two upper, lateral ones between the barely differentiated scales, 2×.



FIGURES 70–73. 70. Castanopsis tribuloides, *lateral view of cymule in anthesis. The large primary bract is lowermost, but no cupular scales show between it and the prominent perianth (arrow),* 65×.—*71.* C. indica,

tanopsis longipetiolata there are few such scales from the beginning, so by maturity the cupule is nearly scaleless (Figs. 67–69, 91). No axillary spine complexes form.

DISCUSSION

Castanopsis shows primitive and advanced character states for the Fagaceae. If multiflowered cymules are primitive in the family, as suggested by Soepadmo (1970, 1972), Forman (1966a), and Kaul (1987), and by widely accepted interpretations of inflorescence evolution in the angiosperms, then it is likely that some associated character states are primitive too. Among the latter possibilities are four-valved cupules, dehiscence between the valves, the cupule free from the nut(s), and spines present on the cupule (Forman, 1966a). The general association of one-flowered cupules with spinelessness, adnation of the cupule to the nut, and irregular or no dehiscence thus suggests those states to be advanced. Forman (1966a) postulated such interpretations based upon other species, and they are supported by my observations. If the interpretations of Hjelmqvist (1948) and Forman (1966a) are correct, the dichasium cupule evolved by phylogenetic fusion of adjacent flower-cupules in the cymule and is thus highly derived. Strong cupular asymmetry approaching anatropy, as in *C. curtisii*, is certainly a derived state, although most species show at least some asymmetry.

There is some developmental evidence that adnation of cupule to nut is only apparent. Rather, it is possible that the basal scar enlarges enormously as the nut grows in species with apparently extensive adnation and that the basal part of the cupule expands simultaneously. The result is wide spacing of the lower cupular lamellae, but distally they remain rather crowded. With this interpretation the figlike, one-nut cupules can be viewed as the products of massive basal but little distal enlargement of the cupule. The distal part of the nut, which in other species enlarges more than the basal part, remains free, as it is in the species without apparent cupular adnation. Detailed developmental investigations, though technologically formidable, could provide further insights into this idea.

In some species, the scales and spines are arranged in concentric rows, but in others there is no apparent order in mature cupules. However, in the latter instances observed for this study, early developmental stages show rather regular rows of cupular scales, and I regard such rows as the primitive condition in the genus. In some species with figlike cupules (e.g., *Castanopsis guineri, C. piriformis*) the parallel rows of scales on the lower part of the mature cupule contrast with the distal, spiral rows, which are the last to form. The cupules of some species of *Quercus* subg. *Cyclobalanopsis* also show spiral lamellations, but most species of that subgenus, all of subg. *Quercus*, and nearly all of *Lithocarpus* have concentric lamellae (Kaul, 1985, 1987, and in press). Thus spiral lamellations are exceptional in the Fagaceae and are likely to have been derived by modification of the concentric pattern through alteration of later ontogenetic stages.

Forman (1966a) interpreted the sutural scales as derived from branched spines because he believed there are intermediates between scales and spines in some species. He thus considered the cupular scales of *Lithocarpus* and *Quercus* also to be modified spines. He saw the spines as single branched entities, but Barnett (1940) interpreted them as axillary to the first-formed cupular appendages. I also interpret the sutural and valvular scales to be homologous and synchronous, and the axillary spines to arise above the valvular but not the sutural scales. Thus intermediates between the two scale types are expected and, in fact, have been observed by Forman (1966a) as well.

Plant spines are sometimes emergences, not stem or leaf homologues, and that was Forman's (1966a) interpretation of the cupular appendages of *Castanopsis*. Evidence in favor of the spines of *Castanopsis* being modified stems are their branching capability (which sometimes occurs in other families in spines originating as emergences) and their position axillary to the scales. However, there are not even ephemeral subtending bracts at the nodes of branching on the spines, as could be expected in a reduced branching system. Furthermore, it is possible that the scales and spines, as defined here, are homologues and therefore not fundamentally different as suggested by the scale/axillary spine

Figs. 47–51). Lowest figure is the mature nut, its basal scar (arrow) clearly evident, 1×.—90.* C. piriformis. *Lateral view of mature cupule (entirely fused* interpretation. For *Castanea*, Fey & Endress (1983) interpreted the valvular scales to be residual pherophylls of a condensed, cymose system and the spines to be axillary, cymose branches, based upon their comparative and developmental studies. I favor that interpretation for *Castanopsis* as well.

If the branched spines are relictual axillary branches—vestiges of a condensed, fused branching system that formed the cupule—then their presence is the primitive condition in the family. Their loss, both within *Castanopsis* and elsewhere in the family, would be the derived state. Spininess due to induration of cupular scales in a few species of *Quercus* and *Lithocarpus* would then be a secondary development.

Whatever interpretation is correct, there are unanswered questions about evolution of the various patterns of spine elaboration and distribution on the cupules. While protection of the immature nuts is a likely function of the spines, the fact that some nonspiniferous species of *Castanopsis* grow in the same forests with spiniferous species suggests that other protective measures are effective too. Detailed studies of life histories of *Castanopsis* and of its fruit predators and disseminators could reveal important information about cupular function.

It is likely that the solitary pistillate flowers of some species of *Lithocarpus* and *Castanopsis* and all species of *Quercus* are the results of phylogenetic elimination of all flowers but one (presumably the terminal one) of a cymule, as suggested by Forman (1966a). However, it is by no means evident that abortive flowers are always phylogenetically abortive—sometimes they are merely normal flowers that failed to produce fruit, probably for lack of pollination or fertilization, or due to competition from other fruits on the same rachis. Such failed flowers are frequent even among species with solitary flowers. In this paper and elsewhere (Kaul, 1987 and in press) examples are illustrated showing failed flowers of multiflowered cymules in every position in the cymules, varying greatly even on a single spike. If there are tendencies for lateral flowers in pistillate cymules of these genera to be phylogenetically abortive, I have seen little convincing evidence. However, such evidence appears in a few staminate spikes of *Lithocarpus* and possibly also of *Castanopsis*.

There are more differences in cupular structure within *Castanopsis* than between it and some species of *Lithocarpus*, and the distinctions between flower-cupules of the latter and dichasium-cupules of the former are not always convincing, especially in *Lithocarpus* species with cupules partially of both types. Thus, once again the generic and infrageneric taxonomy of Fagaceae is questioned: the long history of taxonomic doubt expressed in the literature is not eased by such observations. However, it is premature to propose new alignments because of the confusing levels of apparent parallelism and convergence in these large genera.

MALVACEAE OF JAMMU AND KASHMIR STATE, INDIA[1]

A. R. Naqshi, G. H. Dar, G. N. Javeid, and P. Kachroo[2]

ABSTRACT

The Malvaceae of the Jammu and Kashmir State are reviewed with a complete synopsis of the taxa recorded from this area. The state is situated on the northern fringe of India and comprises three distinct geographical regions: Jammu, Kashmir, and Ladakh. The family has a moderate representation here, but only a relatively few species are indigenous. Forty-one species in 15 genera are recorded in this treatment: 12 species cultivated (with at least half of them escaped from cultivation) and 29 wild species. A definite decline in the number of taxa of Malvaceae has been observed from the subtropical Jammu region through the temperate Kashmir to the cold, arid Ladakh. Malva bucharica *and* Althaea broussonetiifolia *are recorded for the first time from the Indian subcontinent;* Malva microcarpa, M. ambigua, *and* M. mohileviensis *for the first time from India; and* Hibiscus micranthus *is a new record for Jammu and Kashmir State. All the taxa are keyed, and the species are provided with descriptions and usually followed by brief notes on distribution and economic utility.*

In Hooker's *Flora of British India* (1874), Masters recognized 108 malvaceous species in 27 genera and sorted these into four tribes: Malveae, Ureneae, Hibisceae, and Bombaceae. As the tribe Bombaceae is now referred to family Bombacaceae, 97 species in 19 genera remain from Masters's listing. Of these, ten species in seven genera were cited from Jammu and Kashmir State. Many additional species have been described from this area since Hooker's publication, and the nomenclature of most of the species included there has changed.

Lambert (1933), in his list of trees and shrubs for the Jammu and Kashmir forest circles, listed the then-known arborescent taxa of the family. Stewart (1972) catalogued 70 species in 16 genera in West Pakistan and Kashmir. Of these, 30 species in 12 genera, including those based on literature, were listed from the Jammu and Kashmir State. Following Stewart, Abedin (1979) monographed the Malvaceae of West Pakistan, listing 94 specific and infraspecific taxa in 19 genera. However, Jammu and Kashmir materials are poorly represented in this work. Many of the collections referred by Stewart to our state are not mentioned by Abedin.

Lately, many local workers have included the family in floristic works (Javeid, 1970; Javeid & Naqshi, 1973; Singh & Kachroo, 1976; Sharma & Kachroo, 1981; Naqshi & Kachroo, 1982; Dar et al., 1983; Dhar & Kachroo, 1983), but none has given a descriptive account of all the taxa. Therefore, a complete synopsis of the family as it occurs in the Jammu and Kashmir State is given here.

The state is situated on the northern fringe of India between 32°10′ and 37°10′N latitudes and 72°30′ and 80°30′E longitudes. The eastern, northern, and western boundaries of the state comprise a segment of the border of India. To the east of the state lies Tibet, to the north lies China (with a very small portion of the border touching Afghanistan), to the west is Pakistan, and to its south is Himachal Pradesh and a very small part of the Punjab. It covers an area of about 222,000 km^2, which, except for a short belt in Jammu and the valley of Kashmir, is wholly mountainous, from ca. 270 m in Jammu and extending to the heights of the Himalaya in Kashmir and Ladakh (up to ca. 8,128 m at Nanga Parbat). The rock formations in the entire state belong to three broad groups: the Panjal, the Zanskar, and the Tertiary. The Panjal includes the outer hills, outer plains, and the middle mountains; the Zanskar includes the whole of the eastern region from Spiti to Lahul and to the lofty Karakoram in the north; and the Tertiary includes the valley of Kashmir and other river valleys (Wadia, 1953).

---

[1] *Dr. Paul A. Fryxell, Research Botanist, Agronomy Field Laboratory, Texas A&M University, U.S.A., has been kind enough to read the manuscript and confirm identities of the representative taxa included in this treatment. He also supplied useful literature and made helpful suggestions. For all this generous help we are very grateful. Thanks are also due to Professors E. Nasir and S. I. Ali of Pakistan for providing literature.*

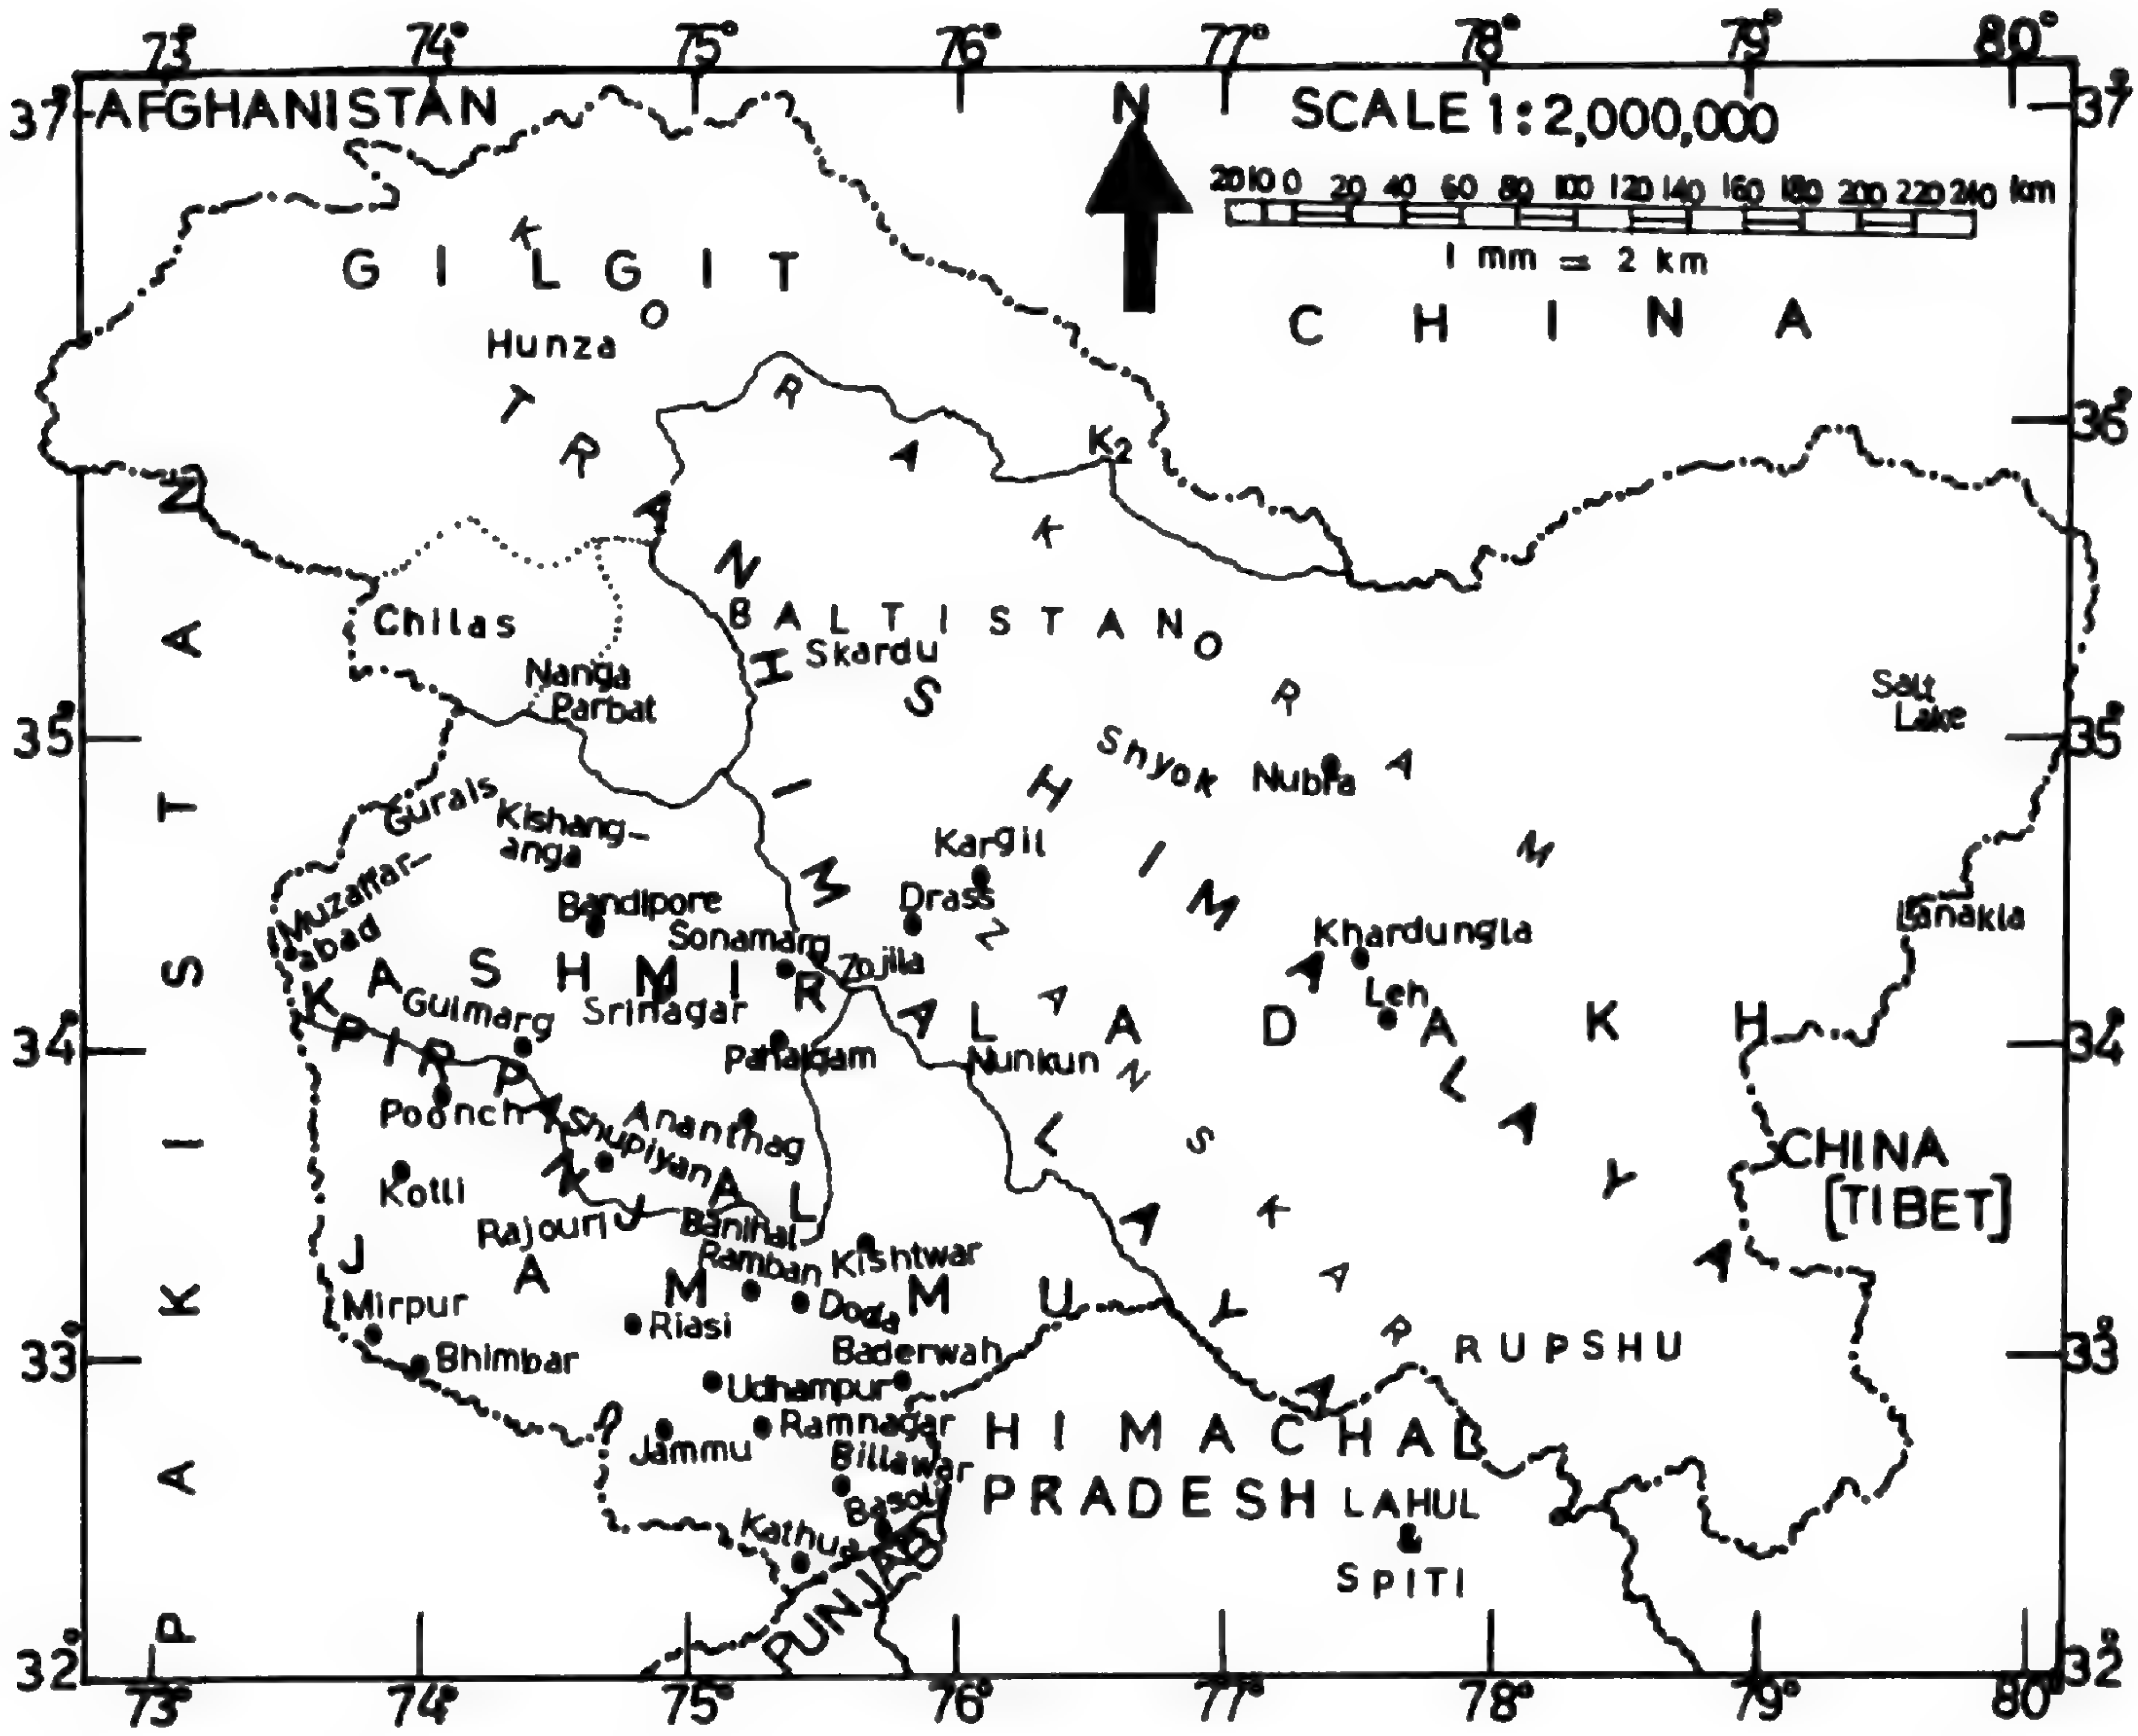

FIGURE 1. Map of Jammu and Kashmir State.

Geographically the state can be divided into three distinct regions, Jammu, Kashmir, and Ladakh (Fig. 1), embracing considerable variation in topography, physiography, and climate. Jammu has mostly a subtropical climate (moist temperate in higher reaches of Chenab Valley), with the southwest monsoons resulting in an average annual rainfall of over 1,100 mm. The mean maximum temperature during summer is as high as 40°C, and the mean minimum during winter as low as 6°C. Floristically the region is largely dominated by broad-leaved, deciduous and evergreen woody elements. Kashmir (separated from the Jammu region by the lofty Pir Panjal range, which also acts as a barrier to the southwest monsoons) is predominantly dry temperate, with an average annual rainfall of ca. 660 mm. The maximum temperature in summer reaches 35°C, and the minimum in winter (usually with heavy snowfalls) decreases to as low as −10°C. The fewer woody genera in Kashmir are evergreen—broad-leaved arborescent species are usually lacking. Ladakh, an extremely barren land with high elevations (above 3,000 m), has a cold, arid climate, approaching arctic cold in winter. The average annual rainfall varies between 80 mm (Leh) and 650 mm (Drass). The temperature in summer goes as high as 30°C and as low as −40°C in winter. The region harbors a desert flora largely dominated by xerophytic elements and, except for more humid valleys, almost lacks natural tree cover.

MATERIALS AND METHODS

Almost all the collections cited in this work were critically examined in the herbarium of the University of Kashmir (KASH) by the authors. The herbarium studies were supplemented by extensive observations in the field. Representative specimens of all our determinations were kindly seen by Dr. Paul A. Fryxell, U.S.A. However, a few collections, mostly made in the Pakistan-occupied part of Jammu and Kashmir State and deposited in various herbaria of Pakistan, were not accessible, and they

have been included with almost full citation of their collectors and places of collection and deposition.

RESULTS

The Malvaceae have a moderate representation in the Jammu and Kashmir State, but only a few species are indigenous. Altogether, 41 species in 15 genera are recorded in this study. Out of these, 12 species are cultivated, with at least half of them escaped from cultivation. Among the escaped cultivated species, *Sidalcea neomexicana*, *Alcea lavateriflora*, *A. pallida*, and *Malva verticillata* var. *rafiqii* are reported for the first time from India. Turning to wild species, *Malva bucharica* and *Althaea broussonetiifolia* are first recorded for the Indian subcontinent; *Malva microcarpa*, *M. ambigua*, and *M. mohileviensis* are new records for India; and *Hibiscus micranthus* is a first record for the Jammu and Kashmir State.

Twenty-seven of the 41 species occur in Jammu Province, 21 in Kashmir, and six in Ladakh. Twelve of the 15 genera occur in Jammu, nine in Kashmir, and only one (*Malva*) in Ladakh. It is evident that there is a marked decline in the number of genera and species as one proceeds from the sub-Himalayan Jammu through the Himalayan Kashmir to the trans-Himalayan Ladakh (Table 1). The number of species in common is highest between Jammu and Kashmir, while it is the lowest between Jammu and Ladakh. Almost all our arborescent species are restricted to Jammu, although *Hibiscus syriacus* is commonly grown ornamentally in Kashmir. None of our taxa except *Lavatera kashmiriana* and a few species of *Malva* reach subalpine and alpine ranges.

None of the taxa recorded here is endemic to the Jammu and Kashmir State. All our genera except *Sidalcea* (a North American plant, collected as an escape from cultivation only once in Kashmir) are shared with Pakistan. As for our other neighboring countries, *Fioria* does not occur in Afghanistan, U.S.S.R., China, and Iran; *Kydia* and *Thespesia* are absent from Afghanistan, U.S.S.R., and Iran; *Malva* and *Lavatera* are not found in Burma; *Sida* is unknown from Afghanistan; *Malvastrum* is unknown from Afghanistan, U.S.S.R., and Burma; and *Urena* does not occur in Afghanistan, U.S.S.R., and Iran. Almost all our species (38) are also in Pakistan, followed by 22 in Iran, 19 each in the U.S.S.R. and China, 11 in Burma, and 10 in Afghanistan. Both our new records for the Indian subcontinent (*Malva bucharica* and *Althaea broussonetiifolia*) grow in the U.S.S.R.

MALVACEAE A. L. DE JUSSIEU, GEN. PL. 271. 1789.

Plants annual, biennial, or perennial herbs, to small trees, mucilaginous, usually pubescent with stellate, furcate, and simple hairs, rarely with ferruginous peltate scales. Leaves alternate, simple, stipulate, petiolate, unlobed to deeply lobed. Flowers axillary, solitary, or fasciculate, or subracemose to paniculate, usually bracteate with an epicalyx of 3–13 free or basally connate segments, sometimes ebracteate, actinomorphic, usually perfect, sometimes polygamodioecious. Calyx usually campanulate or tubular, 5-lobed or -toothed, rarely spathaceous and 2- or 3-lobed, valvate, usually persistent. Corolla polypetalous, 5-merous, adnate basally to the staminal tube, contorted. Stamens numerous, monadelphous with filaments coherent to form a staminal tube, this wholly or partially antheriferous; anthers dorsifixed, monothecous, linear to horseshoe-shaped, solitary, rarely in clusters of 3–5. Carpels (3–)5–many, syncarpous in a single whorl (in ours) around the columella; ovary superior, with as many locules as carpels; placentation axile; style usually divided at the apex into as many (or twice as many) branches as carpels, or sometimes unbranched; stigmas sessile, linear or capitate or discoid. Fruit a dry, loculicidal (or indehiscent) capsule or a schizocarp separating into usually 1-seeded mericarps, rarely follicular and 2–3-seeded. Seeds reniform, ovoid or obovoid, glabrous or pubescent with short and long hairs.

Considerable embryological work has been done on this family (Schnarf, 1931; Venkata Rao, 1954, 1955; Winter, 1960; Ramchandani et al., 1966), and optimistic views are being held about the taxonomic significance of such studies. The structure and development of the seed and seed coat anatomy have also been shown to be of great taxonomic and phylogenetic value (Reeves, 1936; Wunderlich, 1967; Bouman, 1971; Mohana Rao, 1978; Kumar, 1981).

A family of 88 genera and ca. 2,300 species, most abundant in the tropics, common in subtropical and temperate regions, and usually absent from arctic regions. The Ureneae have style branches and stigmas twice as many as the carpels. The Malopeae have carpels irregularly arranged in two or more whorls around the carpophore and the style branches and stigmas are as many as carpels; the fruit is schizocarpic. In the Hibisceae the carpels are regularly arranged in a single whorl around the carpophore, the style branches and stigmas are as many as carpels or the style is unbranched, and the fruit is capsular. The Malopeae do not occur in our area. The Malveae are represented here by *Malva, Lavatera, Alcea, Althaea, Abutilon, Sida, Malvastrum,* and *Sidalcea*; the Hibisceae by *Fioria, Hibiscus, Abelmoschus, Kydia, Gossypium,* and *Thespesia*; and the Ureneae by *Urena*.

KEY TO THE GENERA OF MALVACEAE IN JAMMU AND KASHMIR STATE

1a. Flowers polygamous or polygamodioecious.
  2a. Plants trees; flowers white, polygamous; epicalyx present; anthers in globose head of 3–5; carpels not beaked .... 4. *Kydia*
  2b. Plants herbs; flowers rose-purple, polygamodioecious; epicalyx absent; anthers solitary; carpels beaked .... 15. *Sidalcea*
1b. Flowers bisexual.
  3a. Style branches and stigmas twice the number of carpels, always 10; mericarps glochidiate-spiny .... 14. *Urena*
  3b. Style branches and stigmas as many as carpels or style unbranched; mericarps never glochidiate-spiny.
    4a. Fruit a capsule, the carpels at maturity not separating from one another.
      5a. Style unbranched, ± clavate, or superficially divided into very short branches.
        6a. Plants herbaceous to suffrutescent, not covered with ferruginous peltate scales; leaves lobed; epicalyx segments cordate, foliaceous, persistent; calyx with oil glands; capsule fibrous, loculicidally dehiscent .... 5. *Gossypium*
        6b. Plants small trees, herbaceous portions covered with ferruginous peltate scales; leaves unlobed; epicalyx segments lanceolate, not foliaceous, caducous; calyx without oil glands; capsule ± woody, indehiscent .... 6. *Thespesia*
      5b. Style divided into 5 divergent branches.
        7a. Calyx spathaceous, irregularly 2- or 3-lobed, falling together with corolla and staminal tube .... 3. *Abelmoschus*
        7b. Calyx usually campanulate, regularly 5-lobed, persistent, not falling as a unit with corolla and staminal tube.
          8a. Capsule with 5 conspicuous, scarious, and strongly veined wings .... 1. *Fioria*
          8b. Capsule not winged .... 2. *Hibiscus*
    4b. Fruit a schizocarp, the carpels at maturity (mericarps) separating from one another leaving a distinct central columella.
      9a. Epicalyx present.
        10a. Epicalyx segments 3; staminal tube antheriferous only in the apical part.
          11a. Leaves ovate to lanceolate-oblong, unlobed; flowers yellow; stigmas capitate; mericarps tricuspidate (in ours) .... 13. *Malvastrum*

- 11b. Leaves orbicular-reniform or cordate, mostly lobed or angled; flowers pink-lilac (or white); stigmas linear, decurrent; mericarps awnless.
  - 12a. Stipules foliaceous; epicalyx segments ovate-orbicular, foliaceous, connate at base; mericarps 20–25; style base enlarged in fruit .... 10. *Lavatera*
  - 12b. Stipules not foliaceous; epicalyx segments linear or oblong-ovate, not foliaceous, free; mericarps 8–15; style base not enlarged in fruit .... 7. *Malva*
- 10b. Epicalyx segments 6–12; staminal tube antheriferous almost to the base.
  - 13a. Epicalyx segments 7–12; corolla 2–3 cm in diameter, 0.8–2.2 cm long; staminal tube cylindrical, the anthers brownish purple; mericarps 12–25, unilocular, wingless .... 8. *Althaea*
  - 13b. Epicalyx segments 6–7; corolla 5–8 cm in diameter, 3.5–7 cm long; staminal tube 5-angled, the anthers yellowish; mericarps 20–40, sub-bilocular, often winged .... 9. *Alcea*
- 9b. Epicalyx absent.
  - 14a. Calyx cupular; mericarps 10–20, follicular, 2–3-seeded .... 11. *Abutilon*
  - 14b. Calyx campanulate; mericarps 5–10, not follicular, 1-seeded .... 12. *Sida*

1. **FIORIA** Mattei, Boll. Reale Orto Bot. Giardino Color. Palermo 2: 71. 1916.

Four species, distributed in tropics and subtropics of the Old World; represented in our area by a single species.

Fioria vitifolia (L.) Mattei, Boll. Reale Orto Bot. Giardino Color. Palermo 2: 71. 1916. *Hibiscus vitifolius* L., Sp. Pl. 696. 1753; Masters in Hook. f., Fl. Brit. India 1: 333. 1874; Rakshit & Kundu, Bull. Bot. Surv. India 12: 166. 1970; Ngwe, Union Burma J. Life Sci. 4: 204. 1971; Stewart in Nasir & Ali, Ann. Cat. Vasc. Pl. W. Pak. & Kashm. 480. 1972; Sharma & Kachroo, Fl. Jammu 1: 112. 1981. *H. vitifolius* L. var. *genuinus* Hochr., in Annuaire Conserv. Jard. Bot. Genève 4: 169. 1900. TYPE: Herb. Hermann, Vol. IV, Fol. 39, *Linn. no. 265* (lectotype, BM); see Brenan & Exell, Bol. Soc. Brot. Ser. 2. 32: 72. 1958.

Hibiscus obtusifolius Willd., Sp. Pl. 3: 829. 1801.
H. truncatus Roxb., Hort. Bengal. 51. 1814; Fl. Ind. ed. 1832. 3: 200. 1832.
H. cuspidatus Edgew., J. Asiat. Soc. Bengal 21: 168. 1853.
Fioria vitifolia (L.) Mattei subsp. *vulgaris* (Brenan & Exell) Abedin, Pakistan J. Bot. 9: 59–66. 1977; Fl. W. Pak. 130: 5. 1979. *Hibiscus vitifolius* L. subsp. *vulgaris* Brenan & Exell, Bol. Soc. Brot. ser. 2. 32: 73. 1958.
H. heterotrichus DC., Prodr. 1: 450. 1824. *H. vitifolius* L. var. *heterotrichus* (DC.) Hochr., Annuaire Conserv. Jard. Bot. Genève 4: 170. 1900.

Annual, suffrutescent herbs. Stems and inflorescence axes usually densely tomentose with stellate and glandular hairs. Leaves ovate-cordate, entire or shallowly 3–5-lobed, coarsely serrate, stellately tomentose beneath or on both surfaces. Flowers axillary, solitary or clustered at the ends of branches, usually drooping; pedicels shorter than petioles, articulate at or below the middle. Epicalyx of 7–12 linear segments. Calyx campanulate, 5-lobed; lobes ovate, acute, 3–5-nerved, simple and 2-rayed pubescent within, stellate-tomentose outside. Corolla twisted, 3–5 cm diam., yellow with a purple center; petals obovate, glabrescent. Staminal tube truncate, shorter than corolla, antheriferous throughout. Capsule suborbicular, apiculate, 5-winged, hirsute. Seeds 2–4 in each cell, reniform, minutely tubercled.

Distribution. India, Pakistan, Burma, Sri Lanka, Australia, and tropical Africa. In our area it occurs in Jammu Province only. Sharma & Kachroo (1981: 113) wrongly reported it as a new record for Jammu and Kashmir.

Additional specimens examined. INDIA. JAMMU: Mandal, common along banks of irrigation channels, *B. M. Sharma 765* (KASH); Poonch Dist. Nawal Nadi, *A. Rashid s.n.* (RAW); Rajouri, *Jacquemont 1428* (fide Stewart, 1972: 480).

Abedin (1979) followed Brenan & Exell (Bol. Soc. Brot. Ser. 2. 32: 73. 1958) in placing the specimens of *Fioria vitifolia* from Pakistan and Kashmir under subsp. *vulgaris*, which is said to differ from subsp. *vitifolia* in the density of indumentum and leaf incision. However, the depth of leaf incision, the shape of the leaf lobes, and the density and rigidity of hairs have been found to be highly variable in the species, even within a single plant (Rakshit & Kindu, 1970). Subdivision of the species on the basis of the above-mentioned characters does not, therefore, seem to be satisfactory.

Most previous authors included *Fioria* in *Hibiscus*. This seems almost justified, especially when we consider their only superficial differentiating character of winged (*Fioria*) and nonwinged (*Hibiscus*) capsule. However, for a better understanding of these plants, it is now believed to recognize the two as distinct genera.

2. **HIBISCUS** L., Sp. Pl. 693. 1753; Gen. Pl. 5th Edition. 310. 1754.

Ketmia Miller, Gard. Dict. Abr. 4th Edition. 28. 1754.
Pariti Adans., Fam. Pl. 2: 401. 1763.
Paritium Adr. Juss. in St. Hilaire, Fl. Bras. Mered. 1(2): 255. 1827.

A genus of some 3,000 species distributed chiefly in the tropical and subtropical regions of both hemispheres. Six species occur in our area, of which two are cultivated.

KEY TO THE SPECIES OF *HIBISCUS* IN JAMMU AND KASHMIR STATE

1a. Flowers drooping; petals deeply laciniate; staminal tube much longer than corolla, exserted .... 2. *H. schizopetalus*
1b. Flowers not drooping; petals usually entire; staminal tube shorter than or equaling the corolla, included.
  2a. Epicalyx absent or rarely represented by minute teeth .... 5. *H. lobatus*
  2b. Epicalyx present, represented by conspicuous segments.
    3a. Epicalyx segments radiate; staminal tube antheriferous in the upper half only .... 6. *H. caesius*
    3b. Epicalyx segments not radiate; staminal tube antheriferous throughout.
      4a. Annual herbs; calyx inflated, more so in fruit; seeds glabrous .... 1. *H. trionum*
      4b. Shrubs; calyx not inflated; seeds villous or with a line of long white hairs.
        5a. Plants usually glabrous; leaves elliptic-rhombic, often 3-lobed; pedicels equal to or shorter than petioles; flowers 4–6 cm in diameter; seeds with a line of long white hairs .... 3. *H. syriacus*
        5b. Plants scabrous-bristly; leaves ± ovate, unlobed; pedicels longer than petioles; flowers 1–1.5 cm in diameter; seeds villous .... 4. *H. micranthus*

1. **Hibiscus trionum** L., Sp. Pl. 697. 1753; Masters in Hook. f., Fl. Brit. India 1: 334. 1874; Iljin in Shishkin & Bobrov, Fl. U.R.S.S. 15: 159. 1949; Hu, Fl. China, Malvaceae. 57. 1955; Rakshit & Kundu, Bull. Bot. Surv. India. 168. 1970; Stewart in Nasir & Ali, Ann. Cat. Vasc. Pl. W. Pak. & Kashm. 480. 1972; Riedl in K. H. Rechinger, Fl. Iran. 120: 30. 1976; Singh & Kachroo, Forest Fl. Srinagar. 151. 1976; Abedin in Nasir & Ali, Fl. W. Pak. 1300. 11. 1979. TYPE: *Linn. Herb. no. 875/39*, photo (LINN).

Hibiscus africanus et *H. hispidus* Miller, Gard. Dict. 8th Edition. HIB. 1768.
H. vesicarius Cav., Diss. 3: 171, tab. 64, f. 2. 1787.
H. dissectus Wallich, Cat. no. 3696. 1831, nom. nud.

Annual hispid herbs. Stems with simple and tuberculate-stellate hairs. Leaves orbicular-ovate, the lower leaves usually undivided, the upper leaves palmately 3–5-lobed, the lobes obovate or oblong, pinnatisect, punctate, nearly glabrous or sparsely stellate-pubescent, especially abaxially. Flowers solitary, axillary; pedicels longer than petioles, articulate above the middle. Epicalyx of 8–13 linear, long-hispid segments. Calyx campanulate, 5-lobed, inflated in fruit; lobes deltoid, acute, membranous; with many hispid, green-purplish, raised veins. Corolla 1.5–3 cm diam., pale yellow with a dark purple center; lobes glabrous. Staminal tube shorter than corolla, purplish, antheriferous throughout. Capsule oblong, obtuse, strigose-hispid, black, enclosed in the inflated persistent calyx. Seeds ± reniform, tuberculate-rugose when mature, glabrous.

Distribution. India, Pakistan, Afghanistan, southern U.S.S.R., Burma, China, Iraq, Iran, Turcomania, Transcaucasia, Mediterranean Region, southern Europe to southern Africa, Australia; naturalized in America. In our area it is common in Kashmir Province, often growing as a weed escaped from cultivation. Stewart (1972) gives Poonch, Jammu.

Specimens examined. INDIA. KASHMIR: university campus, *A. R. Naqshi 195* (KASH); Gulmarg, *A. R. Naqshi 514* (KASH); Kokernag, *I. M. Nahvi s.n.* (KASH); Anantnag, collector not known, *s.n.* (KASH); Srinagar, *G. N. Javeid 360* (KASH); Dachigam, *G. Singh 888* (KASH); Ganderbal, *G. H. Dar 3004* (KASH); Shuhama (Ganderbal), *G. H. Dar 2943–44* (KASH), *2942* (PF); Sarich (Ganderbal), *G. H. Dar 1767–68* (KASH); Narbal, *A. R. Naqshi & G. N. Dar 8173–75* (KASH).

This is a species of the eastern Mediterranean Region, now widespread in almost all the continents. Despite the extensive distribution, the species retains its essential morphological characters throughout. However, a number of species related to it have been described. Hochreutiner (1900) retained *H. trionum* s. str. and reduced to varieties some species described by earlier workers. We follow this conservative approach.

A diaphoretic syrup is prepared from its leaves, which contain 0.3% rubber substances. The seeds contain 23.8% oil. In South Africa the plant is said to be used for treatment of round worm, while in

China and Malaya the dried leaves are considered stomachic. An infusion of the flowers is used for itch, for painful skin diseases, and as a diuretic. It is reported to be poisonous to stock, particularly horses.

2. Hibiscus schizopetalus (Masters) Hook. f., Bot. Mag. 106, tab. 6524. 1880; Hu, Fl. China, Malvaceae. 46. 1955; Rakshit & Kundu, Bull. Bot. Surv. India 12: 166. 1970; Ngwe, Union Burma J. Life Sci. 4: 205. 1971; Stewart in Nasir & Ali, Ann. Cat. Vasc. Pl. W. Pak. & Kashm. 479. 1972; Abedin in Nasir & Ali, Fl. W. Pak. 130: 12. 1979. *Hibiscus rosa-sinensis* L. var. *schizopetalus* Masters, Gard. Chron. n.s. 12: 272, f. 45. 1879. TYPE: Gard. Chron. n.s. 12: 272, f. 45. 1879.

Glabrous shrubs with spreading-drooping branches. Leaves elliptic, glabrous, shining, palmately nerved, entire in basal half, serrate in apical half. Flowers solitary, axillary, pendulous; pedicels slender, longer than petioles, articulate at the middle. Epicalyx of 5–8 subulate, ciliate segments 1–2 mm long. Calyx spathaceous, tubular, irregularly 2–5-lobed. Corolla 4–9 cm diam., pinkish; petals deeply laciniate and recurved. Staminal tube much longer than corolla, filiform, pendulous, red, antheriferous in the upper half only. Capsule oblong-cylindrical. Seeds smooth, glabrous.

Distribution. Native of Kenya and Tanganyika (Exell, Fl. Zambes. 1: 470. 1960), cultivated elsewhere. It is commonly cultivated in gardens throughout India, Pakistan, Burma, and a few coastal cities in southern China. In our area it is rarely grown, collected only at Banihal in Jammu Province.

Specimen examined. INDIA. JAMMU: Banihal, *Sirajud-din s.n.* (KASH).

It is reported that the flowers in *H. schizopetalus* drop after anthesis and that fruits seldom form. According to Wilcox & Holf (Hawaii Agr. Exp. Sta. Bull. 29. 1913) it has been used as "male" parent in crosses with *H. rosa-sinensis* L. and its varieties. In 1984 Fryxell labeled the specimen cited above as "apparently a hybrid or a hybrid-derivative of *Hibiscus rosa-sinensis* L. and *H. schizopetalus* (Masters) Hooker."

3. Hibiscus syriacus L., Sp. Pl. 695. 1753; Masters in Hook. f., Fl. Brit. India 1: 344. 1874; Iljin in Shishkin & Bobrov, Fl. U.R.S.S. 15: 152.1949; Hu, Fl. China, Malvaceae. 50. 1955; Kitamura, Fl. Afghan. 270. 1960; Rakshit & Kundu, Bull. Bot. Surv. India 12: 170. 1970; Stewart in Nasir & Ali, Ann. Cat. Vasc. Pl. W. Pak. & Kashm. 480. 1972; Riedl in K. H. Rechinger, Fl. Iran. 120: 29. 1976; Abedin in Nasir & Ali, Fl. W. Pak. 130: 13. 1979. TYPE: Syria: *Linn. Herb. no. 875/24* (LINN).

Ketmia syriaca Scop., Fl. Carniol. 2nd Edition. 2: 45. 1772.
K. syrorum Medikus, Malvaceae: 45. 1787.
K. arborea Moench, Suppl. Meth. 617. 1794.
Hibiscus floridus Salisb., Prodr. 383. 1796.
H. acerifolius Salisb., Parad. Londin. 1: tab. 33. 1805.
H. syriacus L. var. *sinensis* Lemaire, Jard. Fleur. 4: tab. 370. 1854.
H. chinensis sensu Forbes & Hemsley, J. Linn. Soc., Bot. 23: 88. 1886.

Glabrous, branched shrubs. Leaves elliptic-rhombic, acute at the apex, cuneate at the base, irregularly dentate, often 3-lobed. Flowers solitary, axillary, single or double; pedicels equaling or shorter than petioles. Epicalyx of 6–8 linear, single-nerved segments. Calyx campanulate, densely stellate-tomentose, shallowly 5-lobed; lobes triangular-lanceolate, acute. Corolla campanulate, 4–6 cm diam., usually lilac with a purple center; petals obovate, ciliate and stellately villose outside. Staminal tube shorter than corolla, antheriferous to the base. Capsule oblong-ellipsoid, yellowish, stellate-tomentose, shortly beaked at the apex. Seeds reniform, glabrous except for a line of long white hairs.

Distribution. China, cultivated elsewhere. Grown in gardens throughout India, Pakistan, Afghanistan, China, Iran, and other countries. In our area this species is extensively grown as an ornamental shrub or as a hedge plant in the Kashmir Valley.

Additional specimens examined. INDIA. KASHMIR: Beehama (Ganderbal), *G. H. Dar 2866* (KASH), *2866a* (PF); Srinagar University campus, *A. R. Naqshi 8176* (KASH); Nehru Bot. Garden (Cheshma Shahi), *A. R. Naqshi s.n.* (KASH).

A number of single and double horticultural varieties of this species have been described mainly on the basis of flower color, which ranges from purple-pink through pink to pure white. Hu (1955) recognized nine varieties mainly on the basis of floral size and color.

Although the plant is mainly used ornamentally, its stem is said to yield a strong fiber. The seeds contain 24.6% oil. In China, the flowers are reportedly eaten, and the tender leaves are used as a substitute for tea and as a shampoo.

4. **Hibiscus micranthus** L. f., Suppl. Pl. 308. 1781; Masters in Hook. f., Fl. Brit. India 1: 335. 1874; Rakshit & Kundu, Bull. Bot. Surv. India 12: 171. 1970; Stewart in Nasir & Ali, Ann. Cat. Vasc. Pl. W. Pak. & Kashm. 479. 1972. *Hibiscus micranthus* L. f. var. *genuinus* Hochr., Annuaire Conserv. Jard. Bot. Genève 4: 83. 1900. TYPE: *Linn. Herb. no. 875/2* (holotype, LINN).

H. gossypinus DC., Prodr. 1: 453. 1824, non Thunberg, 1800.

Erect shrubs with slender, terete branches, scabrid with scattered stellate bristles on almost all parts. Leaves ± ovate, 1.9–4.5 × 1.5–4 cm, acute or obtuse, serrate, eglandular. Flowers axillary, solitary; pedicels slender, longer than petioles, articulate above or below the middle. Epicalyx of 6–8 filiform, stiff, pubescent segments. Calyx 5-lobed; lobes triangular-lanceolate, pubescent. Corolla 1–1.5 cm diam., white or pink; petals often reflexed, stellately pubescent outside. Staminal tube to 5 mm long, shorter than corolla, antheriferous throughout. Capsule globose. Seeds reniform, black, villous.

Distribution. India, Sri Lanka, Pakistan, tropical Africa, South Africa, Madagascar, Arabia. In our area confined to Jammu Province.

Additional specimens examined. INDIA. JAMMU: Ram Nagar forest, common among hedges and on open roadside slopes; erect pubescent shrubs up to six feet tall with rosy-red flowers, *B. M. Sharma 249* (KASH).

Three varieties of *H. micranthus* are recognized from India and Pakistan (Abedin, 1979), but only var. *micranthus* occurs in our area.

The plant is reportedly valued as a febrifuge in Sri Lanka. This is the first record for Jammu and Kashmir State.

5. **Hibiscus lobatus** (Murray) Kuntze, Revis. Gen. Pl. 3rd Edition. 2: 19. 1898; Rakshit & Kundu, Bull. Bot. Surv. India 12: 169. 1970; Stewart in Nasir & Ali, Ann. Cat. Vasc. Pl. W. Pak. & Kashm. 479. 1972; Abedin in Nasir & Ali, Fl. W. Pak. 130: 18. 1979; Sharma & Kachroo, Fl. Jammu 1: 112. 1981. *Solandra lobata* Murray, Comment. Soc. Regiae. Sci. Gott. 6: 20, tab. 1. 1785. TYPE: Comment. Soc. Regiae. Sci. Gott. 6: 20, tab. 1.

Hibiscus solandra L'Hér., Stirp. Nov. 1: 103, tab. 49. 1789, nom. illeg.; Masters in Hook. f., Fl. Brit. India 1: 336. 1874. *H. solandra* var. *genuinus* Hochr., Annuaire Conserv. Jard. Bot. Genève 4: 128. 1900.
H. pumilis Roxb., Fl. Ind. 3: 203. 1832.
Lagunea lobata Willd., Sp. Pl. 4th Edition. 3: 733. 1800.
L. sinuata Hornem., Hort. Bot. Hafn. 2: 645. 1851.

Annual, erect, pubescent or somewhat hispid herbs. Leaves polymorphic, the lower leaves orbicular-ovate, the upper leaves deeply 3-lobed, the uppermost 3-fid, all cordate, crenate or coarsely serrate, pubescent with simple and stellate hairs on both surfaces. Flowers solitary and axillary, or in terminal racemes; pedicels equal to or longer than petioles, articulate near the apex. Epicalyx segments absent or rarely represented by minute teeth. Calyx 5-lobed, pubescent without; lobes lanceolate, prominently 3-nerved. Corolla 1–2 cm diam.; white to pale yellow; petals obliquely obcordate. Staminal tube shorter than or equaling corolla, pink, antheriferous throughout. Capsule ovoid, beaked, ± wrinkled and pubescent. Seeds ± reniform, black, usually granulated, minutely pubescent.

Distribution. India, Pakistan, Sri Lanka, Laccadive Islands, tropical Africa, Madagascar, and Java. In our area confined to Jammu Province.

Specimen examined. INDIA. JAMMU: Ram Nagar, common under shade on roadside slopes, often associated with *Triumfetta rhomboidea* Jacquem., *Bidens bipinnata* L., and other annuals; erect herbs up to 2 feet tall, flowers white with sticky calyx, *B. M. Sharma 204* (KASH).

6. **Hibiscus caesius** Garcke, Bot. Zeit. 7: 850. 1849; Rakshit & Kundu, Bull. Bot. Surv. India 12: 173. 1970; Stewart in Nasir & Ali, Ann. Cat. Vasc. Pl. W. Pak. & Kashm. 478. 1972; Abedin in Nasir & Ali, Fl. W. Pak. 130: 21. 1979. *H. caesius* Garcke var. *genuinus* Hochr., Annuaire Conserv. Jard. Bot. Genève 4: 160. 1900.

Hibiscus pentaphyllus F. Muell., Fragm. 2: 13. 1859, non Roxb., 1832.
H. gibsonii Stocks ex Harvey, Fl. Cap. 2: 587. 1859–1860; Masters in Hook. f., Fl. Brit. India 1: 339. 1874.
H. heptaphyllus Dalz. & A. Gibson, Bombay Fl. 20. 1861.

Erect, usually suffrutescent herbs; branches bristly or with minute bristle-pointed prickles. Leaves palmately 3–5-lobed, the lobes oblong-elliptic, sharply serrate, glabrous or stellately pubescent. Flowers solitary, axillary; pedicels longer than leaves, articulate near the apex. Epicalyx of usually 10 radiate, needlelike, subspiny segments. Calyx 5-lobed, the lobes lanceolate, acuminate, strongly

3-nerved, distantly ciliate. Corolla 3–5 cm diam., yellow with purple center or completely purple, rarely white with purple center; petals obovate, sparsely stellate-pubescent outside. Staminal tube shorter than corolla, purple, antheriferous in upper half only. Capsule ovoid, beaked; valves setose. Seeds dark brown, pilose.

Distribution. India, Pakistan, Afghanistan, south tropical Africa and north Australia. Rare in our area, reported from the Pakistan-occupied part of Poonch District in Jammu Province.

Specimen examined. INDIA. JAMMU: Poonch Mirpur, in bushes, *Stewart 27244* (RAW).

One more species, *Hibiscus hirtus* L. is reported from Kashmir by Stokoe (fide Stewart, 1972) and probably is based on misidentification and remains yet to be seen. The specimen *B. M. Sharma 249* (KASH) under this name turned out to be *H. micranthus*.

3. ABELMOSCHUS Medikus, Malvaceae 45. 1787; Schumann, Nat. Pflanzenfam. III. 6: 49. 1890; Hochr., Candollea 2: 83. 1924; Taxon 4: 188. 1955.

Laguna Cav., Diss. 3: 173. 1787.
Bamia R. Br. ex Wallich, Pl. Asiat. Rar. 1: 39. 1830.

Six species (Borssum-Waalkes, 1966), distributed in temperate and warm regions. Three species have been recorded form our state, one cultivated.

KEY TO THE SPECIES OF *ABELMOSCHUS* IN JAMMU AND KASHMIR STATE

- 1a. Epicalyx segments caducous before anthesis; corolla white (turning pinkish at maturity), with a dark purple center .... 2. *A. ficulneus*
- 1b. Epicalyx segments persisting until dehiscence of fruit; corolla yellow to yellowish white, with a purple center.
  - 2a. Epicalyx segments 7–12, linear to narrowly lanceolate, 1–2.5 mm wide; corolla 5–7 cm diam.; capsule cylindrical, 7–25 cm long; seeds glabrous .... 1. *A. esculentus*
  - 2b. Epicalyx segments 4–5, ovate-lanceolate, 5–10 mm wide; corolla 7–10 cm diam.; capsule ovate-ellipsoid, 3.5–6 cm long; seeds glabrescent .... 3. *A. pungens*

1. Abelmoschus esculentus (L.) Moench, Methodus 617. 1794; Hu, Fl. China, Malvaceae. 39. 1955; Stewart in Nasir & Ali, Ann. Cat. Vasc. Pl. W. Pak. & Kashm. 475. 1972; Abedin in Nasir & Ali, Fl. W. Pak. 130: 25. 1979. *Hibiscus esculentus* L., Sp. Pl. 696. 1753; Masters in Hook. f., Fl. Brit. India 1: 343. 1874; Iljin in Shishkin & Bobrov, Fl. U.R.S.S. 15: 165. 1949; Ngwe, Union Burma J. Life Sci. 4: 203. 1971; Riedl in K. H. Rechinger, Fl. Iran. 120: 32. 1976. TYPE: "Habitat in Indiis," *Linn. Herb. no. 875/31* (LINN).

Hibiscus ficifolius Miller, Gard. Dict. 8th Edition. 15. 1768.
H. longifolius Willd., Sp. Pl. 4th Edition. 3: 827. 1800.

Annual, erect herbs, strigose-hirsute throughout. Leaves aceriform, wider than long, cordate, angular or palmately 3–7-lobed; lobes ovate to lanceolate, dentate. Flowers solitary and axillary. Epicalyx segments 7–12, linear to narrowly lanceolate, persisting until dehiscence of fruit. Calyx 5-toothed, spathaceous, bilabiate, caducous. Corolla 5–7 cm diam., yellow to yellowish white with a purple center; petals obovate. Staminal tube 2–2.5 cm long, included, antheriferous throughout. Capsule cylindrical, 7–25 cm long, 5-angled, acuminate, strigose-hirsute. Seeds ± globose, glabrous.

Distribution. Cultivated as vegetable in most tropical and many temperate countries; also in the Jammu and Kashmir provinces, known there as "Bhindi."

Additional specimen examined. INDIA. KASHMIR: Chatterhama (Srinagar), 1,700 m, *G. H. Dar 8963–66* (KASH).

According to Abedin (1979), the species is Asian in origin, as the whole genus is mainly of Asiatic distribution. On the basis of its close resemblance to *A. tuberculatus* Pal & Singh, a northern Indian species, Borssum-Waalkes (1966) considered the latter as one of the possible ancestors. This is taken to imply that *A. esculentus* originated in India (Hu, 1955 and Abedin, 1979). Babu (1977), however, thought it originated in Africa.

The species is primarily cultivated for the young fruits, which are eaten fresh or cooked as vegetables. Chopped capsules are used in making mucilaginous soups and sauces. Roasted seeds are also edible and are used as a substitute for coffee. The seeds contain 18% oil and ca. 15% water-soluble proteins. The plant is used in medicine for its diuretic and anticatarrhal effects. The stems furnish fiber and serve as raw material for paper production.

2. Abelmoschus ficulneus (L.) Wight & Arn. ex Wight, Cat. 14. 1833; Stewart in Nasir & Ali, Ann. Cat. Vasc. Pl. W. Pak. & Kashm. 475. 1972; Abedin in Nasir & Ali, Fl. W. Pak. 130: 26. 1979. *Hibiscus ficulneus* L., Sp. Pl. 695. 1753; Masters in Hook. f., Fl.

Brit. India 1: 340. 1874; Ngwe, Union Burma J. Life Sci. 4: 204. 1971. TYPE: Dillenius, Hort. Elth., tab. 157, f. 190.

Laguna aculeata Cav., Diss. 3: 173, tab. 71, f. 1. 1783.
Hibiscus sinuatus Cav., Diss. 3: 147, tab. 52, f. 2. 1787.
Abelmoschus alboruber F. Muell., Fragm. 1: 67. 1859.

Annual, sometimes prickly herbs. Leaves orbicular with cordate base and serrate margin, palmately 3–5-parted, scabrous on both surfaces; lobes obovate to spathulate. Flowers solitary, axillary or in terminal racemes. Epicalyx segments 5–6, lanceolate, falling before expansion of corolla. Calyx 5-toothed, spathaceous, rarely bilabiate, tomentose, caducous. Corolla 3–6 cm diam., white, turning pinkish at maturity, with a dark purple center; petals obovate. Staminal tube ca. 1.5 cm long, included, wholly antheriferous. Capsule pyramidal-ovoid, 3–4 cm long, 5-angled, hispid. Seeds ovoid to clavate-globose, black, striated with pilose stellate hairs.

Distribution. Northern Australia, southern Asia, Malaysia, eastern Africa, and Madagascar. Very rare in our area, this species has been collected from Jammu only (Stewart, 1972: 475).

3. **Abelmoschus pungens** (Roxb.) Voigt, Hort. Calc. 119. 1845; Abedin in Nasir & Ali, Fl. W. Pak. 130: 27. 1979. *Hibiscus pungens* Roxb., Hort. Bengal. 52. 1814, nom. nud., Fl. Ind. ed. 1832. 3: 213. 1832; Masters in Hook. f., Fl. Brit. India 1: 341. 1874. *Hibiscus manihot* L. var. *pungens* (Roxb.) Hochr., Annuaire Conserv. Jard. Bot. Genève 4: 155. 1900. *Abelmoschus manihot* (L.) Medicus, var. *pungens* (Roxb.) Hochr., Candollea 2: 87. 1924. *A. manihot* var. *pungens* (Roxb.) Hochr. sensu Hu, Fl. China, Malvaceae. 36. 1955. TYPE: Roxburgh's Icone *no. 1585* (K).

Annual or perennial herbs, densely covered with long, yellow, bristly hairs. Leaves orbicular to broadly ovate, cordate at base, palmately 3–7-lobed or -parted; lobes variable, ovate to lanceolate, oblong-lanceolate, obovate or elliptic, entire to coarsely serrate. Flowers solitary, axillary, sometimes subracemose towards the stem apex. Epicalyx segments 4–5, ovate-lanceolate, persisting until dehiscence of fruit. Calyx 5-toothed, spathaceous, caducous. Corolla 7–10 cm diam., yellow with a purple center; petals usually obovate. Staminal tube 1.5–3 cm long, included, antheriferous to base. Capsule ovate-ellipsoid, 3.5–6 cm long, 5-angular, short-beaked. Seeds globular or reniform, black, scabrid on the back, glabrescent.

Distribution. Northern India, Pakistan (rare), China, Malaysia, Philippines, and northern Australia. In our area this species has been collected only in the Pakistan-occupied part of Poonch District in Jammu Province and is no doubt very rare.

Specimen examined. INDIA. JAMMU: Poonch District, Nawal Nadi, 11-9-1953, *A. Rashid, E. Nasir & R. R. Stewart s.n.* (RAW).

According to Hu (1955), this species is found wild in China and northern India on grassy banks or along roadsides at altitudes of 1,500–1,600 m. She further reported that this plant (like her *Abelmoschus manihot* "typicus") is extensively cultivated in China for its flowers and roots. The flowers are said to be used in soup for the conservation of health during hot summer months. The root may be used fresh or dried. It is boiled with pork, and the preparation taken internally to cure abscesses. It is also soaked in rape seed oil and used for dressing boils.

The genus *Abelmoschus* was established by Medicus (1787) to accommodate species of *Hibiscus* with caducous calyces. The new genus was subsequently adopted by Gaertner (1791) and Moench (1794). Notwithstanding this, most workers on the Indian flora (Roxburgh, 1832; Masters, 1874; Prain, 1903; Duthie, 1903; Gamble, 1957; Cooke, 1958; and others) did not recognize the new genus but considered *Abelmoschus* as a section of *Hibiscus*. Hochreutiner (1924), however, stressed the need of placing *Abelmoschus* apart from *Hibiscus*, because in the former the calyx, corolla, and stamens are adnate basally and fall together after anthesis, although earlier (1900) he considered *Abelmoschus* only to be a section of *Hibiscus*. Most recent workers on Malvaceae (Hu, 1955; Borssum-Waalkes, 1966; Abedin, 1979) have treated *Abelmoschus* as a distinct genus. We also take this approach and agree with Paul A. Fryxell (1984, pers. comm.) in believing that the species of *Fioria*, *Abelmoschus*, and *Hibiscus* are better understood when separated into distinct genera.

4. **KYDIA** Roxb., Pl. Coromandel 3: 11, tab. 215–216. 1819.

Four or five species, distributed in India, Pakistan, Burma, and China; one species recorded from our area.

Kydia calycina Roxb., Pl. Coromandel 3: 11, tab. 215. 1819; Fl. Ind. ed. 1832. 3: 188. 1832; Masters in Hook. f., Fl. Brit. India 1: 348. 1874; Hu, Fl. China, Malvaceae. 71.

1955; Ngwe, Union Burma Life Sci. 4: 200. 1971; Stewart in Nasir & Ali, Ann. Cat. Vasc. Pl. W. Pak. & Kashm. 480. 1972; Abedin in Nasir & Ali, Fl. W. Pak. 130: 28. 1979; Sharma & Kachroo, Fl. Jammu 1: 110. 1981. TYPE: Roxb., Pl. Coromandel 3: 11, tab. 215. 1819.

Kydia fraterna Roxb., Pl. Coromandel 3: 12, tab. 216. 1819.

Medium-sized trees, the herbaceous portions with stellate pubescence. Leaves broadly cordate to suborbicular, entire or usually 3–5-angled, stellate-pubescent, the midrib (sometimes adjacent nerves also) with a basal gland abaxially. Flowers paniculate, polygamous. Epicalyx segments 4–6, oblong, in fruit obovate-spathulate, spreading stellately, densely stellate-villous, 5-parted; lobes triangular, incurved, persistent, ± enclosing fruit. Corolla rotate, connate at base, 1–2 cm diam., white; petals obovate-obcordate, barbate at the base. Staminal tube 3–5 mm long, included, divided in the apical half into 5 branches, each with a cluster of 3–5 sessile anthers, rudimentary in the carpellate flowers. Ovary globose, villous, 3-carpellate; style with 3 terminal branches, each with a peltate stigma, rudimentary in the staminate flowers. Capsule subglobose, loculicidally 3-valved, stellate-pubescent. Seeds reniform, glabrous.

Distribution. India, Pakistan, Burma, and China. In our area this species occurs, uncommonly, in Jammu Province.

Specimens examined. INDIA. JAMMU: Nandni, uncommon, collected from a slope opposite Brig. Atma Singh's Memorial, small tree, bark gray, young shoots and panicles grayish, leaves hoary, flowers white, *B. M. Sharma 728* (KASH); also reported from Mirpur and Billawar by Lambert (1933).

The wood of this species is straight-grained and good for house building. The liber yields fiber, and the leaves are said to be used as an embrocation.

5. GOSSYPIUM L., Sp. Pl. 693. 1753; Gen. Pl. 5th Edition. 309. 1754.

About 40 species distributed in tropical and subtropical regions; two cultivated species are recorded from our area.

KEY TO THE SPECIES OF *GOSSYPIUM* IN JAMMU AND KASHMIR STATE

1a. Perennial suffrutescent herbs; stipules linear; epicalyx segments connate at the base, ± entire, with 3 small teeth at the apex; filaments equal in length .... 1. *G. arboreum*
1b. Annual herbs; stipules ovate-falcate; epicalyx segments free, laciniate, with 7–9 long and acuminate teeth at the apex; filaments unequal in length, the upper ones longer .... 2. *G. hirsutum*

1. Gossypium arboreum L., Sp. Pl. 693. 1753; Masters in Hook. f., Fl. Brit. India 1: 347. 1874; Hu, Fl. China, Malvaceae. 62. 1955; Stewart in Nasir & Ali, Ann. Cat. Vasc. Pl. W. Pak. & Kashm. 477. 1972; Abedin in Nasir & Ali, Fl. W. Pak. 130: 30. 1979. TYPE: *Linn. Herb. no. 874/3* (holotype, LINN).

Gossypium rubrum Fôrskal, Fl. Aegypt.-Arab. 125. 1775.

Perennial, pubescent, suffrutescent herbs with purple branches. Leaves ovate to orbicular or subreniform, 5–7-parted; lobes oblong-lanceolate, acute, stellate-pilose adaxially, sparsely villous abaxially; stipules linear, caducous. Flowers solitary, axillary. Epicalyx segments 3, foliaceous, cordate, connate at the base, ± entire, with 3 small teeth at the apex, stellately hirsute and villose on the nerves. Calyx cupular, ± 5-dentate. Corolla pale yellow, usually with a maroon center, sometimes all purplish. Staminal tube included, antheriferous throughout; filaments equal in length. Capsule fibrous, ovoid, beaked, with persistent, accrescent epicalyx and calyx. Seeds densely covered with long and short hairs.

Distribution. Origin uncertain, possibly African; widely cultivated in tropical and subtropical regions of the Old World. According to Hu (1955), it has escaped from cultivation in Hainan and southwestern Sichuan in China. In our area it was occasionally grown in the Kashmir Valley until recently. Vernacular name: "Kapas."

Additional specimen examined. INDIA. KASHMIR: Pampore, 6 June 1970, *G. N. Javeid s.n.* (KASH).

2. Gossypium hirsutum L., Sp. Pl. 2nd Edition. 975. 1763; Prokhanov in Shishkin & Bobrov, Fl. U.R.S.S. 15: 178. 1949; Hu, Fl. China, Malvaceae. 66. 1955; Abedin in Nasir & Ali, Fl. W. Pak. 130: 31. 1979. *Gossypium herbaceum* L. var. *hirsutum* Schumann, Nat. Pflanzenf. III. 6: 51. 1890. TYPE: Miller's description (see Fryxell, 1968: 882).

G. religiosum L., Syst. Nat. 12th Edition. 2: 462. 1767.

Annual, erect, hirsute herbs with green or red-tinged branches. Leaves broadly cordate, ± orbicular, 3(–5)-lobed, upper ones sometimes entire and ovate; lobes triangularly ovate, abruptly acuminate, glabrescent with simple and stellate hairs on both surfaces; stipules ovate-falcate, caducous.

Flowers solitary, axillary. Epicalyx segments as in the preceding species but free and with 7–9 long and acuminate teeth at the apex. Calyx cupular, 5-toothed. Corolla pale yellow. Staminal tube as in the preceding species but filaments unequal in length, the upper ones longer. Capsule fibrous, ovoid, beaked. Seeds thickly covered with white pubescence.

Distribution. A native of Central America, acclimatized from Guatemala northwards to the cotton belt of the southern United States and cultivated in all cotton-growing countries. In our area it was grown in Kashmir Valley until recently. Vernacular name: "Kapas."

Specimen examined. INDIA. KASHMIR: exact locality not given, *M. Y. Khan s.n.* (KASH).

A third species, *Gossypium herbaceum* L., has been reported from the Kashmir Valley by Stewart (1972: 478), but we have not seen any specimens.

It is said that cotton thrives in Kashmir, but the practice of growing it here has now nearly ceased.

The various species of cotton are abundantly cultivated in many countries of the world for their seeds, which are densely covered with short and long hairs, forming the cotton of commerce.

6. THESPESIA Solander ex Correa, Ann. Mus. Natl. Hist. Nat. 9: 290, tab. 8, f. 2. 1807, nom. cons. *Azanza* Alef., Bot. Zeit. 19: 298. 1861.

About 15 species, distributed in tropics of both hemispheres; a single species has been reported from our area.

Thespesia populnea (L.) Solander ex Correa, Ann. Mus. Natl. Hist. Nat. 9: 290, tab. 8, f. 2. 1807; Masters in Hook. f., Fl. Brit. India 1: 345. 1874; Hu, Fl. China, Malvaceae. 69. 1955; Ngwe, Union Burma J. Life Sci. 4: 200. 1971; Stewart in Nasir & Ali, Ann. Cat. Vasc. Pl. W. Pak. & Kashm. 484. 1972; Abedin in Nasir & Ali, Fl. W. Pak. 130: 32. 1979. *Hibiscus populneus* L., Sp. Pl. 694. 1753. *Malvaviscus populneus* (L.) Gaertner, Fruct. Sem. Pl. 2: 253, tab. 135, f. 3. 1791. TYPE: Herb. Herm. Volume V, fol. 208, tab. 258 (lectotype, BM).

Hibiscus bacciferus Forster f., Fl. Ins. Austr. 48. 1786.
Thespesia macrophylla Blume, Bijdr. 2: 73. 1825.

Medium-sized bushy trees; herbaceous portions covered with ferruginous, peltate scales. Leaves ovate, cordate at base, shortly acuminate, entire; stipules linear-lanceolate, caducous. Flowers solitary, axillary; pedicels 1–5 cm long, articulate at base. Epicalyx segments 3, lanceolate, caducous. Calyx cupular, truncate, minutely 5-toothed, coriaceous, persistent. Corolla convolute, campanulate, pale yellow with a crimson center. Staminal tube cylindric, included, 5-dentate at the apex, antheriferous for most part; filaments paired, the anthers horseshoe-shaped. Ovary 5-loculate; style ± clavate, unbranched; stigma elongate, scabrous. Capsule ± globose, almost woody but easily compressed, indehiscent. Seeds obovoid, angular, pilose.

Distribution. A coastal plant, common in tropical countries. In Jammu and Kashmir State it has been reported only from Udhampur in the Jammu Province (Lambert, 1933: 3; Sharma & Kachroo, 1981: 113).

According to Ngwe (1971), the bark of this plant is used in treating piles, dysentery, and skin diseases.

7. MALVA L., Sp. Pl. 687. 1753; Gen. Pl. 5th Edition. 308. 1754.

Bismalva Medicus, Malvaceae. 39. 1787.

Over 100 species native to Europe, Asia, and Africa. Several species are naturalized in America, Australia, and New Zealand; represented in our area by nine species, three being cultivated or escapes from cultivation.

KEY TO THE SPECIES OF *MALVA* IN JAMMU AND KASHMIR STATE

1a. Epicalyx segments oblong, oblong-lanceolate, ovate, or ovate-lanceolate.
  2a. Leaves 5–7-lobed; staminal tube with simple or 2-rayed, retrorse hairs .... 4. *M. bucharica*
  2b. Leaves 3–5-lobed; staminal tube stellately pubescent.
    3a. Stipules ovate-lanceolate; flowers 5–15 (rarely fewer than 5) in fascicles; petals 1.5–2 cm wide at apex; mericarps 10–14, glabrous .... 3. *M. mauritiana*
    3b. Stipules lanceolate; flowers solitary or 2–4 in fascicles; petals 1 cm or less wide at apex; mericarps 9–12, glabrous or pubescent.
      4a. Petals oblong-obovate, 0.7–2 × 0.5 cm; mericarps pubescent .... 1. *M. ambigua*
      4b. Petals obovate, 2–3 × 1 cm; mericarps glabrous .... 2. *M. sylvestris*

1b. Epicalyx segments linear to linear-lanceolate.
  5a. Plants biennial or perennial; mericarps 12–15, pubescent, smooth throughout; seeds pubescent .... 5. *M. neglecta*
  5b. Plants mostly annual, rarely biennial; mericarps 9–12, glabrous, striate-rugose at least on sides and margins; seeds glabrous.
    6a. Calyx lobes ± rotate and spreading in fruit; corolla shorter than, equaling, or slightly exceeding calyx; staminal tube 1–2 mm long, glabrous; mericarps with raised reticulation on back, ± winged and acute along margins.
      7a. Flowers solitary or paired, rarely more than 2 but never compact; pedicels distinctly visible, 0.3–2 cm long; calyx 5–6 mm long, slightly enlarged in fruit; margins of mericarps slightly winged, ± entire .... 6. *M. microcarpa*
      7b. Flowers usually many, compactly fasciculate; pedicels generally not visible, 3–5 mm long; calyx 3–5 mm long, enlarged in fruit to ca. 1 cm; margins of mericarps distinctly winged, undulate-toothed .... 7. *M. parviflora*
    6b. Calyx lobes incurved and enclosing the fruit; corolla 1½–2 times as long as calyx; staminal tube 3–5 mm long, glabrous or pubescent; mericarps smooth on back, unwinged and rounded along margins.
      8a. Plants annual, pubescent; leaves suborbicular, 5–7-lobed; petioles 2–9 cm long; fruiting calyx less than 10 mm long; petals retuse, ca. 2 times the length of sepals, the claw ± pubescent; staminal tube retrorsely pubescent; fruit ca. 5 mm diam.; mericarps 12 .... 8. *M. mohileviensis*
      8b. Plants annual to biennial, glabrescent; leaves orbicular, usually 5-lobed; petioles (1.5–)4–20 (–24) cm long; fruiting calyx 10–15 mm long; petals scarcely notched, 1½ times or less the length of sepals, the claw glabrous; staminal tube glabrous or pubescent with simple hairs towards the apex; fruit 5–7 mm diam.; mericarps 10–12 .... 9. *M. verticillata*

1. Malva ambigua Guss., Fl. Sicul. Prodr. 2: 331. 1828; Iljin in Shishkin & Bobrov, Fl. U.R.S.S. 15: 48. 1949. TYPE: described from Sicily (NAP).

Malva sylvestris L. var. *eriocarpa* Boiss., Fl. Orient. 1: 819. 1867.

Biennial to perennial herbs. Stems erect or ascending, usually weak, sparsely pubescent. Leaves ± semiorbicular, usually truncate (to cordate) at base, 3–5-lobed, serrate, glabrescent; stipules lanceolate, 2–4 mm long; petioles 2–8 cm long. Flowers axillary, solitary or in fascicles of 2–4; pedicels 1–3 cm long, with simple or stellate hairs. Epicalyx segments narrowly ovate or oblong. Calyx 3–6 mm long, stellately pubescent, slightly accrescent in fruit; lobes broadly triangular. Petals lilac, oblong-obovate, 0.7–2 × 0.5 mm, claw pubescent. Staminal tube 3–5 mm long, pilose with stellate hairs. Fruit 6 mm diam.; mericarps 9–12, pubescent, with raised reticulation on back. Seeds reticulate, glabrous.

Distribution. U.S.S.R., western and eastern Mediterranean, Iran, Afghanistan, and Pakistan. In our area infrequent in the Kashmir Valley, collected on house tops, waste places, moist sites, and sides of water courses.

Additional specimens examined. INDIA. KASHMIR: Ganderbal, *G. H. Dar 2499* (PF); Srinagar, *G. N. Javeid 590 A* (KASH); Srinagar, around graveyards in association with *Urtica dioica* L., *A. R. Naqshi 8165* (KASH).

First record for India.

2. Malva sylvestris L., Sp. Pl. 689. 1753; Masters in Hook. f., Fl. Brit. India 1: 320. 1874; Iljin in Shishkin & Bobrov, Fl. U.R.S.S. 15: 41. 1949; Kitamura, Fl. Afghan. 171. 1960; Stewart in Nasir & Ali, Ann. Cat. Vasc. Pl. W. Pak. & Kashm. 481. 1972; Abedin in Nasir & Ali, Fl. W. Pak. 130: 37. 1979. TYPE: described from western Europe, *Linn. Herb. no. 870/22* (holotype, LINN).

Biennial to perennial herbs. Stems erect, pubescent to glabrescent with simple (or bifid) hairs. Leaves ± suborbicular, truncate to broadly cordate at base, usually 3-lobed, crenate-dentate, sparsely pilose; stipules lanceolate, scarious, ca. 5 mm long; petioles 2–7 cm long, pilose. Flowers axillary, solitary or in fascicles of 2–4; pedicels ca. 2 cm long. Epicalyx segments ovate-oblong. Calyx 3–6 mm long, glabrescent with stellate hairs; lobes broadly triangular. Petals pink-purple, obovate, emarginate, 2–3 × 1 cm, the claw ciliate. Staminal tube ca. 3 mm long, pilose with stellate hairs. Fruit 5–6 mm diam.; mericarps 10–12, glabrous, reticulate. Seeds sparsely punctate.

Distribution. Western Europe, northern Africa, and Asia. Occasionally cultivated for greens in the Kashmir Valley and at certain places evidently escaped from cultivation, also collected from Ladakh (Stewart, 1972: 481).

Additional specimen examined. INDIA. KASHMIR: Srinagar, *A. R. Naqshi 8153* (KASH).

The species resembles *M. ambigua* Guss. and

M. mauritiana L. but differs from the former in having glabrous fruits and from the latter in having narrower and emarginate petals, and fewer flowers in the fascicles. Riedl (1976) followed Boissier (1867) in treating all of the above three species as *M. sylvestris* varieties *sylvestris*, *eriocarpa* Boiss., and *mauritiana* (L.) Boiss.

Malva sylvestris is believed to have been cultivated by ancient Greeks and Romans as a medicinal and edible plant. An infusion of flowers and leaves is used internally and as a gargle. The infusion, mixed with honey, is taken in case of catarrhal ailments, inflammatory conditions of the digestive tract, and constipation. A paste of leaves and flowers is applied in case of external inflammatory conditions. Flowers are also used in coloring medicine, liquors, and wool. The coloring properties are said to be due to glucoside malvin and diglucoside malvidin in the petals.

3. **Malva mauritiana** L., Sp. Pl. 689. 1753; Iljin in Shishkin & Bobrov, Fl. U.R.S.S. 15: 49. 1949; Abedin in Nasir & Ali, Fl. W. Pak. 130: 38. 1979. *Malva sylvestris* var. *mauritiana* (L.) Boiss., Fl. Orient. 1: 819. 1867; Masters in Hook. f., Fl. Brit. India 1: 320. 1874; Stewart in Nasir & Ali, Ann. Cat. Vasc. Pl. W. Pak. & Kashm. 481. 1972; Riedl in K. H. Rechinger, Fl. Iran. 120: 19. 1976. TYPE: *Linn. Herb. no. 870/24* (holotype, LINN).

Biennial to perennial herbs; stems mostly rigid, erect, rarely ascending, glabrescent with simple and bifid hairs. Leaves orbicular to suborbicular, truncate to shallowly cordate at base, 3–5-lobed, coarsely crenate, sparsely pilose with simple and bi- (tri-)fid hairs; stipules ovate-lanceolate, 3–6 mm long; petioles 4–12 cm long, with a line of dense hairs apically. Flowers axillary, in fascicles of 5–15, rarely fewer than 5; pedicels 1–4 cm long, unequal in length. Epicalyx segments ovate-lanceolate to ovate or oblong. Calyx 5–8 mm long, pilose with stellate hairs; lobes triangular, plicate at angles, accrescent in fruit. Petals dark pink to purple, 2–3 × 1.5–2 cm, obovate, retuse, claw pubescent at base. Staminal tube ca. 5 mm long, pilose with stellate hairs. Fruit 5–7 mm diam.; mericarps 10–14, glabrous, reticulate-wrinkled. Seeds finely punctate.

Distribution. Mediterranean region, western Europe, and U.S.S.R., elsewhere cultivated. In our area collected from Ladakh, where it grows, rare and handsome, along borders of cultivated fields, also reported from Kashmir by Stewart (1972: 481).

Additional specimen examined. INDIA. LADAKH: Nubra, along borders of cultivated fields, *A. R. Naqshi & G. N. Dar 7218* (KASH).

Most authors follow Boissier (1867) in treating this species as a variety of *Malva sylvestris* L. Whitmore (1979) considered *M. mauritiana* as synonymous with *M. sylvestris.*

The species is used for the same purpose as *M. sylvestris.* In the Iranian pharmacopoeia it is employed in a mixture with violets, *Nymphaea candida, Ziziphus jujuba, Alhagi camelorum,* and other species for preparation of the purgative infusion (Hooper, *Useful Plants and Drugs of Iran and Iraq,* 1937).

4. **Malva bucharica** Iljin, Bot. Mater. Gerb. Glavn. Bot. Sada RSFSR 5: 4. 1924; Shishkin & Bobrov, Fl. U.R.S.S. 15: 55. 1949; Riedl in K. H. Rechinger, Fl. Iran. 120: 19. 1976. TYPE: Kurgan-Tyube, *Roshewitz 175* (lectotype, LE).

Perennial herbs; stems erect or ascending, terete, glabrate or with simple to 2-branched hairs, sometimes completely glabrous. Leaves semiorbicular, truncate or ± cordate at base, 5–7-lobed, serrate-dentate, subglabrous, the nerves pilose with usually simple hairs; stipules ovate to broadly lanceolate; petioles 3–15 cm long. Flowers usually 3 in axils, crowded towards apices of branches; pedicels 1.5–5 cm long, much shorter than the subtending leaf; epicalyx segments oblong-lanceolate; calyx 3–7 mm long, glabrous or pubescent with simple and trifid hairs, the lobes accrescent and enclosing the fruit, triangular-ovate. Petals purplish, obovate or oblong-obovate, 0.8–2.2 × 0.4–1.2 cm, deeply notched, claw ± densely pilose. Staminal tube 4–6 mm long, with simple and 2-rayed, retrorse hairs. Fruit 6–7 mm diam.; mericarps (8–)10(–12), glabrous or pubescent, reticulate-rugose on back. Seeds puncticulate.

Distribution. U.S.S.R. and Kashmir. In our area it occurs frequently in the Kashmir Province but has not been collected in Jammu and Ladakh.

Additional specimens examined. INDIA. KASHMIR: Nagin, collector not known, *s.n.* (KASH); Srinagar, *G. N. Javeid 590 B* (KASH); Srinagar, Rambagh, *A. R. Naqshi 8152* (KASH); Srinagar, Hazratbal, roadsides near university gate, *G. H. Dar 7617* (KASH); Srinagar, Rainawari, in graveyards among *Urtica* bushes, *A. R. Naqshi 8178* (PF), *8179–81* (KASH).

In habit this species resembles *M. sylvestris* but differs from it mainly in having simple and two-rayed, retrorse hairs on the staminal tube. First record for Indian subcontinent.

5. Malva neglecta Wallr., Syll. Ratisb. 1: 140. 1824; Iljin in Shishkin & Bobrov, Fl. U.R.S.S. 15: 56. 1949; Hu, Fl. China, Malvaceae. 6. 1955; Kitamura, Fl. Afghan. 271. 1960; Stewart in Nasir & Ali, Ann. Cat. Vasc. Pl. W. Pak. & Kashm. 481. 1972; Singh & Kachroo, Forest Fl. Srinagar. 151. 1976; Riedl in K. H. Rechinger, Fl. Iran 120: 24. 1976; Abedin in Nasir & Ali, Fl. W. Pak. 130: 38. 1979. TYPE: without exact locality, Germany, *Wallroth s.n.* (E).

Malva rotundifolia sensu Maxim., Acta Hort. Petrop. 11: 78. 1890, non L.; Masters in Hook. f., Fl. Brit. India 1: 320. 1874.
M. vulgaris Ten., Fl. Napol. Suppl. 1: 62. 1811–1815.
M. lignescens Iljin, Bot. Mater. Gerb. Glavn. Bot. Sada RSFSR 2: 173. 1921.

Biennial to perennial herbs with woody bases. Stems prostrate or decumbent, pubescent with stellate hairs, especially on younger parts. Leaves orbicular-reniform, cordate at base, crenate-denticulate, occasionally shallowly 5(–7)-lobed on elongated branches, sparsely pilose with simple and stellate hairs adaxially and densely so with stellate hairs abaxially; stipules ovate-lanceolate, ca. 5 mm long; petioles 3–15 cm long, stellately villous. Flowers axillary, 3–4 in a fascicle, those on the lower branches occasionally solitary; pedicels, 0.5–5 cm long, unequal in length, much longer than the flower but shorter than the subtending leaf; epicalyx segments linear to linear-lanceolate; calyx 5–8 mm long, stellately pilose; lobes triangular. Petals purplish to pinkish, sometimes white, 10–13 × 3–4 mm, oblong-obovate, retuse, claw pubescent on the margin. Staminal tube 4–5 mm long, pubescent with simple, ± retrorse hairs. Fruit 5–7 mm diam.; mericarps 12–15, pubescent, smooth. Seeds pubescent.

Distribution. Native to Old World, naturalized in America. In our area occurring widely in Kashmir Valley along wastelands, meadows, and cultivated fields from 1,600 m altitude to the alpine zone; also reported from the Jammu and Ladakh regions. It is commonly used as a wild vegetable under the local name "Sotsal."

Additional specimens examined. INDIA. KASHMIR: Srinagar, Habak, *G. N. Javeid 121* (KASH); Womens' College campus, *D. Sethi 101* (KASH); Harwan, *G. Singh 1986* (KASH); Tangmarg, *A. R. Naqshi 599* (KASH); Rainawari, *A. R. Naqshi 8159–60* (KASH); Ganderbal, exposed hill slopes, *G. H. Dar 2325–27* (KASH); Zakura, 1,630 m, *G. H. Dar 1053–57* (KASH), *1058* (PF); Srinagar (Lal Bazar), *A. R. Naqshi 8166* (KASH); Sonamarg, *G. H. Dar 7679–7682* (KASH); Gund-Haknar, *G. H. Dar 8644* (KASH); Hang (Sonamarg), *G. H. Dar 8643* (KASH); *Chatterhama* (Srinagar), *G. H. Dar 8841* (KASH); Manigam (Lar), *G. H. Dar 5328–31* (KASH).

A number of varieties and forms of this species can be distinguished in our area. However, their recognition is deferred until a satisfactory monographic work on the species within the area is available.

These plants are said to be used in medicine due to the high content of mucilage in the foliage and roots. The leaves contain vitamin C and provitamin A, while the seeds contain about 18% of a light green oil. A decoction of leaves and roots is used as a gargle for treatment of inflammatory conditions of the respiratory tract and as fomentations for external treatment of skin inflammations, ulcerations, and swellings. An infusion of leaves with milk is used for its diuretic effect. A decoction of the leaves is used as an enema to relieve constipation (Dar et al., 1984). The petioles are used for treating babies, instead of glycerine clysters.

6. Malva microcarpa Pers., Syn. Pl. 2: 251. 1806; Riedl in K. H. Rechinger, Fl. Iran. 120: 27. 1976; Abedin in Nasir & Ali, Fl. W. Pak. 130: 41. 1979. *Malva parviflora* var. *microcarpa* (Pers.) Loscos, Trat. Pl. Aragon 2: 203. 1877; Stewart in Nasir & Ali, Ann. Cat. Vasc. Pl. W. Pak. & Kashm. 481. 1972. TYPE: Herb. *Persoon s.n.* (holotype, L).

Annual herbs. Stems prostrate or ascending, stellately villous. Leaves orbicular-reniform, cordate at base, 3–7-angular, crenate to serrate, glabrescent; stipules ovate or lanceolate, 2–4 mm long; petioles 1–10(–25) cm long. Flowers axillary, solitary or paired, rarely more but then never compact; pedicels 0.3–2 cm long, distinctly visible; epicalyx segments linear; calyx 5–6 mm long, slightly enlarged and rotate in fruit; lobes triangular, acute to acuminate. Petals white (sometimes with pinkish tips), equaling or slightly exceeding the calyx. Staminal tube 1–2 mm long, glabrous. Fruit 3–6 mm diam.; mericarps 9–10, glabrous, reticulate, with slightly winged margins. Seeds glabrous.

Distribution. Native to the Mediterranean Region, Malaysia, Iran, Afghanistan, and Pakistan.

In our area it has been collected, infrequently, from Jammu.

Additional specimen examined. INDIA. JAMMU: Tilo Talab, common along drains; annual herbs, mucilaginous when bruised, flowers white, *B. M. Sharma 389* (KASH).

First record for India.

7. **Malva parviflora** L., Demonstr. Pl. 18. 1758; Sp. Pl. 2nd Edition. 269. 1763; Masters in Hook. f., Fl. Brit. India 1: 321. 1874; Iljin in Shishkin & Bobrov, Fl. U.R.S.S. 15: 63. 1949; Kitamura, Fl. Afghan. 271. 1960; Stewart in Nasir & Ali, Ann. Cat. Vasc. Pl. W. Pak. & Kashm. 481. 1972; Riedl in K. H. Rechinger, Fl. Iran. 120: 23. 1976; Abedin in Nasir & Ali, Fl. W. Pak. 130: 42. 1979. TYPE: described from Barbary (north Africa), *Linn. Herb. no. 870/17* (holotype, LINN).

Annual herbs; stems erect or prostrate-ascending, sparsely pubescent with stellate hairs to glabrescent. Leaves orbicular-reniform, cordate at base, crenate-serrate, often shallowly 3–7-lobed, sparsely pubescent with simple or 2-fid hairs on the adaxial surface, usually stellately pilose abaxially; stipules lanceolate to ovate, 2–5 mm long; petioles 3–17 cm long, longer than blade, simple and stellately pubescent, especially apically. Flowers usually in compact axillary fascicles; pedicels 3–5 mm long, generally not visible, subglabrous. Epicalyx segment linear. Calyx 3–5 mm long, pilose with stellate hairs, accrescent in fruit to ca. 1 cm; lobes triangular, mucronate. Petals white, sometimes pinkish at the tips, usually shorter than or equaling the calyx, oblong, slightly narrowed at base, scarcely notched at apex, claw glabrous. Staminal tube ca. 2 mm long, glabrous. Fruit 5–6 mm diam.; mericarps 9–10, glabrous, with raised reticulation and toothed, winglike margins. Seeds glabrous.

Distribution. Mediterranean Region, Anatolia, Iran, Iraq, Afghanistan, Pakistan, India, and Arabia. Many workers (Javeid, 1970; Stewart, 1972; Sharma & Kachroo, 1981) have reported this species from our area, but there is no authentic specimen, because all the specimens under this name turned out to be either *Malva neglecta* or *M. microcarpa*.

8. **Malva mohileviensis** Downar, Bull. Soc. Mosc. 1: 177. 1861; Iljin in Shishkin & Bobrov, Fl. U.R.S.S. 15: 64, pl. 3, f. 1. 1949; Abedin in Nasir & Ali, Fl. W. Pak. 130: 43. 1979. TYPE: vicinity of Mogilev (LE).

Annual herbs; stems erect, ± purplish, pubescent with simple and 2-fid hairs, especially towards the apex. Leaves suborbicular, cordate at base, 5–7-lobed, serrulate to crenulate-dentate, sparsely pubescent with simple or 2-fid hairs on the upper surface, more pubescent and with mixed stellate hairs beneath; stipules lanceolate-ovate, 3–5 mm long; petioles 2–9 cm long. Flowers axillary, in fascicles of 4–7(–many); pedicels 5–10 mm long. Epicalyx segments linear, green to purple. Calyx ca. 5 mm long, green to purple, glabrescent, accrescent and scarious in fruit, the lobes triangular. Petals pinkish, about twice the length of calyx, obovate, retuse, claw slightly pubescent. Staminal tube ca. 4 mm long, retrorsely pubescent. Fruit ca. 5 mm diam.; mericarps 12, glabrous, smooth on the back, transversely rugose along the rounded margins, radially wrinkled on the sides. Seeds minutely puncticulate.

Distribution. Japan, China, U.S.S.R., Pakistan. In our area it occurs infrequently in Kashmir and Ladakh.

Additional specimens examined. INDIA. KASHMIR: Sonamarg, along roadsides just near the Shutkar Bridge, *G. H. Dar 8483* (PF), *8484* (KASH). LADAKH: Leh, *A. R. Naqshi & G. N. Dar 7217* (KASH).

In Tibetan medicine the flowers of this species are used as a diuretic. The leaves and young shoots can be used as a salad or as a vegetable. It is a valuable forage plant due to a high protein content and tender consistency. It has been estimated that this species contains twice as much protein as any other forage plant, so it increases the yield and quality of milk when fed to cows. First record for India.

9. **Malva verticillata** L., Sp. Pl. 689. 1753; Masters in Hook. f., Fl. Brit. India 1: 320. 1874; Iljin in Shishkin & Bobrov, Fl. U.R.S.S. 15: 68. 1949; Hu, Fl. China, Malvaceae. 5. 1955; Stewart in Nasir & Ali, Ann. Cat. Vasc. Pl. W. Pak. & Kashm. 481. 1972; Riedl in K. H. Rechinger, Fl. Iran. 120: 22. 1976; Abedin in Nasir & Ali, Fl. W. Pak. 130: 43. 1979. LECTOTYPE: *Linn. Herb. no. 870/26* (LINN).

9a. **Malva verticillata** var. **verticillata** [see Abedin in Nasir & Ali, Fl. W. Pak. 130: 45. 1979].

M. chinensis Miller, Gard. Dict. 8th Edition. 670. 1768.

Annual or biennial herbs; stems erect, green to purplish, sparsely stellately pubescent. Leaves usually orbicular, cordate to subtruncate at base, usually 5-lobed, coarsely crenate-dentate, glabrescent on the adaxial surface with simple, or 2-fid hairs, more pubescent abaxially with stellate, simple, or 2-fid hairs; stipules lanceolate, 5 mm long; petioles 4–20(–24) cm long, glabrescent, with villous grooves. Flowers axillary, subsessile, in dense and compact fascicles of 5–many; pedicels 5–8 mm long, ± of equal length, all hidden by flowers or fruits. Epicalyx segments linear or linear-lanceolate, acute. Calyx 5–6 mm long, sparsely hirsute with stellate hairs, prominently reticulate-veined, accrescent in fruit to 10–15 mm, the lobes triangular, with long-ciliate margins. Petals purplish, 7–9 mm long, scarcely notched, the claws glabrous. Staminal tube 3–5 mm long, glabrous or pubescent with simple hairs towards the apex. Fruit 5–7 mm diam., enclosed in accrescent calyx, the mericarps 10–12, glabrous, smooth on the back, rugose along the rounded margins, radially striate on the sides. Seeds glabrous.

Distribution. China, Europe, Asia, Ethiopia, Egypt. In our area commonly cultivated in the Kashmir Valley for its leaves which are used as a vegetable, also collected from Jammu and Ladakh. Vernacular names: "Parim sotsal", "Bagh sotsal."

Additional specimens examined. INDIA. KASHMIR: university campus, *A. R. Naqshi 107* (KASH); Chatterhama (Srinagar), *G. H. Dar 7562* (KASH, PF); Beehama, *G. H. Dar 7563–65* (KASH); Hirpur (Pir Panjal), *G. A. Gammie s.n.* (K, fide Abedin, 1979). JAMMU: Poonch Dist., *A. Rashid, E. Nasir & RRS 25586* (RAW).

9b. Malva verticillata var. **rafiqii** S. Abedin in Nasir & Ali, Fl. W. Pak. 130: 45. 1979. TYPE: Hazara District, Pakistan, *S. Abedin & M. Qaiser 9109* (holotype, KUH).

Malva verticillata var. *chinensis* sensu Hu, Fl. China, Malvaceae. 6, tab. 15, f. 5. 1955. Not *M. chinensis* Miller.

Differs from the preceding variety in having smaller habit, comparatively thinner stems, smaller and shallowly 3–5-lobed leaves with shorter (1.5–10 cm) petioles, flowers in looser fascicles of 2–6, pedicels of unequal length, 10–20(–25) mm long, the longer ones not hidden by the clusters of flowers or fruits.

Distribution. China and Pakistan and in the Kashmir Valley.

Additional specimens examined. INDIA. KASHMIR: Ganderbal, *G. H. Dar 1762–66* (KASH); Haknar (Gund), 2,050 m, *G. H. Dar 8640* (PF), *8641–8642* (KASH).

8. ALTHAEA L., Sp. Pl. 686. 1753; Gen. Pl. 5th Edition. 307. 1754.

About 12 species, distributed in Africa, Asia, and Europe; two species are recorded from our area.

1a. Leaves entire to shallowly 3-lobed; corolla almost twice the length of calyx; staminal tube pubescent; mericarps 15–25, pubescent throughout; seeds smooth, not verrucose .... 1. *A. officinalis*
1b. Leaves deeply 3–5-fid or parted; corolla usually less than twice the length of calyx; staminal tube almost glabrous; mericarps 12–18, pubescent towards apex, glabrous at base; seeds minutely whitish-verrucose on back .... 2. *A. broussonetiifolia*

1. Althaea officinalis L., Sp. Pl. 686. 1753; Masters in Hook. f., Fl. Brit. India 1: 319. 1874; Iljin in Shishkin & Bobrov, Fl. U.R.S.S. 15: 131. 1949; Kitamura, Fl. Afghan. 270. 1960; Stewart in Nasir & Ali, Ann. Cat. Vasc. Pl. W. Pak. & Kashm. 417. 1972; Riedl in K. H. Rechinger, Fl. Iran. 120: 39. 1976; Abedin in Nasir & Ali, Fl. W. Pak. 130: 46. 1979. LECTOTYPE: *Linn. Herb. no. 863/1* (LINN).

Perennial herbs, stems erect, with densely tomentose branches. Leaves triangular to broadly ovate, acute, base rounded or truncate, the margin irregularly serrate-dentate, sometimes superficially 3-lobed, densely pubescent on both surfaces, especially beneath; stipules linear-lanceolate, caducous. Flowers axillary, borne on many-flowered peduncle; pedicels 2–10 mm long. Epicalyx segments 8–12, linear. Calyx with the lobes connate below the middle, 5-lobed, 6–12 mm long, persistent. Corolla pinkish to white, 2–3 cm diam.; petals broadly obovate to oblong-obovate, 1.2–2.2 cm long, slightly notched at apex, the claw with ciliate margin. Staminal tube cylindric, with short-papillose hairs. Mericarps 15–25, minutely stellate-pubescent throughout. Seeds smooth, glabrous.

Distribution. Europe, Palestine, Syria, Turkey, Iran, Afghanistan, Pakistan, India. Though the species has been collected in the Kashmir Valley, it appears to be rare in our area now. A report from Baramulla, Kashmir is in Stewart (1972).

Additional specimens examined. INDIA. KASHMIR: Bandipur, *Jacquemont 1082*; Pampore, *Drum 15029.*

Abedin (1979) described the fruit of this species as glabrous in his key, perhaps an error.

2. Althaea broussonetiifolia Iljin in Shishkin & Bobrov, Fl. U.R.S.S. 15: 678. 1949. TYPE: Stalingrad (Olim Zarizyn), *Wunderlich 1839* (LE).

Perennial herbs; stems ± erect, densely stellate-pubescent on almost all parts. Leaves deeply 3–5-fid or -parted with irregularly dentate, oblong-lanceolate lobes, densely pubescent on both surfaces, especially beneath; stipules linear, caducous. Flowers on axillary and terminal racemose-paniculate peduncles; pedicels much shorter than calyx. Epicalyx segments 7–9, lanceolate. Calyx lobes 5, connate below the middle, 6–10 mm long, persistent. Corolla pink, 2–2.5 cm diam.; petals obovate to oblong-obovate, 8–15 mm long, slightly notched at apex, the claw fringed-pubescent. Staminal tube cylindric, almost glabrous. Mericarps 12–18, stellate-pubescent except at base. Seeds sparsely and minutely whitish-verrucose, especially in the lower part.

Distribution. U.S.S.R. The taxon, hitherto considered endemic to the U.S.S.R., has been collected in the Kashmir Valley. Apparently it is rare in our area.

Additional specimens examined. INDIA. KASHMIR: Narbal-Suzeath, on the borders of vegetable gardens, *A. R. Naqshi 8167* (PF), *8168* (KASH); Shalteng (Srinagar), *G. N. Javeid 596* (KASH).

First record for Indian subcontinent.

9. **ALCEA** L., Sp. Pl. 687. 1753; Gen. Pl. 5th Edition. 307. 1754.

About 60 species distributed chiefly in eastern Mediterranean Region; represented in our area by three species, all cultivated or escapes from cultivation.

KEY TO THE SPECIES OF *ALCEA* IN KASHMIR AND JAMMU STATE

1a. Upper leaves undivided or shallowly lobed.
  2a. Stem and branches sparsely setose with stellate hairs when young, ± glabrous at maturity .... 1. *A. rosea*
  2b. Stem and branches densely bristly with persistent stellate hairs .... 3. *A. pallida*
1b. Upper leaves palmately lobed almost to the base .... 2. *A. lavateriflora*

1. Alcea rosea L., Sp. Pl. 687. 1753; Iljin in Shishkin & Bobrov, Fl. U.R.S.S. 15: 126. 1949; Zohary, Israel J. Bot. 12: 12. 1963; Abedin in Nasir & Ali, Fl. W. Pak. 130: 49. 1979. TYPE: *Linn Herb. no. 869/1* (LINN).

Biennial (or perennial) herbs; stem erect, sparsely setose with stellate hairs when young, ± glabrous at maturity. Leaves orbicular-ovate, cordate at base, obtuse at apex, the lower ones shallowly 5–7-lobed, the upper leaves undivided or shallowly 3-lobed, crenate-dentate, scabrous with stellate pubescence on both surfaces; stipules ovate, tricuspidate. Flowers axillary, solitary or subfasciculate, the inflorescences spikelike towards the apices due to shorter pedicels and gradual diminution of the subtending leaves into leaflike bracts. Epicalyx 6–7-lobed, the lobes ovate-lanceolate. Calyx campanulate, 5-lobed, densely stellate-pubescent like the epicalyx. Corolla 5–8 cm diam., of various colors but usually red; petals obovate-cuneate, notched at apex, the claw barbate. Staminal tube 5-angled, glabrous. Fruit depressed, covered by persistent calyx; mericarps 20–40, stellate-pubescent, channeled and winged dorsally. Seeds reniform, pubescent.

Distribution. According to Zohary (1963), "Wild *A. rosea* L. seems to be indigenous almost exclusively on the Aegean islands and the adjacent Balkan Peninsula. The areas of its origin are no doubt the northeastern Mediterranean countries, but not China which is beyond the natural range of the genus." *Alcea rosea* is cultivated as an ornamental almost everywhere. In the Kashmir Valley it often grows as an escape from cultivation, together with the two following species. Sharma & Kachroo (1981) reported this species from Batote, Jammu.

Additional specimens examined. INDIA. KASHMIR: Srinagar, *G. N. Javeid 33* (KASH); Sind Valley, Prang, *G. H. Dar 6217* (KASH); Ganderbal, *G. H. Dar 6619* (KASH, PF); university campus, *A. R. Naqshi & G. N. Dar 8169* (KASH); women's college campus, *D. Sethi 30* (KASH).

The flowers and seeds of this species are said to have diuretic properties, and the roots and seeds are used as demulcents. According to Dar et al. (1984), a decoction of the roots boiled with water and milk is applied externally for treating dermatitis and goiter; it is also given to pregnant women to ease delivery. A decoction of flowers with milk and "gud" is reportedly applied for boils.

2. Alcea lavateriflora (DC.) Boiss., Fl. Orient. 1: 828. 1867; Riedl in K. H. Rechinger, Fl. Iran. 120: 65. 1976; Abedin in Nasir & Ali, Fl. W. Pak. 130: 50. 1979. *Althaea lavateriflora* DC., Prodr. 1: 437. 1824; Kitamura, Fl. Afghan. 270. 1960. TYPE: Prope Seydeol rodius Lipain, *Meryon.*

Alcea persarum Bornm. sensu Zohary, Israel. J. Bot. 12: 15. 1963.

This species resembles *A. rosea* L. in habit and flowers but differs chiefly in having deeply palmate-lobed leaves, especially towards the apices of branches, and in having narrower calyx lobes.

Distribution. Turkey, Greece, and Bulgaria; occasionally cultivated in Iraq, Iran, Pakistan, and elsewhere.

Additional specimens examined. INDIA. KASHMIR: university campus, *A. R. Naqshi & G. N. Dar 8170* (KASH); Ganderbal, Power House, *G. H. Dar 6620–6621* (KASH); Prang, *G. H. Dar 6216* (KASH, PF).

3. Alcea pallida (Waldst. & Kit.) Besser, Enum. Pl. 2: 872. 1822; Iljin in Shishkin & Bobrov, Fl. U.R.S.S. 15: 118. 1949; Zohary, Israel J. Bot. 12: 11. 1963; Abedin in Nasir & Ali, Fl. W. Pak. 130: 50. 1979. *Althaea pallida* Waldst. & Kit. in Willd., Sp. Pl. 3: 773. 1800; Stewart in Nasir & Ali, Ann. Cat. Vasc. Pl. W. Pak. & Kashm. 477. 1972. TYPE: described from Hungary (Prague).

This species also resembles *A. rosea* L. in general habit, leaves, and flowers but differs in having dense, persistent, stellate hairs on the stem and branches and in having transversely rugose wings on the mericarps.

Distribution. Central Europe, Balkan Peninsula, and Asia Minor; cultivated elsewhere.

Additional specimens examined. INDIA. KASHMIR: Sind Valley, Ganderbal, *G. H. Dar 6618* (KASH, PF).

All species of *Alcea* L. are raised as ornamentals in the Kashmir Valley under the local name of "Saz Posh." They are often grown in close associations. The three species were, until now, referred to *Althaea rosea* (L.) Cav. However, the genera *Alcea* and *Althaea* differ so markedly, particularly in the structures of the staminal column and carpels, that they are no longer considered a single genus. In fact *Alcea* approaches more closely *Lavatera* than *Althaea*.The species of *Alcea* contain 12–14% fiber in the stem and are suitable for paper production. The flowers contain mucilage and are used for gargling. They are also taken internally as an emollient for treatment of catarrhal gastric complaints. A dye extracted from the petals is used for coloring wines, vinegar, liquors, food products, silk, and wool.

10. LAVATERA L., Sp. Pl. 690. 1753; Gen. Pl. 5th Edition. 308. 1754.

Some 45 species, chiefly Mediterranean, but extending to the Canaries, northwest Himalaya, central Asia, eastern Siberia, Australia, and the U.S.A. (California); represented in Jammu and Kashmir by a single species.

Lavatera kashmiriana Cambess. in Jacquem., Voy. Inde 4: 29, tab. 32. 1844; Masters in Hook. f., Fl. Brit. India 1: 319. 1874; Iljin in Shishkin & Bobrov, Fl. U.R.S.S. 15: 78. 1949; Riedl in K. H. Rechinger, Fl. Iran. 120: 14. 1976; Singh & Kachroo, Forest Fl. Srinagar. 151. 1976; Abedin in Nasir & Ali, Fl. W. Pak. 130: 51. 1979. TYPE: India. Kashmir: *Jacquemont s.n.* (K).

Malva cachemiriana (Cambess.) Alef., Osterr. Bot. Z. 12: 258. 1862.

Lavatera cachemiriana var. *haroonii* sensu Abedin in Nasir & Ali, Fl. W. Pak. 130: 52. 1979.

Lavatera thuringiaca L. var. *macromera* Litw., Russk. Bot. Zurn. 7: 117. 1922. *L. thuringiaca* subsp. *macromera* (Litw.) Iljin, Bot. Syst. Leningrad 5: 7. 1924.

Perennial, densely stellate-pubescent herbs with erect terete stems. Leaves orbicular, the base truncate to slightly cordate, margin crenate-serrate, 3–7-angled or palmatifid to parted; stipules foliaceous, persistent. Flowers solitary, axillary; pedicels 3–6 cm long, articulate near the apex. Epicalyx segments 3, foliaceous, connate in the lower half, ovate-orbicular, mucronate, accrescent in fruit. Calyx 5-lobed, longer than epicalyx, the lobes triangular to deltoid, accrescent in fruit. Corolla 4–7.5 cm diam., pink-lilac; petals obovate, deeply notched. Staminal tube densely pubescent at base, antheriferous in the upper half. Fruit discoid; mericarps 20–25, glabrous, ± rugose. Seeds glabrous.

Distribution. India (Himalayan Mountains), Pakistan, Afghanistan, U.S.S.R., Iran. Stewart (1972) reported it for Poonch, Jammu.

Additional specimens examined. INDIA. KASHMIR: Sonamarg, *A. R. Naqshi 3975* (KASH); Aharbal, *A. R. Naqshi 7523* (KASH); Baltal, *A. R. Naqshi 4010–12* (KASH); Harwan, *G. Singh 1984* (KASH); Hadurah (Ganderbal), *G. H. Dar 2176* (KASH); Naranag, *G. H. Dar 4142–43, 45* (KASH), *4144* (PF); Soraphraw (Sind Valley), *G. H. Dar 8594* (PF), *8595–96* (KASH); Najwan (Kangan), *G. H. Dar 6827* (KASH); Sonamarg, *G. H. Dar 7787* (KASH), *7788* (PF); Harwan, *G. N. Javeid 361* (KASH); Ferozpur Nullah (Gulmarg), *U. Dhar 1258* (KASH).

In Kashmir, this species serves as a vegetable to hill tribes under the name of "Wan Sotsal." It can be raised as an ornamental. Its seeds contain about 12% oil, and a small amount of vitamin C is present in the stem and leaves. The plant has the capacity of yielding a good quality of fiber for binder twine, string, and ropes.

Based on leaf pubescence Abedin (1979) recognized two varieties as follows: adaxial surface of leaf with dense stellate hairs (var. *cachemiriana*) and adaxial surface of leaf except veins with simple and fascicled hairs (var. *haroonii*). Close scrutiny of a number of collections from different parts of our state, however, revealed that the varietal distinction does not hold up. The difference in the pubescence of upper leaf surface does not seem to be constant, and intermediate conditions are not uncommon.

11. **ABUTILON** Miller, Gard. Dict. Abr. 4th Edition. 1: AB. 1754; 8th Edition. 1768.

Over 150 species distributed in the tropics and subtropics of both hemispheres; represented in our area by four species.

KEY TO THE SPECIES OF *ABUTILON* IN JAMMU AND KASHMIR STATE

- 1a. Corolla 2.5–3.5 cm diam.; staminal tube 5–8 mm long; mericarps (14–)15–20 ..... 4. *A. indicum*
- 1b. Corolla 1–2 cm diam.; staminal tube 1–4 mm long; mericarps 10–16.
  - 2a. Annual herbs; staminal tube glabrous ..... 2. *A. theophrastii*
  - 2b. Perennial suffruticose herbs; staminal tube stellate-pubescent to puberulent.
    - 3a. Calyx lobes deltoid-ovate, erect in fruit; petals 10–12 mm long; fruit cylindrical; mericarps usually 10; seeds furfuraceous-dotted ..... 1. *A. ramosum*
    - 3b. Calyx lobes lanceolate, reflexed in fruit; petals 7–9 mm long; fruit ovoid; mericarps 13–16; seeds stellately pilose ..... 3. *A. bidentatum*

1. **Abutilon ramosum** (Cav.) Guill. & Perr. in Guill. et al., Fl. Seneg. Tent. 1: 68. 1831; Masters in Hook. f., Fl. Brit. India 1: 328. 1874; Stewart in Nasir & Ali, Ann. Cat. Vasc. Pl. W. Pak. & Kashm. 477. 1972; Abedin in Nasir & Ali, Fl. W. Pak. 130: 55. 1979; Sharma & Kachroo, Fl. Jammu 1: 111. 1981. *Sida ramosa* Cav., Diss. 1. 28, tab. 6, f. 1. 1785. TYPE: Senegal, *Adanson* (holotype, MA, photo; isotype, P).

Abutilon sparmanoides Guill. & Perr. in Guill. et al., Fl. Seneg. Tent. 1: 70. 1831.
A. elaeocarpoides Webb, Fragm. Fl. Aethiop. 53. 1854.
A. sidoides A. Gibson, Bombay Fl. 18. 1861.

Perennial, suffruticose herbs, tomentose with stellate and long, spreading hairs. Leaves broadly ovate, the base cordate, the apex acuminate, the margin coarsely crenate-serrate, often 3-lobate; stipules filiform to linear. Flowers axillary or terminal, solitary or paired or divided above dichotomously as in a cyme; pedicels shorter than petioles. Calyx cupular, 5-lobed; lobes deltoid-ovate, acuminate-cuspidate. Corolla yellow, ca. 1.5 cm diam.; petals 10–12 mm long. Staminal tube very short, puberulous. Fruit cylindrical; mericarps usually 10, biaristate with awns ca. 2 mm long. Seeds 2–3 per mericarp, furfuraceous-dotted.

Distribution. Tropical Africa, Arabia, Pakistan, and India. Confined in our area to the Jammu Province. For a Billawar report see Lambert (1933).

Additional specimen examined. INDIA. JAMMU: Ram Nagar, among *Carissa spinarum* L., tomentose green shrub with yellow flowers, *B. M. Sharma 674* (KASH).

2. **Abutilon theophrastii** Medicus, Malvenfam. 28. 1787; Hu, Fl. China, Malvaceae. 31. 1955; Kitamura, Fl. Afghan. 269. 1960; Stewart in Nasir & Ali, Ann. Cat. Vasc. Pl. W. Pak. & Kashm. 477. 1972; Riedl in K. H. Rechinger, Fl. Iran. 120: 7. 1976; Abedin in Nasir & Ali, Fl. W. Pak. 130: 61. 1979. LECTOTYPE: India: Herb. Cliff. (BM).

Sida abutilon L., Sp. Pl. 685. 1753.
Abutilon avicennae Gaertner, Fruct. Sem. Pl. 2: 251, tab. 135, f. 1. 1791; Masters in Hook. f., Fl. Brit. India 1: 327. 1874.
A. behrianum F. Muell. in Trans. & Proc. Philos. Inst. Victoria 1: 13. 1855.

Annual, velutinous herbs. Leaves orbicular or broadly ovate, the base deeply cordate, the apex acuminate, the margin crenulate or undulate; stipules caducous. Flowers axillary, solitary or in few-flowered terminal racemes; pedicels shorter than petioles. Calyx 5-lobed; lobes ovate or lanceolate, acute. Corolla yellow, 1–2 cm diam.; petals 1–1.2 cm long, obovate. Staminal tube 2–4 mm long, glabrous. Fruit hemispherical; mericarps 12–16, strongly birostrate with awns 3–5 mm long. Seeds 3 per mericarp, stellate-pilose.

Distribution. Native to India, introduced and naturalized in northern America, northern Asia, and westward to southern Europe. Confined in our area to the Kashmir Valley, where this is the only *Abutilon* growing now, although some other species have been reported by earlier workers. Vernacular name: "Yachkad."

Additional specimens examined. INDIA. KASHMIR: university campus, *A. R. Naqshi 189* (KASH); Srinagar, *A. R. Naqshi 3981* (KASH); Narbal, *A. R. Naqshi & G. N. Dar 8171* (PF), *8172* (KASH); Shalteng, *G. N. Javeid s.n.* (Sind Valley) (KASH); *G. H. Dar 8820* (KASH); Jhelum River, cultivated fields, *R. R. & I. D. Stewart 4980* (RAW).

Abutilon, especially *A. theophrastii*, has been long cultivated for its coarse fiber suitable for making ropes, sackcloth, binder twine, string, and fishing nets. Its fiber is fairly tough, water resistant, and brittle. In America this is said to be preferred over jute and Manila hemp. The stem is used for paper manufacture and as fuel. The seeds yield up to 30% of a yellow, tasteless, and odorless oil, which approaches cotton oil, sesame oil, and peanut oil in its chemical composition. The oil is suitable for use in food and for hydrogenation. Inferior grades may be used as varnish oil and in soap manufacture. The flowers are used for coloring wines and, in China, for making ink. A decoction of roots and infusion of flowers is used internally and externally against inflammatory conditions.

3. Abutilon bidentatum Hochst. ex A. Rich., Tent. Fl. Abyss. 1: 68. 1847; Masters in Hook. f., Fl. Brit. India 1: 326. 1874; Kitamura, Fl. Afghan. 269. 1960; Stewart in Nasir & Ali, Ann. Cat. Vasc. Pl. W. Pak. & Kashm. 475. 1972; Riedl in K. H. Rechinger, Fl. Iran. 120: 5. 1976; Abedin in Nasir & Ali, Fl. W. Pak. 130: 63. 1979. TYPE: Abyssinia, prope Aguar, prov. Modat, *Schimper 1003* (K).

Abutilon cornutum Dalz. ex T. Cooke, Fl. Bombay 1: 98. 1901.
A. pakistanicum Jafri et Ali in Jafri, Fl. Karachi. 220. 1966.

Perennial, suffruticose herbs, canescent-tomentose with stellate, weak, spreading hairs. Leaves broadly ovate, the base deeply cordate, the apex acute-acuminate, the margin crenate-dentate, rarely 3-angular; stipules filiform. Flowers solitary, axillary; pedicels longer or shorter than petioles. Calyx 5-lobed, slightly accrescent; lobes lanceolate, ultimately reflexed. Corolla pale yellow to yellow, 1–1.5 cm diam.; petals 7–9 mm long, obovate. Staminal tube 2–3 mm long, stellate-pubescent. Fruit ovoid; mericarps 13–16, acute-acuminate, awn 1–2 mm long. Seeds 3 per mericarp, sparsely pilose with stellate hairs.

Distribution. India, Pakistan, Iran, tropical Africa, and Arabia. Apparently confined to the Jammu region in our area. Stewart (1972) reported it from the Kashmir Valley, but we have not seen any specimens. Also note: Jammu: Billawar (Lambert, 1933: 3; Sharma & Kachroo, 1981: 111); Poonch, Mirpur. Kashmir: Jhelum Valley road; Barsala (Stewart, 1972: 476).

4. Abutilon indicum (L.) Sweet, Hort. Brit. 1st Edition. 54. 1826; Masters in Hook. f., Fl. Brit. India 1: 326. 1874; Hu, Fl. China, Malvaceae. 32. 1955; Ngwe, Union Burma J. Life Sci. 4: 207. 1971; Stewart in Nasir & Ali, Ann. Cat. Vasc. Pl. W. Pak. & Kashm. 476. 1972; Riedl in K. H. Rechinger, Fl. Iran. 120: 6. 1976; Abedin in Nasir & Ali, Fl. W. Pak. 130: 69. 1979; Sharma & Kachroo, Fl. Jammu 1: 111. 1981. *Sida indica* L. in Torner, Cent. Pl. 2: 26. 1756. LECTOTYPE: *Linn. Herb. no. 866/29* (LINN).

Sida populifolia Lam., Encycl. 1: 7. 1783. *Abutilon populifolium* (Lam.) Sweet, Hort. Brit. 1st Edition. 53. 1826. *A. indicum* var. *populifolium* (Lam.) Wight & Arn. ex Masters in Hook. f., Fl. Brit. India 1: 326. 1874.
A. indicum var. *microphyllum* Hochr., Annuaire Conserv. Jard. Bot. Genève 6: 20. 1902.
A. badium Husain & Baquar, Phyton 15: 229. 1974.

Perennial, suffruticose herbs to subshrubs, canescent with stellate hairs; branches and petioles generally purple on one side. Leaves broadly ovate, the base cordate, the apex acute or acuminate, the margin coarsely dentate, sometimes 3-angular; stipules linear. Flowers solitary, axillary; pedicels longer than petioles. Calyx 5-lobed, not or slightly accrescent in fruit; lobes lanceolate to ovate, mucronate, ultimately reflexed. Corolla orange-yellow to yellow, 2.5–3.5 cm diam.; petals 1–1.5 cm long, obovate. Staminal tube 5–8 mm long, stellate-hirsute. Fruit ovoid-truncate; mericarps (14–)15–20, very short-awned, erect at maturity. Seeds 3 per mericarp, minutely stellate-pilose.

Distribution. Tropics and subtropics of the New and Old worlds. Confined to the Jammu region in our area.

Additional specimens examined. INDIA. JAMMU: Ram Nagar forest, common along hedges; erect shrubs, profusely branched, flowers orange-yellow, *B. M. Sharma 110* (KASH). KASHMIR: *Falconer 273* (fide Stewart, 1972: 476).

According to Ngwe (1971), the bark of this plant is used as an anthelmintic and the roots as a diuretic. The seeds are utilized in the treatment of piles and coughs, and as emollients and demulcents. The leaves are also said to be medicinal.

12. SIDA L., Sp. Pl. 683. 1753; Gen. Pl. 5th Edition. 306. 1754.

About 150 species distributed in the tropics and subtropics of both hemispheres; represented in our area by five species.

Key to the Species of *Sida* in Jammu and Kashmir State

- 1a. Branches, petioles, pedicels, and calyx pubescent with stellate hairs mixed with simple, spreading hairs up to 3 mm long.
  - 2a. Leaves cordate, palmately nerved; calyx 4–5 mm long; fruit 3–4 mm diam.; mericarps 5, muticous with pilose mucro .... 1. *S. cordata*
  - 2b. Leaves usually ovate, suborbicular-subcordate, or lanceolate, penninerved; calyx 5–10 mm long; fruit 5–8 mm diam.; mericarps 9–10, birostrate with apical awns 3–5 mm long covered with stiff reflexed hairs .... 4. *S. cordifolia*
- 1b. Branches, petioles, pedicels, and calyx pubescent with stellate hairs only.
  - 3a. Leaves ovate-oblong; calyx tube subangular; corolla white, 1–1.5 cm diam.; mericarps 7–8, coriaceous; awns connivent, ± inflexed; seeds farinose .... 5. *S. ovata*
  - 3b. Leaves elliptic, obovate, oblong or rhomboid; calyx tube not angular; corolla yellow, up to 1 cm diam.; mericarps 5, membranous; awns not connivent, erect; seeds not farinose.
    - 4a. Leaves 1–6.5 × 0.6–5 cm; flowers subfasciculate; pedicels in fruit up to 1 cm long; mericarps densely stellate-pilose all over .... 2. *S. yunnanensis*
    - 4b. Leaves 1–2 × 0.5–1.2 cm; flowers solitary (–paired); pedicels in fruit 1–2 cm long; mericarps pubescent at apex only .... 3. *S. alba*

1. Sida cordata (Burm. f.) Borssum Waalkes, Blumea 14: 182. 1966; Stewart in Nasir & Ali, Ann. Cat. Vasc. Pl. W. Pak. & Kashm. 483. 1972; Abedin in Nasir & Ali, Fl. W. Pak. 130: 77. 1979; Sharma & Kachroo, Fl. Jammu 1: 109. 1981. *Melochia cordata* Burm. f., Fl. Indica 143. 1768. TYPE: (G).

Sida veronicifolia Lam., Encyl. 1: 5. 1783; Hu, Fl. China, Malvaceae. 23. 1955. *S. humilis* var. *veronicifolia* (Lam.) Masters in Hook. f., Fl. Brit. India 1: 322. 1874.
S. radicans Cav., Diss. 1: 8, tab. 9, f. 3. 1785.
S. morifolia Cav., Diss. 1: 9, tab. 10, f. 2. 1785.
S. humilis Cav., Diss. 5: 277, tab. 134, f. 2. 1788. *S. veronicifolia* Lam. var. *humilis* (Cav.) K. Schum., Fl. Bras. 12(3): 320. 1891.
S. humilocularis L' Hér., Stirp. Nov. 1: 117. bis 56. 1789.

Perennial, prostrate to procumbent herbs. Branches, petioles, pedicels, and calyx stellate-pubescent and villose with long, spreading hairs. Leaves cordate, palmately nerved, stellate-hispid on both surfaces, the hairs adaxially often simple, the apex acuminate, the margin evenly crenate to serrate. Flowers axillary, solitary, fasciculate or subpaniculate; pedicels 1.5–2.5 cm long, in fruit up to 3.5 cm. Calyx 4–5 mm long; lobes deltoid, acuminate. Corolla yellow, 7–10 mm diam., slightly exceeding the calyx. Staminal tube 2–3 mm long, hirsute with simple hairs. Fruit depressed-globose, 3–4 mm diam.; mericarps 5, muticous, membranous, truncate and pilose at apex. Seeds glabrous.

Distribution. Tropical and subtropical regions of the world. Confined in our area to the Jammu region.

Additional specimens examined. INDIA. JAMMU: Gajansu, common; herbs with long trailing branches among hedges, *B. M. Sharma 569* (KASH); Jammu & Kashmir road, *R. R. Stewart s.n.* (RAW).

A distinctive species distinguishable from all other local species by its cordate leaves with palmate venation and by its mucronate mericarps. The species shows great variation in its indumentum and inflorescence. At least two taxa, *Sida veronicifolia* and *S. humilis*, are occasionally recognized on the basis of variation in the inflorescence. In the former the flowers are described as fasciculate or subpaniculate, whereas in the latter they are solitary. However, a close study of herbarium specimens has shown variation in the inflorescence to be continuous, so any division on this basis is not justified. Similarly Cavanilles (Class. Diss. Dec. 5: 277. 1788) distinguished *Sida multicaulis* Cav. and *S. humilis* on the basis of stem pubescence. The former has tomentose-canescent stems, while the latter has scabrous ones. However, Masters (1874) did not see this difference in the Indian material and, accordingly, interpreted *S. multicaulis* as synonymous with *S. humilis*.

2. Sida yunnanensis Hu, Fl. China, Malvaceae. 16, tab. 16, f. 7. 1955; Abedin in Nasir & Ali, Fl. W. Pak. 130: 79. 1979. TYPE: China. Yunnan: *Forrest 11088* (K, BM).

Sida obovata Wallich, Cat. no. 1864. 1828, nom. nud. *S. rhombifolia* var. *obovata* Wallich ex Masters in Hook. f., Fl. Brit. India 1: 324. 1874.

Perennial, suffruticose herbs or undershrubs; almost all parts stellate-pubescent. Leaves variable; elliptic, oblong, oblong-elliptic, rhomboid or obovate, 1–6.5 × 0.6–5 cm, penninerved, the base obtuse or cuneate, the apex obtuse or acutish, margin serrate-crenate, the abaxial surface velutinous, adaxially green and glabrescent. Flowers subfasciculate, axillary and terminating the upper branches; pedicels 3–6 mm long, in fruit up to 1 cm. Calyx 4–6 mm long; lobes triangular, acuminate, carinate at base. Corolla yellow, ± 1 cm diam., slightly longer than calyx. Staminal tube ca.

3 mm long, sparsely hirsute or subglabrous. Fruit depressed-globose, 4–5 mm diam.; mericarps 5, membranous, densely stellate-pilose, birostrate with convergent apical awns less than 1 mm long. Seeds glabrous.

Distribution. Burma, China, India, and Pakistan. In our area confined to the Jammu region, where it is common along roadsides in the Nagrota-Salora area, in orchards at Tilo Talab, Udhowalla, and elsewhere.

Additional specimen examined. INDIA. JAMMU: Nandni, common on roadsides; erect shrubby perennial with yellow flowers, leaves whitish-gray beneath, *B. M. Sharma 688* (KASH).

In having subfasciculate flowers and pubescent birostrate mericarps, this species is close to *Sida spinosa* L. However, the broad elliptic or obovate leaves with very short petioles of the former can easily be differentiated from the ovate-lanceolate, long-petiolate leaves of the latter species.

The plants are said to yield good bast fiber. The roots are used to relieve rheumatism.

3. Sida alba L., Sp. Pl. 2nd Edition. 960. 1753; Stewart in Nasir & Ali, Ann. Cat. Vasc. Pl. W. Pak. & Kashm. 483. 1972; Abedin in Nasir & Ali, Fl. W. Pak. 130: 81. 1979. TYPE: *Linn. Herb. no. 866/2* (LINN).

Perennial, suffruticose, stellate-pubescent herbs. Leaves small, elliptic to obovate, 1–2 × 0.5–1.2 cm, penninerved, evenly crenulate-serrate. Flowers mostly solitary, sometimes paired; pedicels 5–6 mm long, in fruit 1–2 cm. Calyx 4–6 mm long; lobes triangular, acute to acuminate. Corolla yellow, 6–10 mm diam., slightly longer than calyx. Staminal tube 2–3 mm long, hirsute. Fruit depressed-globose, 4–6 mm diam.; mericarps 5, membranous, pubescent at apex, birostrate with convergent apical awns less than 1 mm long. Seeds glabrous.

Distribution. India, Pakistan, and China. In our area apparently confined to Pakistan-occupied area in Jammu Province. Stewart (1972: 483) reported *Sida alba* from Mirpur, Poonch, in Jammu. The *S. alba* of Sharma & Kachroo (1981: 110) has turned out to be *S. yunnanensis*.

The differences between *Sida alba*, *S. spinosa*, and *S. alnifolia* L. seem to be few. In fact, Riedl (1976) cited *S. alba* and *S. alnifolia* as synonyms of *S. spinosa*. However, a thorough study of the type specimens of these three species, together with field observations and analysis of enough herbarium material from different geographical regions is needed to gain an insight into their ranges of variation and to ascertain their relationships.

4. Sida cordifolia L., Sp. Pl. 684. 1753; Masters in Hook. f., Fl. Brit. India 1: 324. 1874; Hu, Fl. China, Malvaceae. 25. 1955; Ngwe, Union Burma J. Life Sci. 4: 207. 1971; Stewart in Nasir & Ali, Ann. Cat. Vasc. Pl. W. Pak. & Kashm. 483. 1972; Riedl in K. H. Rechinger, Fl. Iran. 120: 3. 1976; Abedin in Nasir & Ali, Fl. W. Pak. 130: 83. 1979. TYPE: *Linn. Herb. no. 866/12* (LINN).

Sida herbacea Cav., Diss. 1: 19, tab. 13, f. 1. 1785.
S. holosericea Willd. ex Sprengel, Syst. Veg. 3: 112. 1826.

Perennial, suffruticose herbs; branches, petioles, pedicels, and calyx stellate-hispid and long-villose with simple, spreading hairs ca. 3 mm long. Leaves usually ovate, suborbicular-subcordate or lanceolate, penninerved, the base subcordate or rounded, the apex obtuse or acute, the margin irregularly crenate, uniformly stellate-hirsute on both surfaces, the hairs longer beneath. Flowers axillary, solitary or paired or fasciculate; pedicels 4–7 mm long, in fruit up to 2 cm. Calyx 5–10 mm long; lobes triangular or deltoid, acute to acuminate. Corolla yellow, 1–1.3 cm diam., slightly longer than calyx. Staminal tube 3–5 mm long, hirsute. Fruit subdiscoid, 5–8 mm diam.; mericarps 9–10, stellate-strigose at apex, birostrate with divergent apical awns 3–5 mm long covered with stiff reflexed hairs. Seeds glabrous except hilum.

Distribution. Common in tropical and subtropical countries. Confined to the Jammu region in our area. Jammu: Rajouri (Stewart, 1972: 483); Jammu (Sharma & Kachroo, 1981: 110; Lambert, 1933: 3).

The plant is said to be used as a tonic, emollient, and astringent. The bark is considered useful in urinary troubles.

5. Sida ovata Fôrskal, Fl. Aegypt.-Arab. 124. 1775; Stewart in Nasir & Ali, Ann. Cat. Vasc. Pl. W. Pak. & Kashm. 483. 1972; Riedl in K. H. Rechinger, Fl. Iran. 120: 4. 1976; Abedin in Nasir & Ali, Fl. W. Pak. 130: 86. 1979. TYPE: Arabia, Surdud, *Fôrskal* (C).

Sida grewioides Guill. & Perr. in Guill. et al., Fl. Seneg. Tent. 1: 71. 1830; Masters in Hook. f., Fl. Brit. India 1: 323. 1874.

Perennial, suffruticose herbs with all parts stellate-pubescent. Leaves ovate-oblong, penninerved, the base cuneate or rounded, the apex obtuse, the margin ± entire towards base, obtusely crenate or crenate-serrate elsewhere, stellate-pubescent on both surfaces. Flowers axillary, solitary or paired; pedicels 5–8 mm long, in fruit 1(–1.5) cm. Calyx 4–6 mm long, the tube slightly angular; lobes triangular-deltoid, acuminate. Corolla white, 1–1.5 cm diam., slightly longer than calyx. Staminal tube to 3 mm long, pubescent. Fruit depressed-globose, 3–5 mm diam.; mericarps 7–8, coriaceous, reticulate toward the margins, glabrous except awns; awns 2, connivent, ca. 0.5 mm long, ± inflexed. Seeds farinose.

Distribution. In drier parts of Africa, Arabia, India, and Pakistan. In our area reported from Mirpur (Pakistan-occupied area) in Jammu Province. Note the following reports: Jammu: Poonch, Mirpur (Lambert, 1933: 3; Stewart, 1972: 483; Sharma & Kachroo, 1981: 110).

Sida spinosa L., Sp. Pl. 683. 1753, has been reported from Jammu by Lambert (1933). This is probably based on misidentification, because *Sharma 688* (KASH) under this name turned out to be *Sida yunnanensis.*

13. MALVASTRUM A. Gray, Mem. Am. Acad. Arts n.s. 3: 21. 1849, nom. conserv.

Fourteen species (Hill, 1982), distributed in tropical and subtropical America and in Australia; one species is known from our area.

Malvastrum coromandelianum (L.) Garcke, Bonplandia 5: 297. 1857; Hu, Fl. China, Malvaceae. 11. 1955; Stewart in Nasir & Ali, Ann. Cat. Vasc. Pl. W. Pak. & Kashm. 481. 1972; Riedl in K. H. Rechinger, Fl. Iran. 120: 36. 1976; Abedin in Nasir & Ali, Fl. W. Pak. 130: 89. 1979; Sharma & Kachroo, Fl. Jammu 1: 109. 1981. *Malva coromandeliana* L., Sp. Pl. 687. 1753. LECTOTYPE: *Linn. Herb. no. 870/3* (LINN).

Malva carpinifolia Desr. in Lam., Encycl. 3: 754. 1789.
Malva tricuspidata Aiton, Hort. Kew. 2nd Edition. 4: 210. 1811. *Malvastrum tricuspidatum* (Aiton) A. Gray, Plantae Wright. 1: 16. 1852; Masters in Hook. f., Fl. Brit. India 1: 321. 1874.

Erect to suberect, herbaceous or suffruticose, sparsely pubescent plants with simple and 4-fid, appressed hairs. Leaves ovate to lanceolate-oblong, coarsely serrate, acute or obtuse; stipules linear-lanceolate, acuminate. Flowers axillary, solitary or fascicled, sessile or with pedicels to 5 mm long. Epicalyx segments 3, linear, persistent. Calyx 5-lobed; lobes ovate, acuminate. Corolla yellow, 1.5–2 cm diam.; petals obliquely obovate, pubescent at base. Staminal tube 2–4 mm long, glabrous, antheriferous only at the apical end. Fruit discoid, ca. 6 mm diam.; mericarps 8–14, reniform, sparsely stellate-pilose, tricuspidate with an apical and 2 dorsal awns at the middle, 1-seeded. Seeds reniform, glabrous.

Distribution. Native to North America, distributed in tropical regions of both New and Old worlds. In our area it occurs in the Jammu region only. Lambert (1933: 3) reported the species from Billawar, Jammu, Mirpur.

Additional specimens examined. INDIA. JAMMU: Rihari, common in waste places; semierect gregarious herbs with yellow flowers, *B. M. Sharma 453* (KASH); Poonch, Bufliaz, 2,000 m, *G. Singh & H. Kiran 775.*

14. URENA L., Sp. Pl. 692. 1753; Gen. Pl. 5th Edition. 309. 1754.

About six species distributed in the warmer regions of both hemispheres; represented in our area by a single species.

Urena lobata L., Sp. Pl. 692. 1753; Masters in Hook. f., Fl. Brit. India 1: 329. 1874; Hu, Fl. China, Malvaceae. 73. 1955; Ngwe, Union Burma J. Life Sci. 4: 206. 1971; Stewart in Nasir & Ali, Ann. Cat. Vasc. Pl. W. Pak. & Kashm. 484. 1972; Abedin in Nasir & Ali, Fl. W. Pak. 130: 92. 1979; Sharma & Kachroo, Fl. Jammu 1: 111. 1981. LECTOTYPE: *Linn. Herb. no. 873/1* (LINN).

Urena monopetala Lour., Fl. Cochinch. 418. 1790.
U. diversifolia Schum., Danske Vidensk.-Selsk. Nat.-Math. Afd. 4. 4: 82. 1829.

Erect, herbaceous to suffruticose, ± stellate-tomentose plants. Leaves stellate-pubescent on both surfaces, densely so and ± tomentose abaxially, evenly serrate, with a basal nectary on 1–3 middle nerves beneath, variable in shape and size: the lower leaves usually subcordate or suborbicular, angled or shallowly 3-lobed at the apex; the middle leaves ovate; the upper leaves ovate to ovate-elliptic; stipules linear, caducous. Flowers axillary, usually solitary or in fascicles of 2–3; pedicels 2–3 mm long, in fruit up to 5 mm. Epicalyx segments 5, connate basally, linear-lanceolate. Calyx 5-parted, almost as long as the epicalyx; lobes ovate or ovate-lanceolate, keeled. Corolla pink with a darker center, ca. 2 cm diam.; petals obovate, 1–1.5 cm long. Staminal tube ca. 1.5 cm long, antheriferous in the apical part; anthers subsessile. Carpels 5, style branches and stigmas 10. Fruit subglobose, 1 cm or less diam.; mericarps 5, triangularly obovoid, coriaceous, stellate-pubescent and glochidiate-spiny, shortly awned. Seeds pubescent to glabrescent.

Distribution. Tropical regions of both hemispheres. Confined to the Jammu region in our area. Udhampur (Stewart, 1972: 484).

Additional specimen examined. INDIA. JAMMU: Udhowala Ashram, common in orchards; erect shrubs, 1.2 m high, with pink flowers, leaves variable, *B. M. Sharma 111* (KASH).

A variable species sometimes divided into a number of varieties. Hu (1955), mainly on the basis of leaf shape and the nature and density of hairs, recognized five varieties from China. As we have very little material at hand, no attempt is made to segregate the various varieties at present.

An important fiber-yielding plant. The bast-fiber from the stems is said to be more lasting than jute. In Cuba, Madagascar, Nigeria, and Brazil it is cultivated for making coffee sacks. The roots are used in rheumatism, and the twigs are chewed for relieving toothache.

15. SIDALCEA A. Gray, in Benth. Pl. Hartw. 300. 1848.

About 35 species distributed in western North America, chiefly in California and Oregon; one species has been recorded from our area.

Sidalcea neomexicana A. Gray subsp. **thurberi** (Robinson ex A. Gray) Hitchcock, in Univ. Wash. Publ. Bot. 18. 1957. *S. parviflora* Greene var. *thurberi* Robinson ex A. Gray, Syn. Fl. N. Amer. 11: 305. 1897. TYPE: described from Santa Monica, Los Angeles County, California, U.S.A.

Perennial, erect, glabrescent-glabrous herbs, glaucous throughout. Leaves orbicular, palmately lobed or divided; stipules small, deciduous. Inflorescence terminal, racemose; bracts mostly bifid. Flowers usually polygamodioecious, the pistillate flowers smaller than the perfect or staminate ones. Epicalyx absent; pedicels and calyces stellate-pubescent. Calyx 4–7 mm long; lobes triangular-ovate, acuminate. Corolla rose-purple, 10–16 mm long. Staminal tube biseriate, glabrous except for a few retrorse hairs on the apical portion. Mericarps beaked, reticulate on angles, smooth on back, indehiscent, 1-seeded.

Distribution. From southern Monterey County (Jolon) to eastern San Bernardino County, California, U.S.A.

Additional specimen examined. INDIA. KASHMIR: Srinagar, Emporium Garden, in grassy lands, an escape from cultivation, 4/5/1967, *G. N. Javeid 6* (KASH).

The species is restricted to America, and its occurrence in Kashmir is interesting. It is probable that seeds were brought and raised ornamentally in our area in the 1960s. We have a single specimen identified as "*S. malvaeflora* A. Gray." The specimen comprises a single upper leaf and inflorescence and has been determined by Paul A. Fryxell, as *S. neomexicana* subsp. *thurberi.*

THREE NEW SPECIES OF *NECTANDRA* FROM THE VENEZUELAN GUAYANA[1]

Jens G. Rohwer[2]

ABSTRACT

Three new species of Nectandra *from the Venezuelan Guayana are described in advance of a complete monograph of the genus.*

During work towards a monograph of the genus *Nectandra*, several undescribed species were found. Three of these occur within the area of the *Flora of the Venezuelan Guayana*, currently in preparation at the Missouri Botanical Garden. Since the treatment of the Lauraceae for this flora is scheduled to appear before the monograph of *Nectandra* will be completed, the new species are published here in anticipation of the more complete work.

All three new species are somewhat similar to *Nectandra globosa* (Aubl.) Mez, and two of them seem to be closely related to it. They differ from *N. globosa* and from each other mainly by striking characters of the indumentum in addition to less conspicuous differences in venation, leaf shape, flowers, and fruits. While any one of these characters alone would hardly warrant recognition on the specific level, their combination makes the entities described below quite distinct.

Nectandra aurea Rohwer, sp. nov. TYPE: Venezuela. Apure: Dtto. San Fernando, mouth of the Río Arauca at its intersection with the Río Orinoco, 66°36′W, 7°24′N, 35 m, 14–15 May 1977 (fl, immature fr), *Davidse & González 13215* (holotype, MO). Figure 1.

Arbor, ad 15 m alta. Ramuli novelli ± angulati vel longitudinaliter exarati, dense rufo- vel aurantio-tomentosi, vetustiores teretes, dense griseo-tomentelli, demum tarde glabrescentes. Folia alterna, lanceolata vel raro lanceolato-elliptica, (7–)9–17(–19) cm longa, 2.8–5(–6) cm lata, nervis lateralibus utroque costae latere 5–7(–9) sub angulo 35–50° prodeuntibus, in sicco rigide chartacea vel subcoriacea, laevia, apice in acumen angustata, basi acuta margine (sub)plano, folia novella supra ± dense et molliter (sed plerumque inconspicue) flavido-tomentella, subtus dense et ± adpresse aureo-sericeo-tomentella, raro axillis nervorum rufo-tomentosa, vetustiora supra praeter costam leviter pubescentem glabrescentia, subtus indumento fere persistente vel tarde deminuente sed demum sparso. Inflorescentiae axillares, breviter thyrsoideae, 2–5(–9) cm longae, pedunculo 1–2(–3) cm longo, dense rufo- vel aurantio-tomentosae, cymis lateralibus 2–4, 1–3(–4)-furcatis. Pedicelli 0.5–2.5 mm longi. Flores 5–8(–9.5) mm diametro. Tepala elliptica, intus papillosa, exteriora interioribus paulo majora, ad 4 mm longa. Stamina papillosa, subsessilia, 0.7–0.9 mm longa, exteriores 6 late pentagona vel quadrato-rhombica, apice paulo producto, obtuso vel late subrotundato, serie prima secunda plerumque paulo latiora, interiores 3 apice late rotundata vel paene truncata. Staminodia parva sed crassiuscula, apice papillosa, inter stamina seriei tertiae ± celata et basi eis connata. Pistillum ± gracile, glabrum, 1.5–2 mm longum, stylo crasso ovarium ± aequante. Receptaculum profunde urceolatum, intus (interdum parce modo et inaequaliter) adpresse pubescens. Fructus (non nisi immaturus notus) ovato-ellipticus. Cupula profunda, campanulata, iam ca. 11 mm diametro et 9 mm profunda, margine integro.

Tree to 15 m. Twigs at first ± angular or longitudinally furrowed, densely covered with curled reddish longer hairs (0.5–1.5 mm long) over an extremely dense layer of very short yellowish hairs, older twigs roundish with the short hairs persistent for a long time and becoming grayish. Leaves alternate, lanceolate or rarely lanceolate-elliptic, (7–)9–17(–19) cm long, 2.8–5(–6) cm wide, with 5–7(–9) pairs of lateral veins diverging at 35–50°, dried laminae stiffly chartaceous to subcoriaceous, smooth (secondaries slightly prominent below), the apex tapering towards a narrow acumen, the base acute, flat or nearly so, young leaves above ±

---

[1] *Most of the work for this paper was conducted at the Missouri Botanical Garden during a long-term visit in 1986–1987. The author is most grateful to the director and the staff of this institution for friendly reception and continuous support. The visit was made possible through a postdoctoral scholarship grant from the Deutsche Forschungsgemeinschaft.*

ANN. MISSOURI BOT. GARD. 75: 1525–1532. 1988.

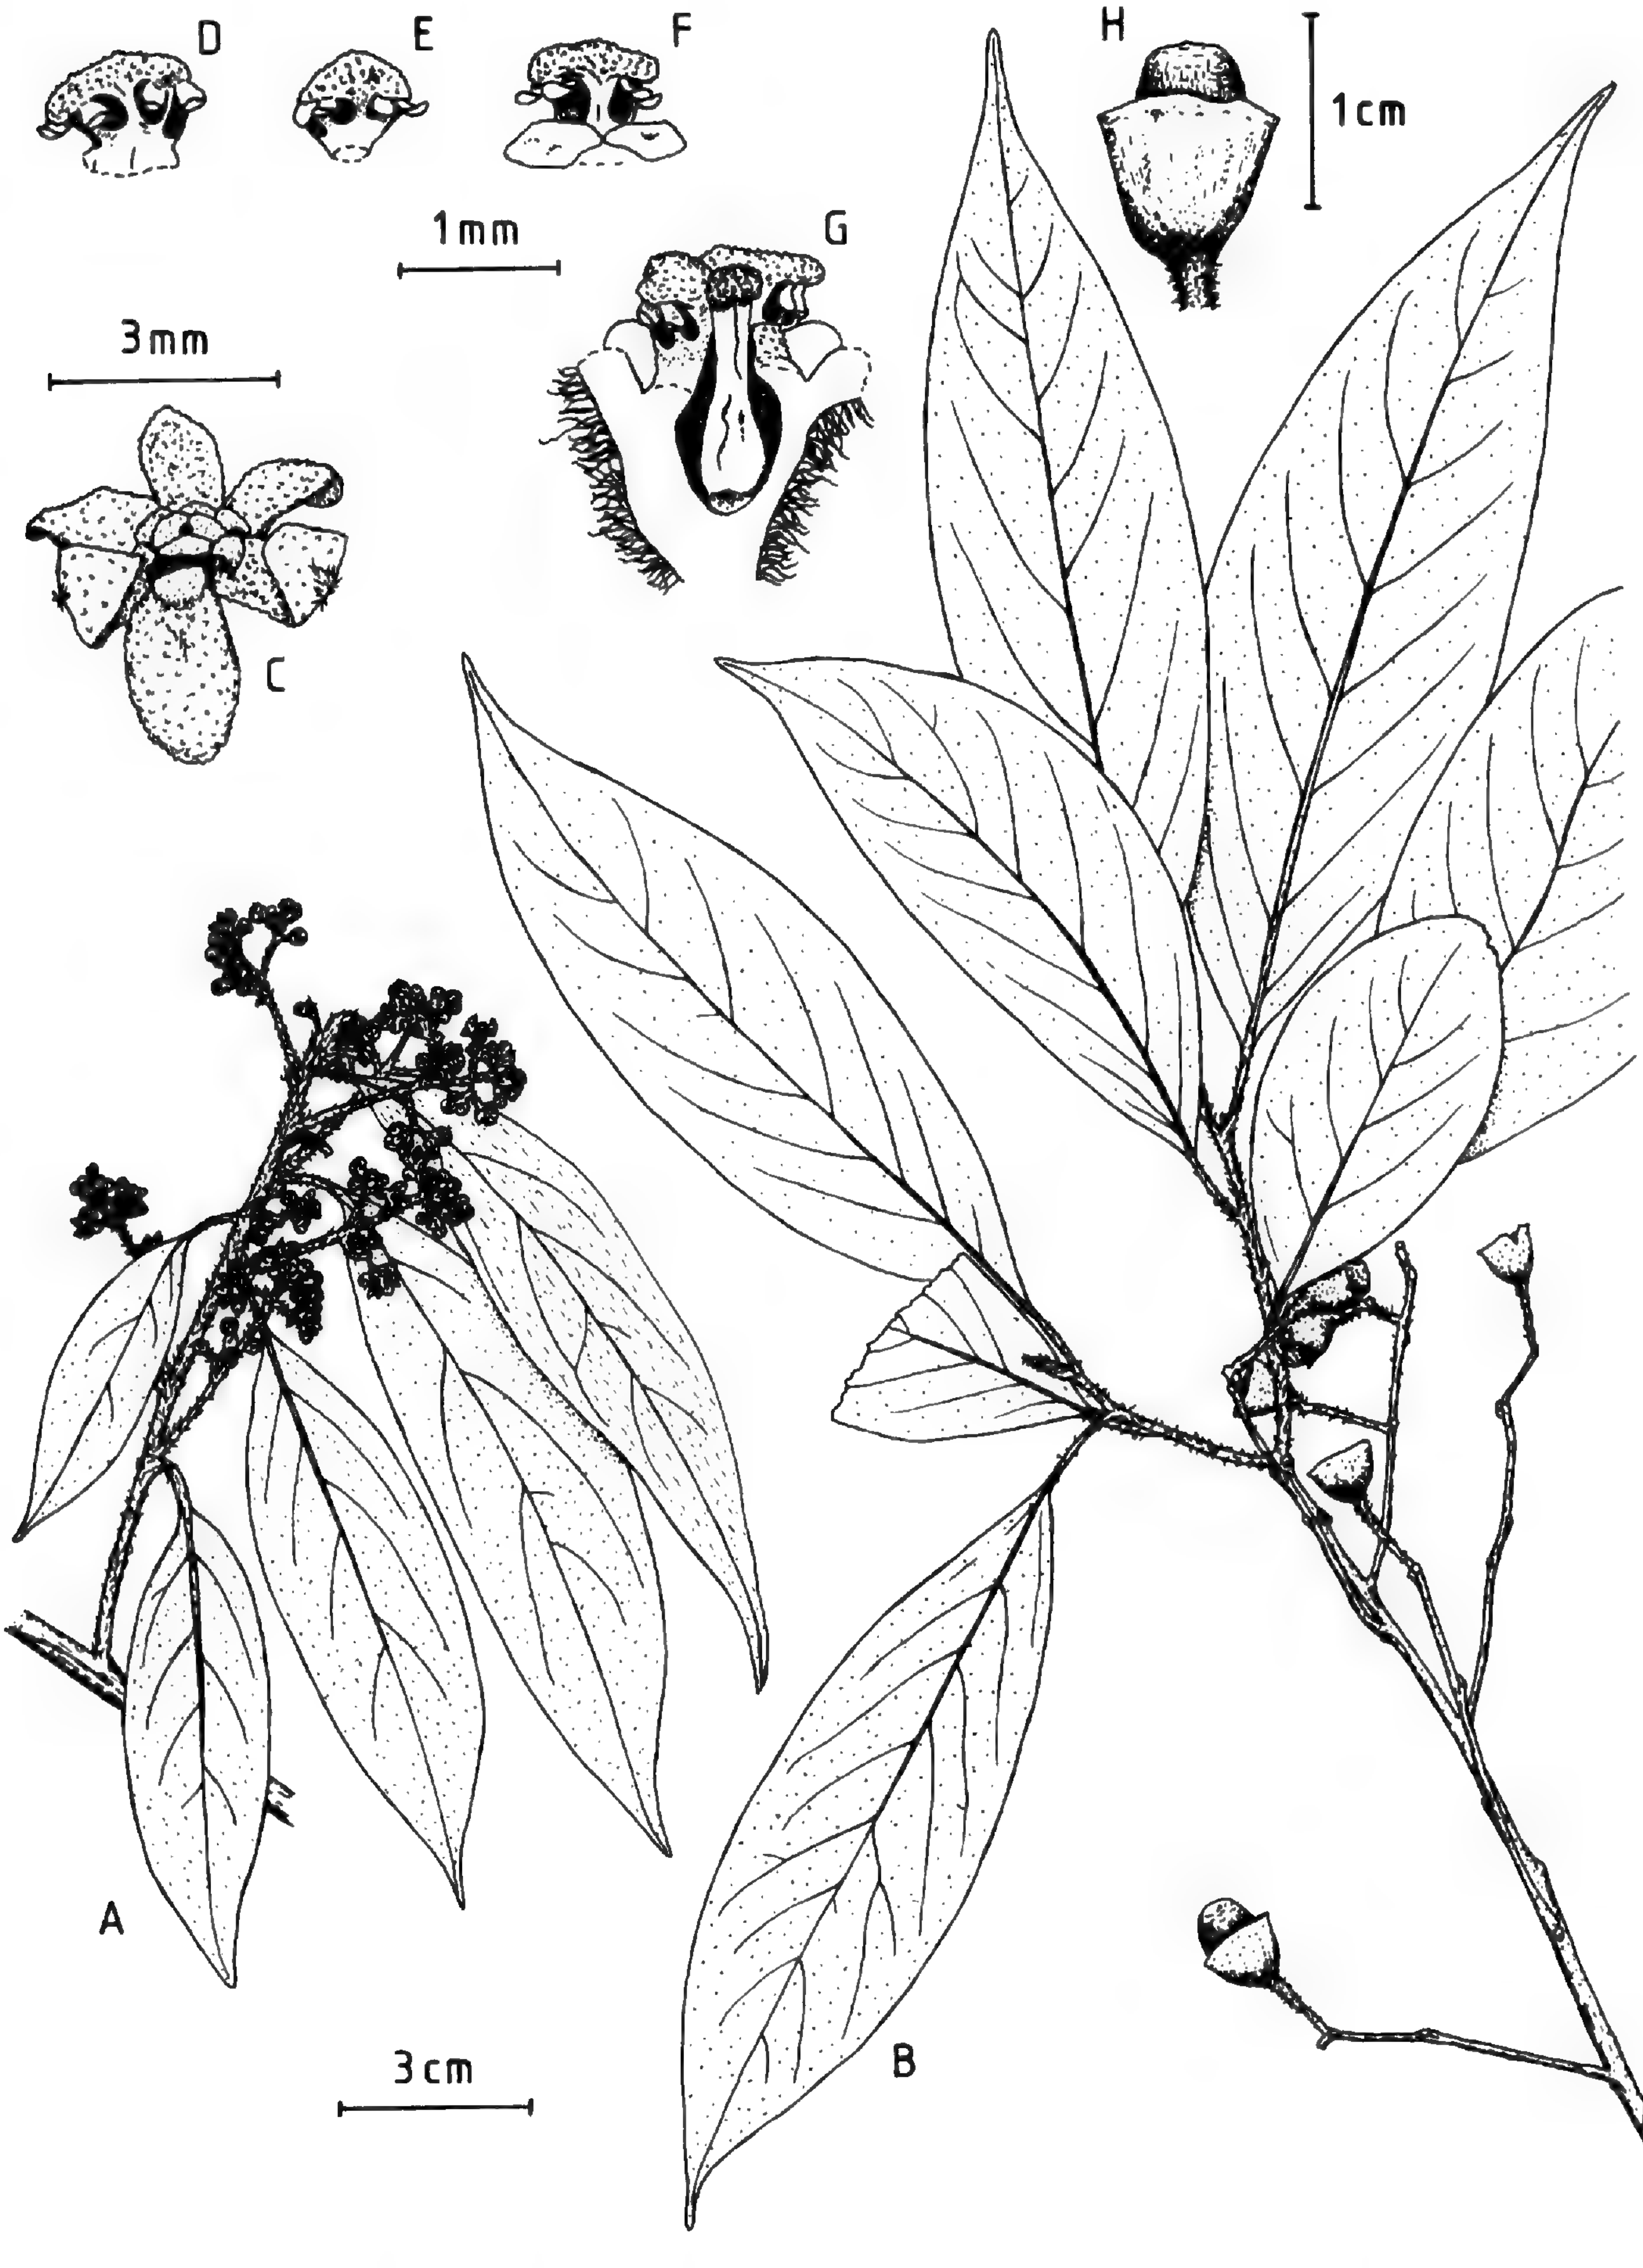

FIGURE 1. Nectandra aurea.—*A. Habit, flowering branch.—B. Habit, fruiting branch.—C. Flower, seen obliquely from above.—D. Stamen of the first whorl, seen from inside.—E. Stamen of the second whorl, seen from inside.—F. Stamen of the third whorl, seen from outside.—G. Receptacle with ovary, staminode, and two inner stamens, cut open, tepals and outer stamens removed.—H. Fruit. Vouchers: A,* Davidse & González 14492; *B–H,* Davidse & González 13215.

densely yellowish pubescent (often inconspicuous but soft to the touch), below densely and often shining golden-pubescent, hairs predominantly appressed but with a few ± erect reddish hairs, these rarely forming indistinct tufts in the vein axils, older leaves above glabrescent except for some hairs on midrib, below with an almost persistent indumentum, or very slowly subglabrescent. Inflorescences short thyrsoids, axillary to distal leaves or occasionally some of them axillary to cataphylls below the terminal bud, covered with the same kind of indumentum as the young twigs, 2–5(–9) cm long with a peduncle of 1–2(–3) cm, with 2–4 lateral cymules below a terminal cluster of cymules, the cymules branched 1–3(–4) times. Pedicels 0.5–2.5 mm long. Flowers 5–8(–9.5) mm diam. Tepals elliptic, up to 4 mm long, papillose on the inside, the outer ones slightly larger than the inner ones. Stamens papillose, subsessile, 0.7–0.9 mm long, the outer 6 broadly pentagonal to broadly rhombic, with a slightly prolonged, broadly triangular, obtuse to almost rounded apex, those of the first whorl (opposite the outer tepals) usually slightly wider than those of the second whorl, the 3 inner stamens broadly rounded to almost truncate at the apex. Staminodes small but thickish, papillose at the tip, hidden between the stamens of the third whorl and united with them at the very base. Pistil ± slender, glabrous, 1.5–2 mm long, the style relatively thick and about as long as the ovary. Receptacle deeply urceolate, on the inside covered with tightly appressed hairs (sometimes only in patches). Fruit (known only immature) ovoid-elliptic, its cupule deep, campanulate, already about 11 mm diam. and 9 mm deep, with an entire margin.

Additional specimens examined. VENEZUELA. APURE: Dtto. San Fernando, banks of the Río Arauca, 5 km directly (in a straight line) SW of El Faro, 7°19′N, 66°54′W, 35 m, 18–19 May 1977 (fl), *Davidse & González 13412* (MO); Dtto. Pedro Camejo, banks of the Río Orinoco, opposite Isla Pantallo, 48 airline km NE of Puerto Páez, 6°13′N, 67°09′W, 40 m, 24–25 Feb. 1978 (fl), *Davidse & González 14492* (MO). BOLÍVAR: Dtto. Cedeño, ± 20 km al E de Túriba, 6–11 Dec. 1970 (fl), *Marcano-Berti 2595* (MER); margen del Caura, Temblador, 100 m, 28 Mar. 1939 (fl), *Ll. Williams 11612* (F, US); Las Trincheras, 80 m, 11 June 1984 (fl, immature fr), *S. López P. et al. 4598* (NY); same data, (fl), *S. López P. et al. 4664* (NY).

Nectandra aurea is a small to medium-sized tree of gallery forest formations on the banks of the Orinoco River and its tributaries. It is easily recognized by the characteristic pubescence on young leaves, young twigs, and inflorescences. The tertiary venation is rather inconspicuous above and below, and the young leaves tend to dry with a much lighter and more yellowish color than the mature leaves, which dry medium brown above. The deep campanulate cupule is also quite unusual, but it seems to become wider towards maturity and therefore may not be a reliable specific character.

Allen (1964) cited the collection *Williams 11612* under *N. pisi* Miq. (= *N. globosa* (Aubl.) Mez). With only this specimen at hand, one might indeed think of it as an unusually hairy variant of *N. globosa*. In that species, however, the leaves are generally more elliptic and much wider when mature, the veins are more distinct, and the immature cupules are constricted, not expanded towards the margin.

Nectandra fulva Rohwer, sp. nov. TYPE: Venezuela. Amazonas: Dep. Río Negro, 0–1 km E of Cerro de Neblina Base Camp on Río Mawarinuma, 140 m, 0°50′N, 66°10′W, 27 Nov. 1984 (fl, fr), *Liesner & Kral 17338* (holotype, MO). Figure 2.

Arbor, ad 20 m alta (raro frutex). Ramuli novelli ± angulati, apice ipso ± dense cupreo-subtomentosi, celeriter autem densitate indumenti deminuente, nigricantes. Folia alterna, (ob)lanceolato-oblonga vel (ob)lanceolato-elliptica, raro elliptica, 12–26 cm longa, 3.3–8.5 cm lata, nervis lateralibus utroque costae latere (6–)7–9(–10) sub angulo 50–55(–65)° prodeuntibus, in sicco rigide chartacea, supra plerumque nervis paulo impressis venulis parum elevatis, subtus costa nervisque prominentibus venulis paulo elevatis, apice acuminata, basi acuta vel subcuneata, basi ipsa autem plerumque paulo producta, margine plano, folia novella (si circa anthesin pullulantia) supra dense et molliter flavido- vel fulvo-tomentella, subtus parce et inconspicue puberula sed costa nervisque pilis aliquantum majoribus rufescentibus praedita, vetustiora utrinque (supra primum interveniis) subglabrescentia. Inflorescentiae axillares, laxe thyrsoideae, 7–12(–15) cm longae, pedunculo 3.5–6(–7.5) cm longo, pedunculo modice cupreo- et floribus dense flavido-tomentellae, cymis lateralibus (2–)4(–6), 2–4-furcatis. Pedicelli 3.5–7 mm longi. Flores (7–)9–10 mm diametro. Tepala elliptica vel anguste-elliptica, intus papillosa, aequalia vel exteriora interioribus aliquantum majora, ad 4.5 mm longa. Stamina papillosa, 0.9–1.4 mm longa, filamentis brevissimis, serie prima suborbicularia vel late rhomboidea apice rotundato vel obtuso, serie secunda paulo angustiora, ± ovata vel trullata apice acuto vel parabolico, serie tertia ± rectangularia, apice truncata vel late rotundata. Staminodia parvula sed crassiuscula, apice papillosa, inter stamina seriei tertiae ± celata et basi eis connata. Pistillum elongatum, 1.7–2.7 mm longum, stylo papilloso ovarium glabrum ± aequante. Receptaculum profunde urceolatum, intus glabrum. Fructus (non nisi immaturus notus) oblongus vel ovato-oblongus, ca. 14 mm longus et 8 mm diametro. Cupula ± hemispherica, ca. 10 mm diametro et 5 mm profunda, margine paulo 6-dentato.

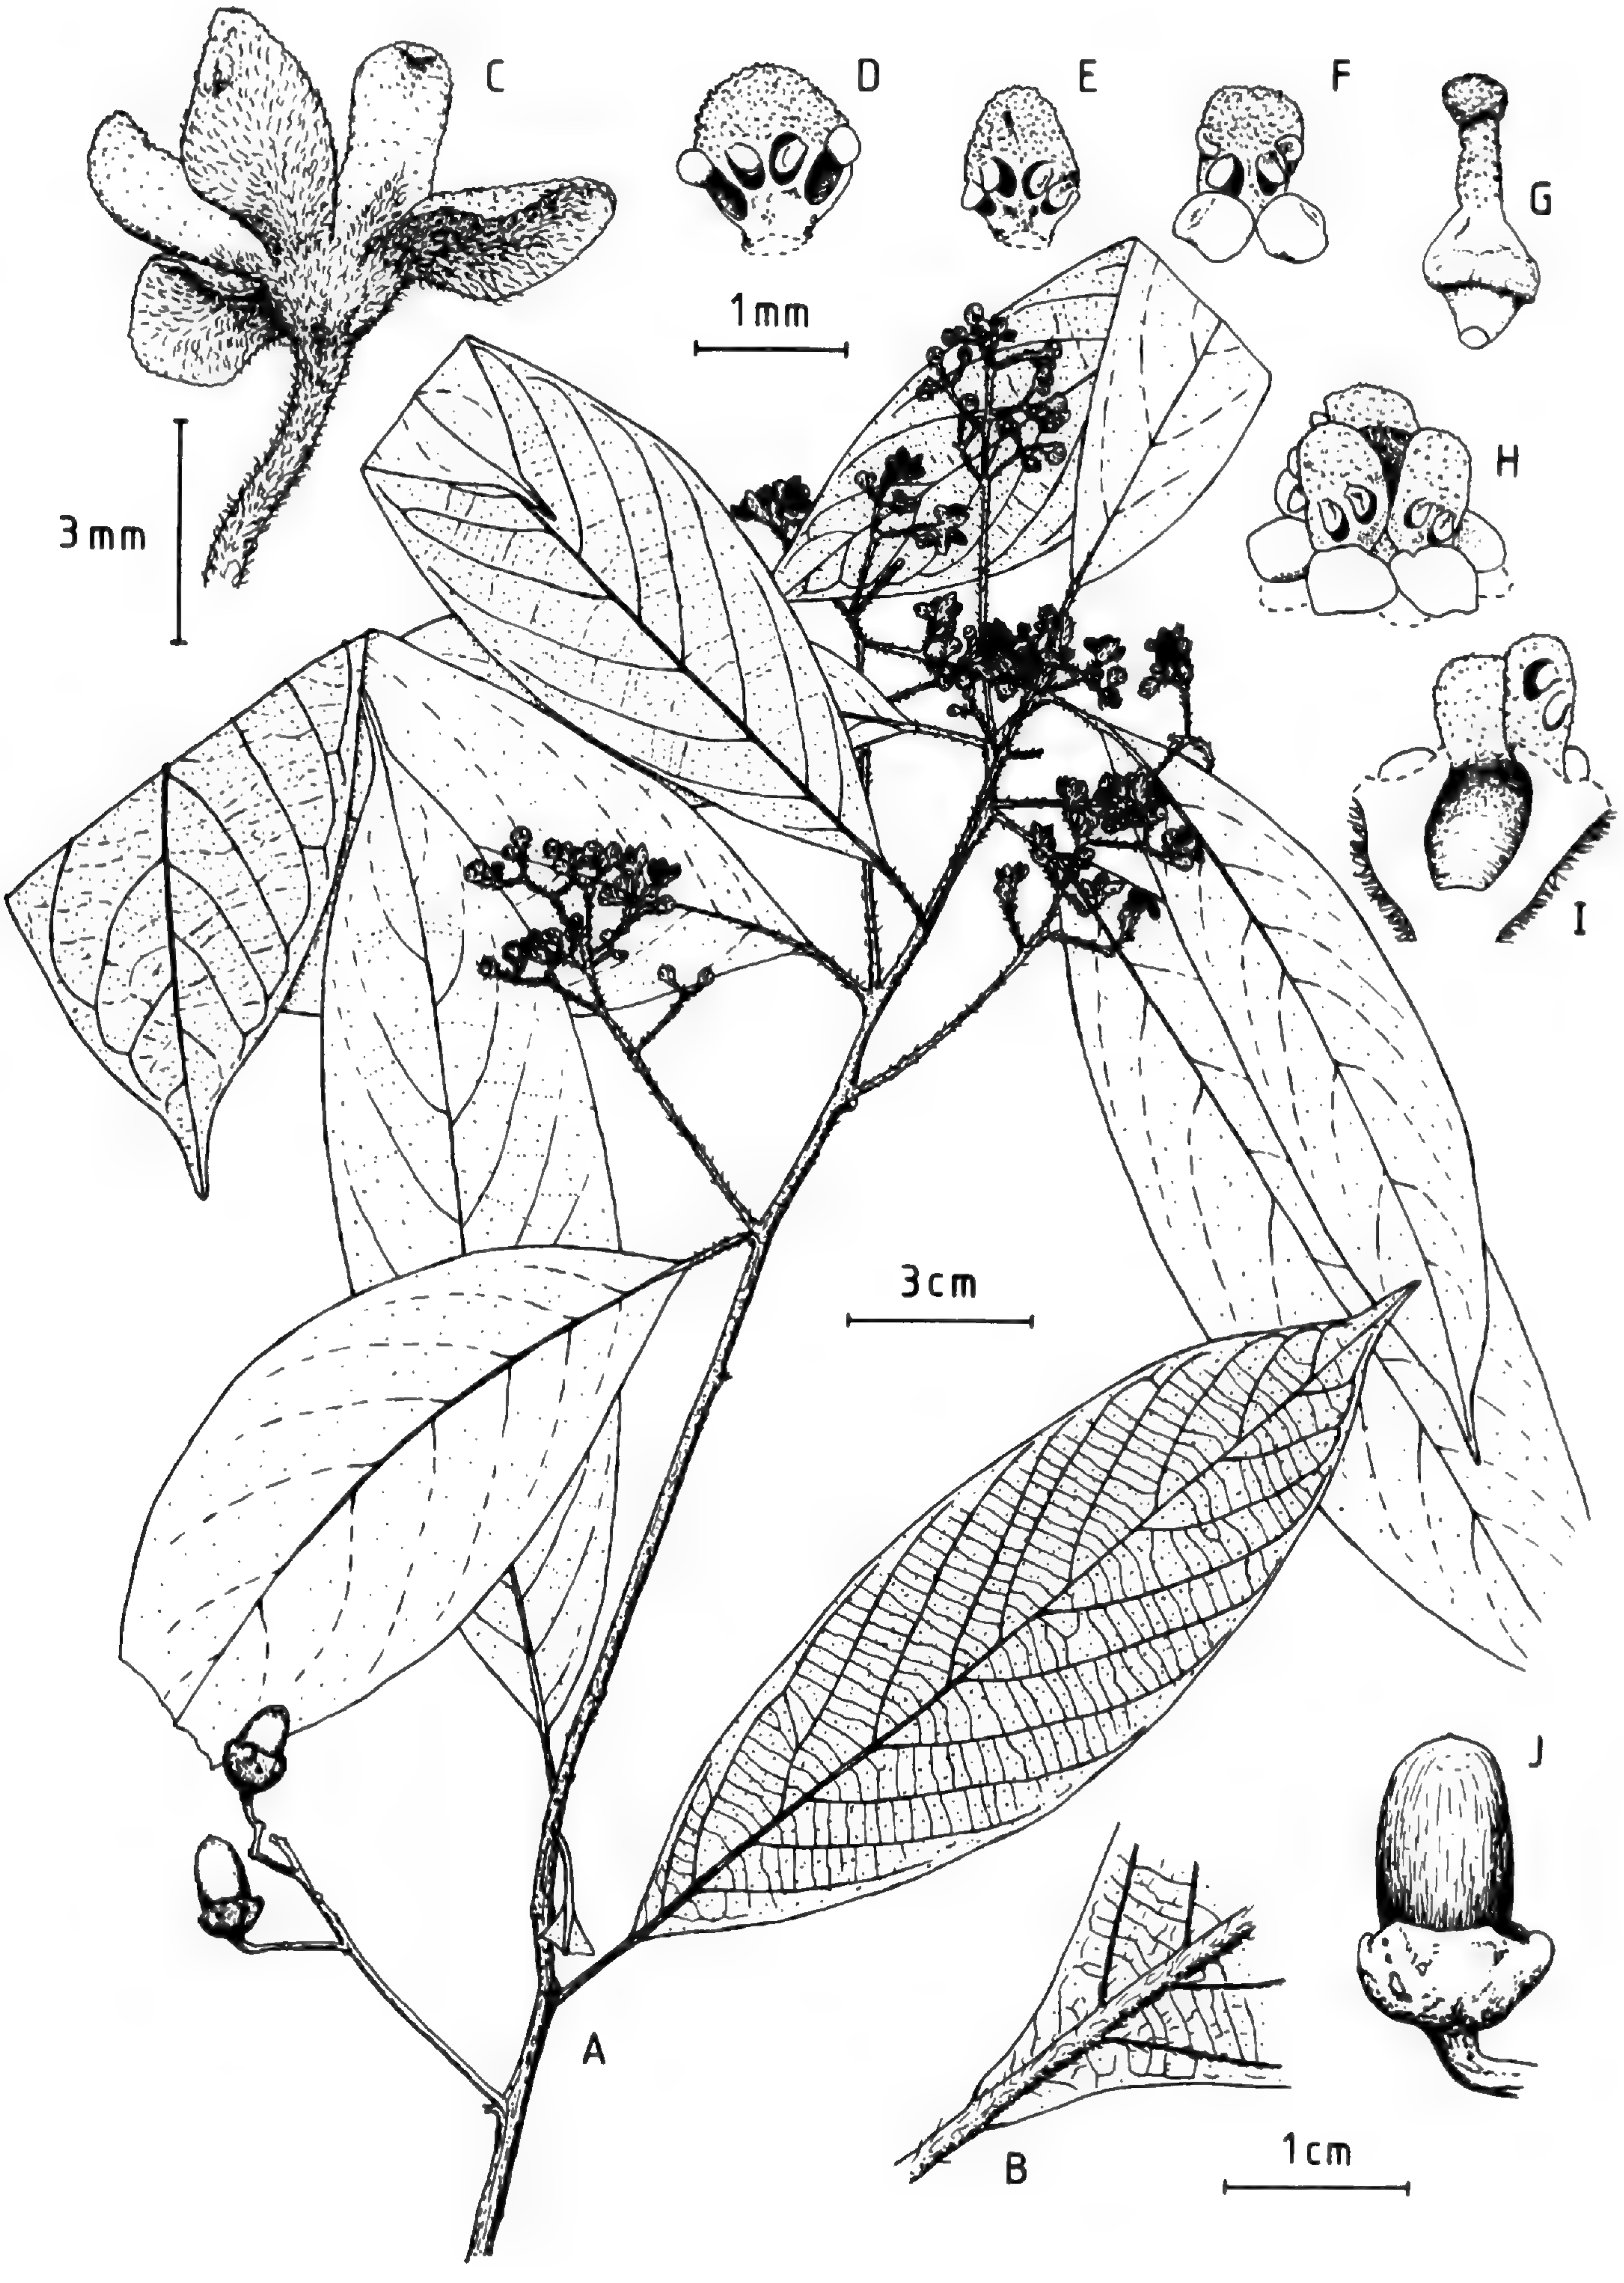

FIGURE 2. Nectandra fulva.—*A. Habit.*—*B. Leaf base.*—*C. Flower, seen from side.*—*D. Stamen of the first whorl, seen from inside.*—*E. Stamen of the second whorl, seen from inside.*—*F. Stamen of the third whorl, seen from outside.*—*G. Ovary.*—*H. Stamens of the third whorl, with stigma and staminode between them, glands and scars of outer stamens at the periphery.*—*I. Receptacle with two inner stamens, cut open; tepals, outer stamens, and ovary removed; semischematic.*—*J. Fruit. Vouchers: A, C–J,* Liesner & Kral 17338; *B,* Gentry & Stein 46954.

Tree (rarely shrub) to 20 m. Twigs at first ± angular, immediately below the terminal bud with a relatively dense copper-colored indumentum of very short to moderately long (ca. 1 mm) curled to almost straight hairs, these quickly becoming sparser below the tip and revealing the blackish epidermis. Leaves alternate, (ob)lanceolate-oblong to (ob)lanceolate-elliptic, rarely elliptic, 12–26 cm long, 3.3–8.5 cm wide, with (6–)7–9(–10) pairs of lateral veins diverging at 50–55(–65)°, dried laminae stiffly chartaceous, above usually with the secondary veins slightly impressed and the tertiary veins very slightly raised, below with midrib and secondaries prominent and the tertiary veins noticeably raised, ± at right angles to the secondary veins, the apex acuminate, the base acute or almost cuneate, at the very base often extended into a short projection along the petiole, margin flat; young leaves (only those developed around flowering time, see below) very densely covered above with predominantly short strongly curled yellowish hairs, soft to the touch, below with a (moderately) sparse indumentum of short appressed hairs between the secondary veins and slightly longer more reddish curled hairs on the veins, the indumentum of older leaves first worn off between the secondary veins above, later slowly subglabrescent. Inflorescences ± lax thyrsoids, axillary to distal leaves, 7–12 (–15) cm long with a peduncle of 3.5–6(–7.5) cm, this with a moderately dense to sparse indumentum similar to that of the twigs, becoming shorter, denser and more yellowish towards the flowers, with (2–)4(–6) lateral cymules below the terminal cymule or cluster of cymules, the cymules branched 2–4 times. Pedicels 3.5–7 mm long. Flowers (7–)9–10 mm diam. Tepals elliptic to elongate-elliptic, up to 4.5 mm long, papillose on the inside, ± equal or the outer ones somewhat larger than the inner ones. Stamens papillose, 0.9–1.4 mm long, with very short filaments, these in the outer whorls sometimes adnate to the tepals, the stamens of the first whorl suborbicular to broadly rhomboid, with a rounded or obtuse tip, those of the second whorl slightly narrower, ± ovate to slightly angular, with an acute to parabolic tip, the third whorl almost rectangular, truncate to broadly rounded at the apex. Staminodes very small but thickish, papillose at the tip, hidden between the stamens of the third whorl and basally united with them. Pistil elongate, 1.7–2.7 mm long, the style papillose and about as long as the glabrous ovary. Receptacle deeply urceolate, glabrous on the inside. Fruit (known only immature) elongate to ovoid-elongate, its cupule nearly hemispherical, ca. 10 mm diam. and 5 mm deep, with a tendency to develop 6 thick teeth on the margin, each corresponding to the midvein of a tepal.

Additional specimens examined. VENEZUELA. AMAZONAS: Dep. Río Negro, Neblina Base Camp on the Río Mawarinuma, 0°50′N, 66°10′W, 140 m, 17 July 1984 (fl), *Davidse & Miller 27417* (MO); same data, 120 m, 17 July 1984 (fl), *Davidse 27520* (MO); Cerro Neblina, between base camp and Puerto Chimo along Río Mawarinuma, 150–180 m, 0°50′N, ca. 66°08′W, 26 Apr. 1984 (fl), *Gentry & Stein 46954* (MO); upstream end of large island in Río Mawarinuma just upstream from Neblina Base Camp, 0°50′N, 66°10′W, 160 m, 27 Nov. 1984 (fl, immature fr), *Kral 71844* (MO); 1–3 km E of Cerro de Neblina Base Camp on Río Mawarinuma, 140 m, 0°50′N, 66°10′W, 8 Feb. 1984 (immature fr), *Liesner 15739* (MO); same data (post fl), *Liesner 15755* (MO); along Río Mawarinuma, 0–5 km E of Cerro de La Neblina Base Camp, 140 m, 0°50′N, 66°10′W, 10 Mar. 1984 (immature fr), *Liesner & Funk 16521* (MO); along Río Mawarinuma, 2–6 km E of Base Camp, between Base Camp and "Puerto Chimo" camp, 160 m, 0°50′N, 66°08′W, 26 Apr. 1985 (fl), *Thomas 3189* (MO, NY, US).

Nectandra fulva is known from only one population near the Neblina Base Camp on the Río Mawarinuma. The tendency to develop dentate or even thickly lobed cupules is a very rare character in *Nectandra*, and it suggests a close relationship with the group around *N. acutifolia* (Ruiz & Pavón) Mez. The structure of the indumentum and the presence of often distinct gland dots in the leaves further support this conclusion. *Nectandra fulva* differs, however, from the other species in this group (among other characters) by less elongate anthers and the lack of an inrolled leaf base.

Nectandra fulva shows an interesting dimorphism in the indumentum of leaves developed during the flowering and fruiting periods. Only those from the flowering period show the dense indumentum on the upper surface described above. In those from the fruiting period there are only somewhat curled reddish hairs, moderately dense on the major veins and sparse from the beginning between them. While these sparsely hairy new leaves are developed, some of the older ones may still show remnants of the dense indumentum developed during flowering time.

Nectandra ruforamula Rohwer, sp. nov. TYPE: Venezuela. Amazonas: 0.5 to 2 km N of San Carlos de Río Negro, ca. 20 km S of confluence of Río Negro & Brazo Casiquiare, 1°56′N, 67°03′W, 120 m, 10 May 1979 (fl), *Liesner 7318* (holotype, MO). Figure 3.

Arbor, ad 10 m alta. Ramuli novelli ± angulati, dense rufo-tomentelli, vetustiores plerumque ± teretes et pilis coactis inconspicuis fumosi, demum glabrescentes (in typo autem ramuli permanifeste angulati et pubescentia persistente). Folia alterna, elliptica vel lanceolato-elliptica, 8.5–20(–26) cm longa, 2.7–8(–10) cm lata, nervis lateralibus utroque costae latere 5–7(–9) sub angulo 35–50(–55)° prodeuntibus, in sicco subcoriacea, supra griseo-virentia vel raro olivacea, costa nervisque impressis venulis paulo impressis, subtus ± fusca, costa nervisque prominentibus venulis elevatis, apice anguste acuminata, basi acuta vel raro obtusa, basi ipsa autem plerumque angustata vel quidem paulo producta, margine subplano vel recurvulo, folia novella utrinque costa nervisque rufo-tomentella, supra interveniis glabra vel paulo pallido-tomentella, subtus indumento densiore, interveniis plerumque pilis brevibus adpressis pallidis modice sparsis et pilis crispatis ± erectis rufescentibus (ut in venis) sparsis, ventustiora supra (interdum praeter basin costae) glabrescentia, subtus subglabrescentia, pilis brevibus adpressis pallidis valde inconspicuis persistentibus. Inflorescentiae axillares, breviter et ± dense thyrsoideae, 2–7 cm longae, pedunculo 1–2.5 (–3.5) cm longo, dense rufo- vel fusco-tomentellae, cymis lateralibus (0–)2–4, 1–2(–3)-furcatis. Pedicelli 1–3 mm longi. Flores 5.5–7.5 mm diametro. Tepala elliptica, intus papillosa, aequalia vel exteriora interioribus paulo majora, ad 3.5 mm longa. Stamina papillosa, 0.7–0.9 mm longa, filamento evidente sed anthera breviore, exteriores 6 depresse obtrullata vel fere transverse elliptica, apice paulo producto obtuso, serie prima secunda plerumque paulo latiora, interiores 3 apice late rotundata vel paene truncata. Staminodia parva sed crassiuscula et paulo capitata, intrinsecus paulo glandulosa, extrinsecus papillosa, inter stamina seriei tertiae ± celata. Pistillum crassiusculum, glabrum vel stylo aliquantum papillosum, 1.4–1.8 mm longum, stylo crasso ovario breviore. Receptaculum late urceolatum (hemisphericum sed supra staminibus staminodiisque fere praeclusum), intus glabrum vel pilis sparsis adpressis. Fructus (immaturus, ex *Maguire & Politi 28001*) ellipticus. Cupula profunda, subhemispherica, iam ca. 11 mm diametro et 6 mm profunda, margine integro.

Tree to 10 m. Twigs at first ± angular, densely covered with a rusty red indumentum of erect and somewhat curled longer hairs (0.3–0.8 mm) over an extremely dense layer of very short hairs, older twigs usually roundish and with much of the indumentum persistent for a long time as a matted gray layer over the epidermis, finally glabrescent (in the type collection all twigs strongly angular and covered with a dense reddish indumentum). Leaves alternate, elliptic to lanceolate-elliptic, 8.5–20(–26) cm long, 2.7–8(–10) cm wide, with 5–7(–9) pairs of lateral veins diverging at 35–50 (–55)°, dried laminae subcoriaceous, above grayish green (older leaves rarely olive), with impressed midrib and secondaries, the tertiary veins usually slightly impressed, below yellowish brown to reddish brown, midrib and secondaries prominent, the tertiary veins noticeably to distinctly raised, ± at right angles to the secondary veins, the apex narrowly acuminate, the base acute or rarely obtuse but at the very base attenuate or at least extended into a short projection along the petiole, almost flat or slightly curved downwards; young leaves on both sides with erect curled reddish hairs on midrib and secondaries, the intercostal fields glabrous or with some paler hairs above, below indumentum denser both on veins and in the intercostal fields, the latter usually with pale, short, appressed hairs and with longer reddish hairs similar to those on the veins; older leaves glabrescent above (some hairs on base of midrib often persistent), subglabrescent below, with the inconspicuous, pale, short, appressed hairs persistent for a long time. Inflorescences short and ± dense thyrsoids, axillary to distal leaves, covered with an indumentum similar to that of the young twigs (but becoming shorter and more grayish brown towards the flowers), 2–7 cm long with a peduncle of 1–2.5(–3.5) cm, with (0–)2–4 lateral cymules below a terminal cluster of cymules, the cymules branched 1–2(–3) times. Pedicels 1–3 mm long. Flowers 5.5–7.5 mm diam. Tepals elliptic, up to 3.5 mm long, papillose on the inside, equal or the outer ones slightly larger than the inner ones. Stamens papillose, 0.7–0.9 mm long, the outer 6 with short but distinct filaments; anthers broadly obtrullate to almost transversely elliptic, with a slightly prolonged obtuse apex, those of the first whorl (opposite the outer tepals) usually slightly wider than those of the second whorl, the 3 inner stamens broadly rounded to almost truncate at the apex. Staminodes small but thickish with a small heart-shaped head, slightly glandular on the adaxial side, papillose on the abaxial side, hidden between the stamens of the third whorl. Pistil relatively stout, glabrous or somewhat papillose at the style, 1.4–1.8 mm long, the style relatively thick, reaching about ½–⅔ the length of the ovary. Receptacle broadly urceolate (hemispherical but above closed by stamens and staminodia), on the inside glabrous or with a few tightly appressed hairs. Fruit (immature, after *Maguire & Politi 28001*, see below) elliptic, its cupule deep, roughly hemispherical but slightly contracted at the margin, already about 11 mm diam. and 6 mm deep, with an entire margin.

Additional specimens examined. VENEZUELA. AMAZONAS: Dep. Atabapo, Cucurital de Caname, southern bank of the middle part of Caño Caname, 3°40′N, 67°22′W, 100 m, 30 Apr.–1 May 1979 (fl), *Davidse et al. 17008* (MO); Río Orinoco 1–10 km below San Fernando de Atabapo, 150 m, 11 May 1954 (fl), *Level 65* (F, NY, US); 4–7 km NE of San Carlos de Río Negro along road, ca. 20 km S of confluence of Río Negro & Brazo Casiquiare, 1°56′N, 67°03′W, 120 m, 19 May 1979 (fl), *Liesner 7550* (MO); Río Atabapo, along Yavita–Pimichin trail near Yavita, 125–140 m, 10 June 1959 (fl), *Wurdack & Adderley 42902* (MO, NY); Cerro Sipapo (Paráque), near base camp, 125 m, 28 Dec. 1948 (fr), *Maguire & Politi 28001* (US).

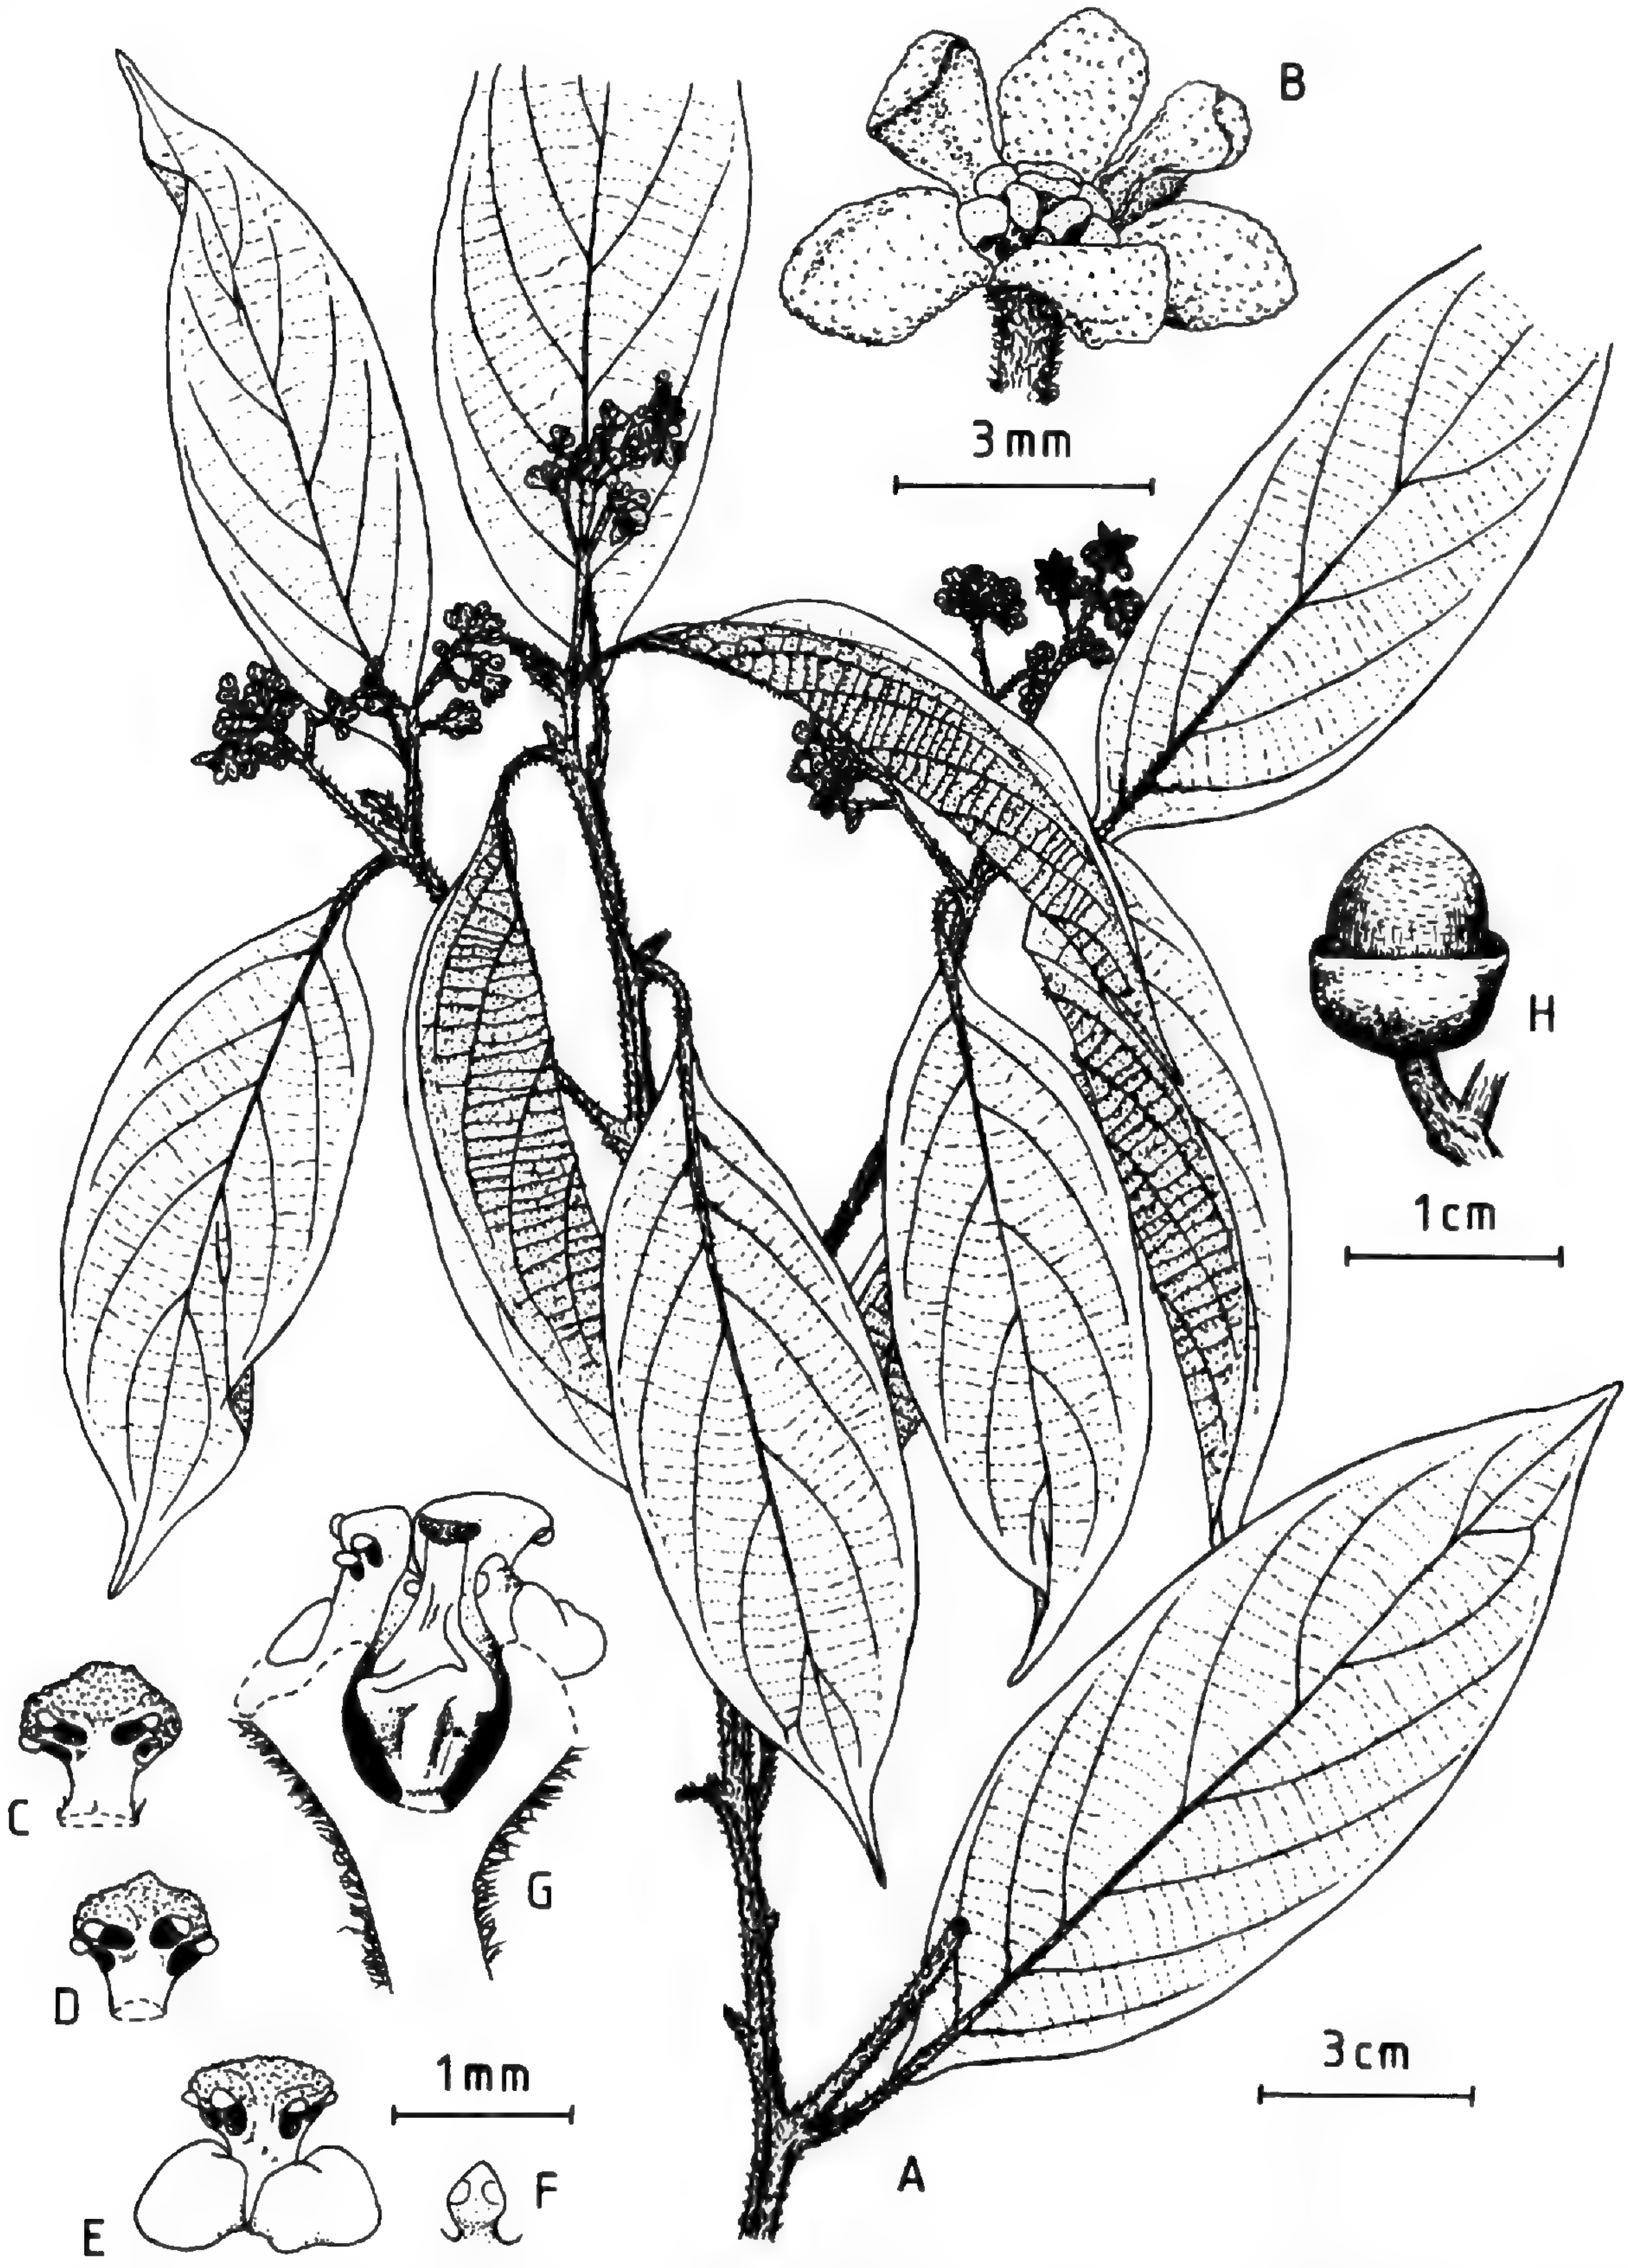

FIGURE 3. Nectandra ruforamula.—*A. Habit.—B. Flower, seen from side.—C. Stamen of the first whorl, seen from inside.—D. Stamen of the second whorl, seen from inside.—E. Stamen of the third whorl, seen from outside.—F. Staminode with glandular patches, seen from inside.—G. Receptacle with ovary, staminode, and two inner stamens, cut open; tepals and outer stamens removed.—H. Fruit. Vouchers: A–G,* Liesner 7318; *H,* Maguire & Politi 28001.

Nectandra ruforamula occurs in the lowland region that connects the basins of the Orinoco and the Amazon. At present it is only known from the Venezuelan side, but it is likely to occur in Colombia as well. *Nectandra ruforamula* is recognized mainly by its dense reddish indumentum on the young twigs, but the leaves have a characteristic appearance, too. They usually show a marked difference between a grayish green upper surface with impressed reticulation and a reddish brown lower surface with raised reticulation.

Despite these rather obvious characters, there is a problem with the delimitation of *N. ruforamula* against *N. globosa* (Aubl.) Mez. The type collection of *N. ruforamula* is not fully representative of the species but has been selected because it is so strikingly unlike any other species of *Nectandra*, including *N. globosa*. In the other collections, however, the reddish indumentum (which in the type collection covers the entire twigs) is restricted to the apical part of the branchlets. Further from the tip it quickly turns into a gray matted mass in which individual hairs can hardly be resolved, and which imperceptibly intergrades with the grayish bark still further down. Where this gray indumentum prevails over the reddish hairs, the specimens may become similar to *N. globosa*, and three of the collections included here (*Level 65, Maguire & Politi 28001, Wurdack & Adderley 42902*) have been cited under its synonym *N. pisi* Miq. by Allen (1964). *Nectandra ruforamula* is treated as a separate entity here because in *N. globosa* the tertiary reticulation is less distinct, even the youngest leaves never show erect curled reddish hairs, and the dry leaves are usually medium to dark brown on both sides.

The fruiting collection, *Maguire & Politi 28001*, is placed here with some doubt. It shows the characteristic color of the leaves, but it altogether lacks the reddish hairs, and the tertiary venation is somewhat less conspicuous than should be expected in leaves of this size. The indumentum, however, is lost or significantly altered with age in most species of *Nectandra*.

A SYNOPSIS OF *MATELEA* SUBG. *DICTYANTHUS* (APOCYNACEAE: ASCLEPIADOIDEAE)[1]

Warren Douglas Stevens[2]

ABSTRACT

Matelea *subg.* Dictyanthus *comprises thirteen currently known species ranging from northwestern Mexico to southern Nicaragua. One of the species is provided with a new combination,* M. aenea, *and five are described as new,* M. eximia, M. hamata, M. lauta, M. macvaughiana, *and* M. suffruticosa. *The synopsis provides descriptions and a key.*

The genus *Dictyanthus* was described by Decaisne in de Candolle's *Prodromus* in 1844. The description was based on a Sessé & Mociño collection which had been distributed by Pavón. A few years later, sometime in the late 1840s, *Dictyanthus pavonii* was introduced into European botanical gardens and became relatively well known. During this period the species was illustrated in horticultural journals and was provided with several new names. The next treatment of the genus was that of Bentham & Hooker in their *Genera Plantarum* (1876). They considered the genus to comprise three or four Mexican species. Six years later, Hemsley (1882) treated the genus in *Biologia Centrali-Americana, Botany* and recognized four species, one of which was described as new. In Engler & Prantl's *Die natürlichen Pflanzenfamilien*, Schumann (1895) again considered *Dictyanthus* to be a Mexican genus of three or four species. Next, Standley in his *Trees and Shrubs of Mexico* (1924) included six species, one of which was described as new. Woodson (1941), in providing a generic revision of the North and Central American Asclepiadaceae, reduced *Dictyanthus* to a subgenus of *Matelea* and made new combinations for the ten species he recognized. These were listed with partial synonymy to document the subgenus. In the present treatment there are recognized seven of the species Woodson listed, two are reduced to synonymy, and one is excluded from the subgenus. To these are added five new species and one species resurrected from Woodson's synonymy. Finally, Standley & Williams (1969) included the two Guatemalan species of the subgenus in their treatment of Asclepiadaceae in *Flora of Guatemala*. This summarizes the taxonomic history of *Dictyanthus*, except for the description of individual species. Since Woodson's generic revision, no species have been added to or removed from the subgenus, and no species belonging to the group have been described since 1930.

Matelea belongs to the New World tribe Gonolobeae, which can be distinguished within the subfamily by having the pollinia partially sterile and excavated on one or both faces and oriented more or less horizontally along the margin of the style apex. Woodson (1941) recognized three genera in the tribe, *Matelea*, *Gonolobus*, and *Fischeria*, reducing many previously recognized genera to synonymy. While the larger generic concepts offer significant advantages, it seems clear that reinstating some segregates would improve all the circumscriptions. *Matelea* is the least satisfactory of the concepts but, although certain small segregates, notably *Macroscepis* and *Pherotrichis*, can easily be recognized, the bulk of the species require more careful consideration than has yet been possible. Most of Woodson's subgenera of *Matelea* are ill-conceived, but *Dictyanthus* is such a distinctive group that Woodson expressed some misgivings about submerging it. He correctly noted, however, that *Matelea altatensis* (Brandegee)

ANN. MISSOURI BOT. GARD. 75: 1533–1564. 1988.

Woodson, which he included in subgenus *Dictyanthus*, is intermediate with the larger group of *Matelea*. To *M. altatensis*, which is here excluded from the subgenus, can be added the additional intermediate species *M. aspera* (Miller) W. D. Stevens and *M. sepicola* W. D. Stevens. Subgenus *Dictyanthus* is separated from the rest of *Matelea* by having the corona deeply five-lobed with the axis of each lobe entirely adnate to the corolla; also partially diagnostic are 1) simple inflorescences, 2) a mixed indumentum with at least some of the trichomes glandular and at least some of the long trichomes uncinate, and 3) narrowly fusiform follicles with thickish projections. Thus, while adequate generic and subgeneric circumscriptions within the Gonolobeae are yet to be established, *Dictyanthus* is an easily defined but not entirely discrete group within the current concept of *Matelea* and is here treated as such.

To interpret properly the following key and descriptions, the following should be considered. 1) The description of the indumentum has been simplified and, to a certain extent, generalized by the convention of referring to all trichomes as either short, glandular, or long and by modifying these terms as appropriate. These trichomes are, unless otherwise indicated, uniseriate and multicellular and have straight or uncinate tips. Short trichomes are less than 0.1 mm long, typically about 0.05 mm. Short trichomes on the inner surface of the corolla, when present, are somewhat different in form and have a glassy appearance when dried. Glandular trichomes are the same length to slightly shorter than the short trichomes, with which they are almost always mixed, and have a short stalk, an inflated middle, and a short apiculum. The glandular trichomes are probably not secretory, but the inflated part frequently collapses on drying, giving these the appearance of normal capitate glandular trichomes. Long trichomes are typically much longer than 0.1 mm. The maximum length of long trichomes is given only for the stem. Trichomes on other structures tend to be shorter. When only long trichomes are present on a structure, as is often the case on the leaf blade, they often occur in two discrete lengths, giving much the same appearance as mixed long and short trichomes. 2) The terminology used for describing the surfaces of the leaves and seeds is according to Stearn (1966). 3) The leaves are described essentially according to Hickey (1973). The same terminology is employed to describe the shape of the bracts, calyx lobes, and corolla lobe apices. *The leaf length has been considered to be the length of the midrib.* In all cases the leaves are described on the basis of the largest leaf of each specimen examined. The largest leaves, especially on specimens of the erect species, tend to be near the middle of the stems; the lower leaves tend to be broader and the upper leaves tend to be narrower. 4) The inflorescence and floral characters are described only on the basis of examples in anthesis. The bracts are described on the basis of the largest bract of each inflorescence. The first bract (opposite the first flower) tends to be the largest, and the subsequent bracts are gradually reduced in size. 5) The corolla lobes are considered to be distinct from the limb; thus the corolla is composed of the tube, limb, and lobes. The descriptions of flower colors have been much simplified. In general, only the basic color pattern of the corolla has been described. This color pattern applies only to the inner surface of the corolla, and considerable care should be exercised in attempting to discern the pattern by examining the outside of pressed flowers. 6) Measurements of bipollinia are taken in lateral view and in the normal orientation they assume when removed; the depth or thickness is ignored. The length of the pollinium is measured from the point of attachment of the corpusculum to the tip, including the caudicles of most other asclepiad bipollinia; in most species of the Gonolobeae there is no sharp demarcation of the caudicles from the pollinia.

In the preparation of this synopsis, 694 specimens of 302 collections from 41 herbaria were examined. A list of the specimens examined is available on request. Ten of the thirteen species were studied in the field and nine were cultivated.

TAXONOMIC TREATMENT

Matelea subgenus **Dictyanthus** (Decaisne) Woodson, Ann. Missouri Bot. Gard. 28: 236–237. 1941. *Dictyanthus* Decaisne in de Candolle, Prodr. 8: 605. 1844. TYPE: *Dictyanthus pavonii* Decaisne.

Tympananthe Hasskarl, Flora 47: 258–259. 1847. TYPE: *Tympananthe suberosa* Hasskarl.

Rytidoloma Turczaninow, Bull. Soc. Imp. Naturalistes Moscou 25(2): 319–320. 1852. TYPE: *Rytidoloma reticulatum* Turczaninow.

Plants erect, trailing, or twining, herbaceous or woody, with or without a woody or fleshy caudex. Woody parts typically with thick, fissured, corky bark. Indumentum variable and often mixed; trichomes multicellular, uniseriate, simple, straight or uncinate, of 3 general types: short nonglandular, short glandular, and long nonglandular. Leaves ovate in general outline, apex mostly acuminate to attenuate, base lobate, with acropetiolar colleters; exstipulate but with an interpetiolar fringe of long trichomes and colleters. Inflorescence extra-axillary, a condensed, simple, helicoid cyme or reduced to a single flower with or without an apparent peduncle. Calyx 5-lobed nearly to base, with 1 or 2 colleters below each sinus within. Corolla deeply to shallowly campanulate; tube mostly convoluted, with raised parts opposite corona lobes and sacs formed between them. Corona digitately 5-lobed, lobes connate below or free, adnate to gynostegium and adnate for their entire length to corolla. Gynostegium stipitate, apex ± pentagonal and concave to apiculate, terminal anther appendages covering margin of apex. Corpusculum sagittate; caudicles winged, hardly distinct from pollinia; pollinia flattened, excavated and hyaline along upper margin, obliquely obovate. Follicles fusiform, with few to numerous, thick to thin, straight to arcuate projections. Seeds obovate, flattened, with a raised, smooth or radially grooved, entire or toothed margin, the surface otherwise verrucate to rugose, pale to dark brown; with a white apical coma.

KEY TO SPECIES OF *MATELEA* SUBG. *DICTYANTHUS*

1a. Corolla tube with parallel vertical lines, these only occasionally with a few cross connections.
  2a. Pedicels less than 6 mm long; corolla lobes less than 7 mm long; corona lobes sagittate in outline, less than half the length of the corolla tube .... 2. *M. tuberosa*
  2b. Pedicels more than 6 mm long; corolla lobes more than 7 mm long; corona lobes linear to linear-spathulate in outline, more than half the length of the corolla tube.
    3a. Calyx and outer surface of corolla glabrous; corolla tube with ca. 5 lines between each corona lobe .... 6. *M. lauta*
    3b. Calyx and outer surface of corolla distinctly hairy; corolla tube with 15 or more lines between each corona lobe.
      4a. Corolla base–sinus length more than 12.5 mm, with a narrow band of short trichomes around corona lobes within; long trichomes of peduncles and pedicels mostly uncinate; twining woody vines without thickened caudices .... 4. *M. pavonii*
      4b. Corolla base–sinus length less than 12.5 mm, glabrous around corona lobes within; long trichomes of peduncles and pedicels straight; erect or weakly twining herbaceous vines with thickened caudices .... 5. *M. macvaughiana*
1b. Corolla tube with circular lines or with distinct reticulations, or without a distinct pattern.
  5a. Corolla entirely glabrous within; corona lobes basally connate and forming a prominent disk; inflorescence bracts more than 1.5 mm wide, elliptic in general shape .... 3. *M. hamata*
  5b. Corolla with dense short trichomes within, at least on limb; corona lobes basally connate or not, but not forming a disk; inflorescence bracts less than 1.5 mm wide, linear or ovate in general shape.
    6a. Corona lobes spathulate, with prominent, purple-black, deeply rugose tips; long trichomes of internodes uncinate.
      7a. Peduncle less than 1 mm long; calyx lobes less than 5 mm long; corolla sharply reflexed from tip of corona lobe to sinus; plants of the Isthmus of Tehuantepec .... 11. *M. suffruticosa*
      7b. Peduncle more than 1 mm long; calyx lobes more than 5 mm long; corolla not reflexed beyond corona lobe tip; plants of the Yucatan Peninsula.
        8a. Corolla lobes 7–12 mm long, length to width (sinus–sinus) ratio greater than 0.80, margins revolute, limb and lobes patent or slightly reflexed; corolla densely gray-purple-reticulate .... 13. *M. yucatanensis*
        8b. Corolla lobes 5–9 mm long, length to width (sinus–sinus) ratio less than 0.80, margins not revolute, limb and lobes ascending; corolla yellow-green when fresh, sometimes drying darker and somewhat reticulate .... 12. *M. aenea*
    6b. Corona lobes of various shapes but never modified as above; long trichomes of internodes rarely uncinate.
      9a. Corolla deeply campanulate, base–sinus length 7 mm or more, margins strongly revolute; corona lobes more than 4.5 mm long, linear or linear-spathulate.
        10a. Corolla tube with circular lines .... 7. *M. standleyana*
        10b. Corolla tube with a reticulate pattern or without a distinct pattern.
          11a. Gynostegium apex apiculate; twining vines without thickened caudices; plants from southeast of the Isthmus of Tehuantepec.
            12a. Corolla limb with irregular roundish reticulations, indumentum within restricted to the reticulations; septa connecting corona lobes to gynostegium each with a prominent tooth; calyx lobes 6 mm or less wide .... 8. *M. ceratopetala*
            12b. Corolla limb with circular lines only occasionally merging, the veins themselves forming a regular angular reticulum, indumentum within uniformly distributed, not restricted to veins; septa of corona entire; calyx lobes 6 mm or more wide .... 9. *M. eximia*
          11b. Gynostegium apex shallowly concave; erect or weakly twining vines, mostly from thickened caudices; plants from northwest of the Isthmus of Tehuantepec .... 10. *M. dictyantha*
      9b. Corolla shallowly campanulate to nearly rotate, base–sinus length 11 mm or less, margins slightly or not at all revolute; corona lobes less than 4.5 mm long, short-spathulate with acute apices .... 1. *M. hemsleyana*

1. **Matelea hemsleyana** Woodson, Ann. Missouri Bot. Gard. 28: 237. 1941, based on *Dictyanthus parviflorus* Hemsley. *Dictyanthus parviflorus* Hemsley, Biol. Cent. Amer., Bot. 2: 329. 1882, not *Matelea parviflora* (Torrey) Woodson. TYPE: México. Chiapas: "les montagnes pres in village indien de Cancunc" [?Cancuc, Mpio. Chilón, Chiapas], June, year not given (fl), *Ghiesbreght 663* (holotype, K, not seen; isotypes, GH, MO, NY). Figure 1.

Dictyanthus prostratus Brandegee, Univ. Calif. Publ. Bot. 7: 329. 1920, not *Matelea prostrata* (Willdenow) Woodson. *Matelea diffusa* Woodson, Ann. Missouri Bot. Gard. 28: 236. 1941, based on *Dictyanthus prostratus* Brandegee. TYPE: México. Veracruz: "Acanoxica" or "Acasonica" [Acaxónica], Aug. 1919 (fl), *Purpus 8411* pro parte (holotype, UC; isotypes, GH, MO, NY, US(2), VT).

Plants erect to trailing or rarely weakly twining. Stems 20–60(–90) cm long, with a woody caudex to 4 cm long and 2 cm wide, this with thin to thick corky bark, also often with short woody stems above caudex, these with or without corky bark, the herbaceous stems with dense short and glandular trichomes and sparse to dense, mostly straight long trichomes to 3 mm long. Leaf blade ovate to very wide-ovate, 13–34 mm long, 13–36 mm wide, with mostly uncinate long trichomes and often with scattered glandular trichomes below, surface smooth, smaller veins sharply raised below, apex acuminate to attenuate or rarely obtuse, base lobate, lobes overlapping to divergent, with 2–6(–8) acropetiolar colleters, margin often somewhat thickened and revolute; petiole 7–18(–26) mm long, with dense short and glandular trichomes and sparse to dense, mostly uncinate long trichomes. Peduncle 1–4 mm long, with dense short and gladular trichomes and sparse to dense, straight or uncinate long trichomes; bracts linear or lorate to lanceolate, 2–4 mm long, with indumentum of leaf or nearly glabrous; pedicel 3–5 mm long, with indumentum of peduncle. Calyx lobes narrow-ovate or occasionally lanceolate, 4–6 mm long, 1.5–2.5 mm wide, apex acute to attenuate, with one colleter below each sinus, abaxial surface with scattered glandular trichomes and scattered to dense, straight or uncinate long trichomes, adaxial surface glabrous. Corolla shallowly campanulate, base to sinus length 3–6 mm, limb not distinct, margin slightly revolute; lobes (3–)4–6(–7) mm long, apex acute or occasionally rounded, patent or slightly reflexed at tip, margin slightly revolute; glabrous within except with dense short trichomes on limb and lobes and these sometimes extending down raised ridges within tube, indumentum on outside of straight long trichomes or sometimes the limb and lobes nearly glabrous; tube convoluted, with the raised parts opposite the corona lobes, forming shallow pockets between them, with corona lobes in distinct pockets in bases of raised parts; moderately to densely brown-purple-reticulate, becoming clear pale purple on and around corona lobes. Corona lobes 1–1.5 mm long, basically short-spathulate with an acute apex, the upper surface with a narrow ridge extending as a short spur to edge of gynostegium. Gynostegium 1–1.5 mm high and 1.5–2 mm wide at apex, short-stipitate, apex convex and slightly bilobed. Corpusculum 0.18–0.22 mm long, 0.08–0.10 mm wide, pollinia 0.58–0.91 mm long, 0.26–0.34 mm wide. Follicles 48–70 mm long, 10–18 mm wide, green with white markings, glabrous or with sparse short and glandular trichomes, with 28–54 projections to 2 mm long, arcuate and somewhat reflexed proximally, straight and leaning forward distally. Seeds ca. 4 mm long, ca. 3 mm wide, with a raised margin, this irregularly toothed distally, inside this margin slightly convex on one side and slightly concave on the opposite side, both sides verrucate, concave side with a narrow ridge from apex to near center, apparently pale brown; coma ca. 25 mm long.

Found in Mexico (Michoacán, Estado de México, Morelos, Veracruz, Chiapas), Guatemala, and El Salvador (Fig. 2). Collected at elevations of somewhat below 800 m to nearly 2,600 m, but mostly 1,000–1,500 m, on slopes and hills, mostly in grasslands, but sometimes in open pine–oak forests, on volcanic cinder and rocky clay soils. Flowering mostly from June through September, but flowering specimens also collected once each in April and November; specimens with mature-sized fruits collected August–December.

Only those specimens of *Purpus 8411* with the locality given as "Acanoxica" or "Acasonica" [Acaxónica] and a date of August 1919 are to be considered types of *Dictyanthus prostratus*.

Collections from the part of the range centered around the state of Morelos differ somewhat from plants in the rest of the range. Woodson, according to his annotations, considered the Morelos plants to be *Matelea hemsleyana* and the others *M. diffusa*. Standley & Williams (1969) also considered the plants from southern Mexico to El Salvador to be *M. diffusa*, but perhaps without seriously considering the plants from Morelos. Standley (1924) considered the two species to be synonymous. Plants from around Morelos tend to be shorter and more erect and to have thicker caudices, larger, more distinctly veined leaves, larger flowers (to nearly

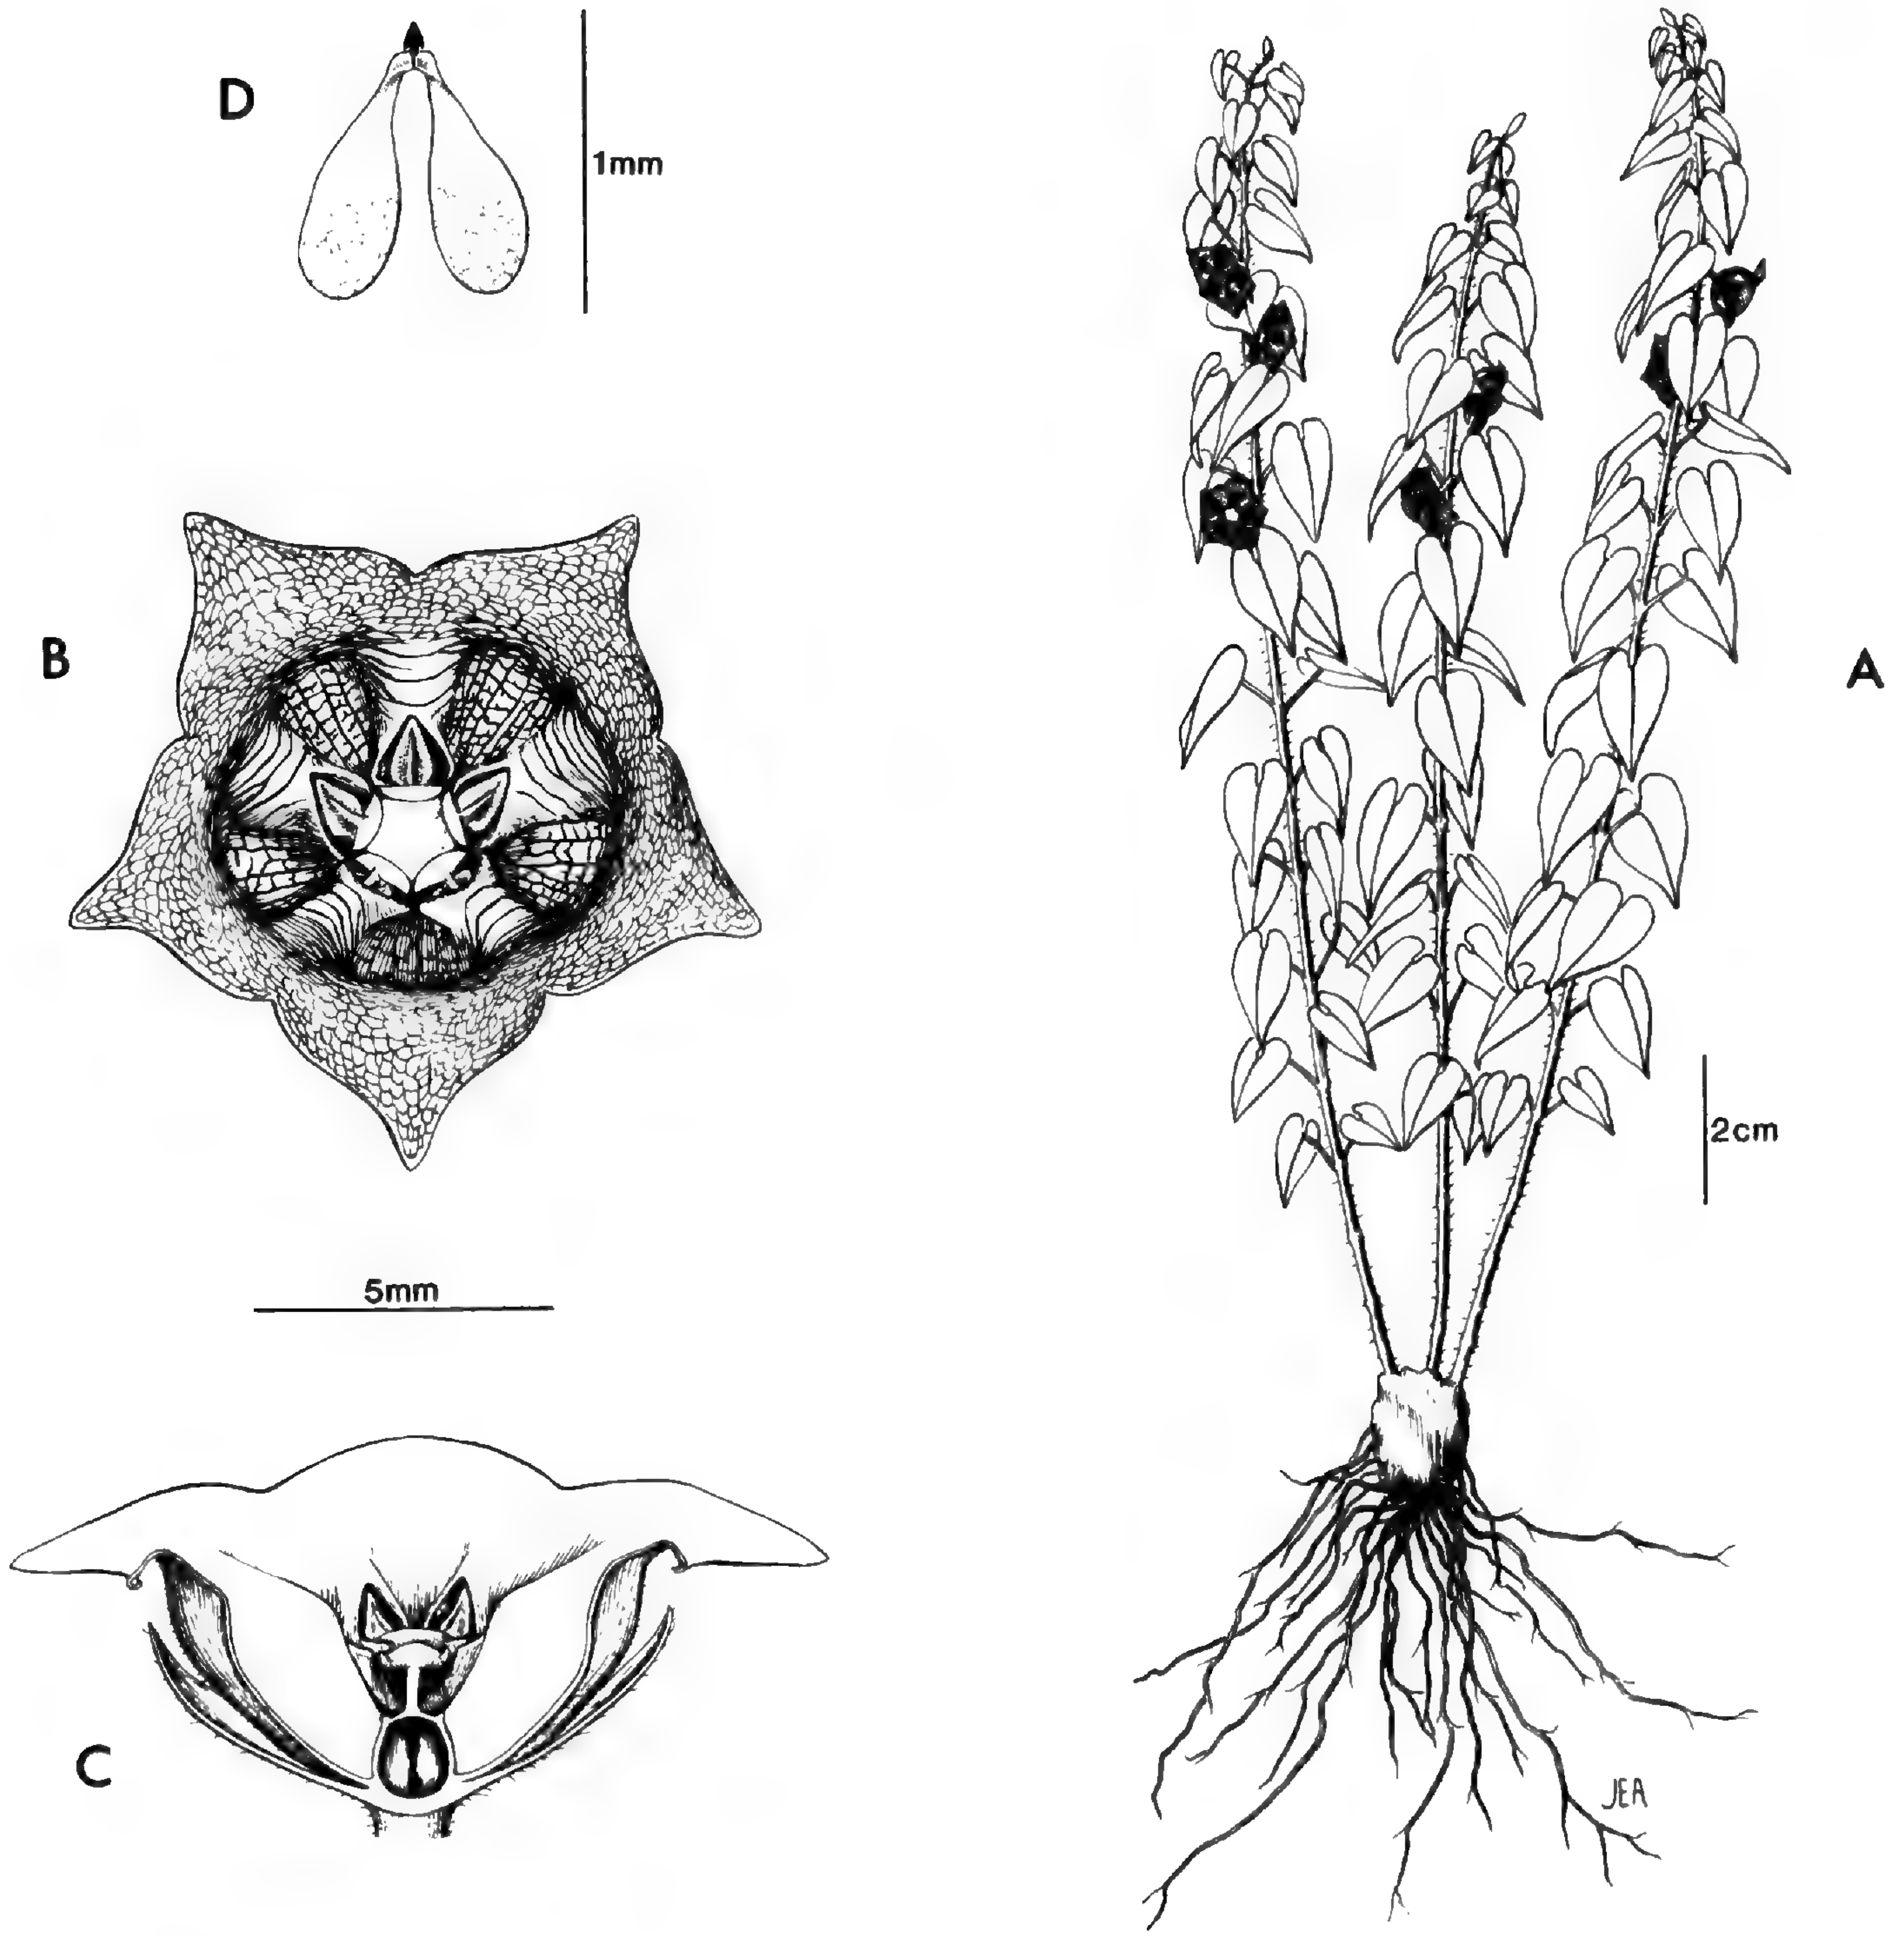

FIGURE 1. Matelea hemsleyana (Stevens C-162, *a cultivated specimen of* Stevens 1399).—*A. Habit.—B, C. Flowers.—D. Bipollinium.*

twice as large), and proportionately longer corona lobes. In describing *Dictyanthus prostratus* (= *Matelea diffusa*), Brandegee considered it to be different from *D. parviflorus* (= *M. hemsleyana*) in having "five minute scales attached to the middle of the gynostegium representing an inner corona." There seems to be no such character, and the "scales" were most likely the remains of the attachments of the corona lobes to the gynostegium, which are typically torn free when the flower is pressed. Despite the differences described above, no known characters faithfully differentiate the two elements. It may well be that further collection will demonstrate that some level of taxonomic recognition is preferable. In this regard, it is curious that this is the only species in the subgenus inhabiting both sides of the continent, a distinctly uncommon phenomenon among the viney milkweeds.

2. **Matelea tuberosa** (Robinson) Woodson, Ann. Missouri Bot. Gard. 28: 237. 1941. *Dictyanthus tuberosus* Robinson, Daedalus 27: 180–181. 1891/1892 [1893]. LECTOTYPE (here chosen): México. Jalisco: slopes of barranca near Guadalajara, 10 Sep. 1891 (fl), *Pringle 3568* (lectotype, GH; isolectotypes, F, VT). Lectoparatype: México. Jalisco: Guadalajara, in ravines, (15 July–3 Aug. fide McVaugh, 1956, p. 215) 1886 (fl), *Palmer*

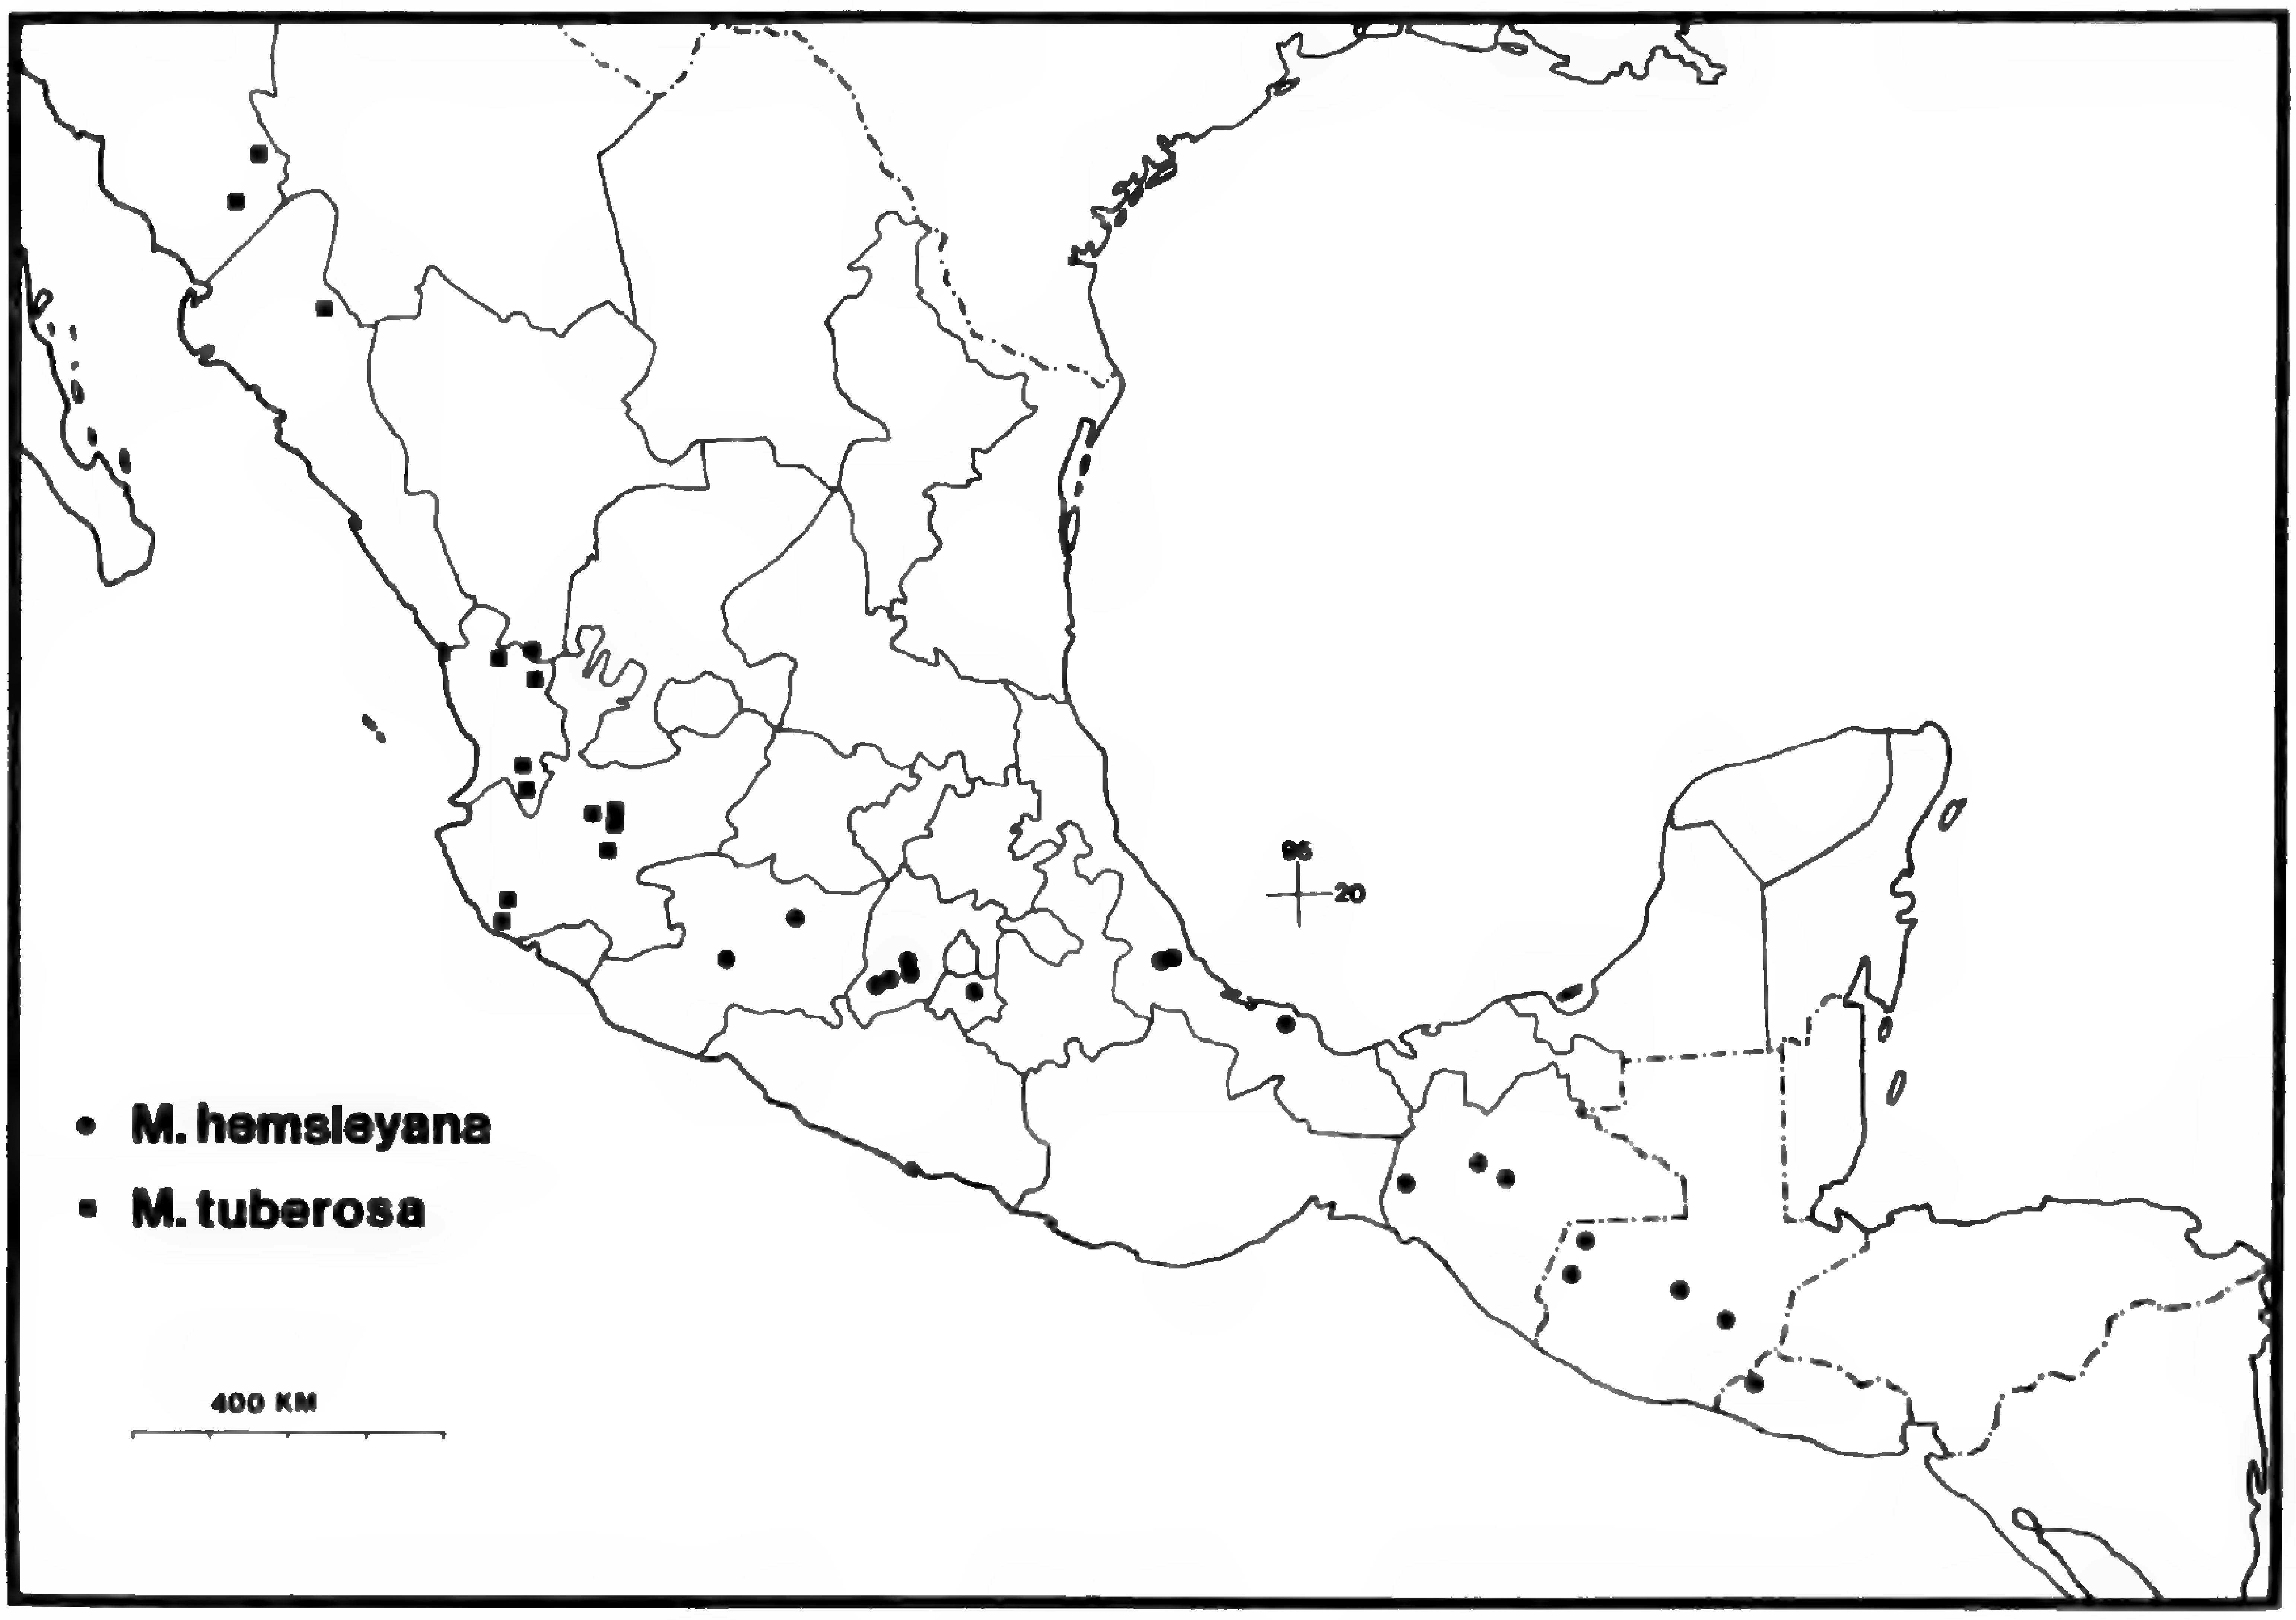

FIGURE 2. *Distributions of* Matelea hemsleyana *and* M. tuberosa.

251 (lectoparatype, GH; isolectoparatypes, ENCB, G, K, MO, ND, NY(2), P, PH, US, WU). Figure 3.

Plants erect to trailing or sometimes weakly twining. Stems 10–70(–100) cm long, with a woody caudex to 5 cm long and 3 cm wide, this with thick corky bark, otherwise typically herbaceous and lacking bark (rarely subshrubs with erect, branched woody stems), with dense short trichomes, very sparse glandular trichomes, and sparse to dense, mostly straight long trichomes to 2 mm long. Leaf blade ovate to very wide-ovate, 17–45 mm long, 17–40 mm wide, with mostly uncinate long trichomes, surface smooth, smaller veins sharply raised below, apex acuminate to attenuate, base lobate, lobes mostly convergent to descending, with 3–6 (–9) acropetiolar colleters, margin often somewhat thickened and revolute; petiole 7–31 mm long, with dense short trichomes, very sparse glandular trichomes, and sparse to dense, mostly uncinate long trichomes. Peduncle 0.5–9 mm long, with dense short trichomes, very sparse glandular trichomes, and sparse to dense, straight or uncinate long trichomes; bracts linear or lorate to lanceolate, 2–8 mm long, with mostly uncinate long trichomes; pedicel 4–5 mm long, with indumentum of peduncle. Calyx lobes lanceolate to narrow-ovate or elliptic, 5–9 mm long, 1.5–3.5 mm wide, apex acute to attenuate, with one colleter below each sinus, abaxial surface with sparse to dense, straight or uncinate long trichomes, adaxial surface glabrous. Corolla deeply campanulate, base to sinus length 6–10 mm, limb revolute; lobes 2.5–6 mm long, apex acute, slightly to strongly reflexed, margins strongly revolute; glabrous within except with dense short trichomes on limb and lobes, indumentum outside of short trichomes on tube and of straight or uncinate long trichomes on limb and lobes, occasionally with a few long trichomes scattered along tube and occasionally distal third of lobes glabrous; with a pair of ridges within tube opposite each corona lobe, ridges of adjacent pairs almost coming together at base and forming pockets at base of corolla, with the corona lobes in distinct pockets in the bases of the furrows between the paired ridges; within the tube with fine gray-brown vertical lines, limb densely gray-brown-reticulate. Corona lobes ca. 2 mm long (but borne distinctly above base of corolla), shape elaborate but basically sagittate in outline, adnate to gynostegium by a thin septum. Gynostegium ca. 2 mm high and ca. 2 mm wide at apex, stipitate, apex broadly and shal-

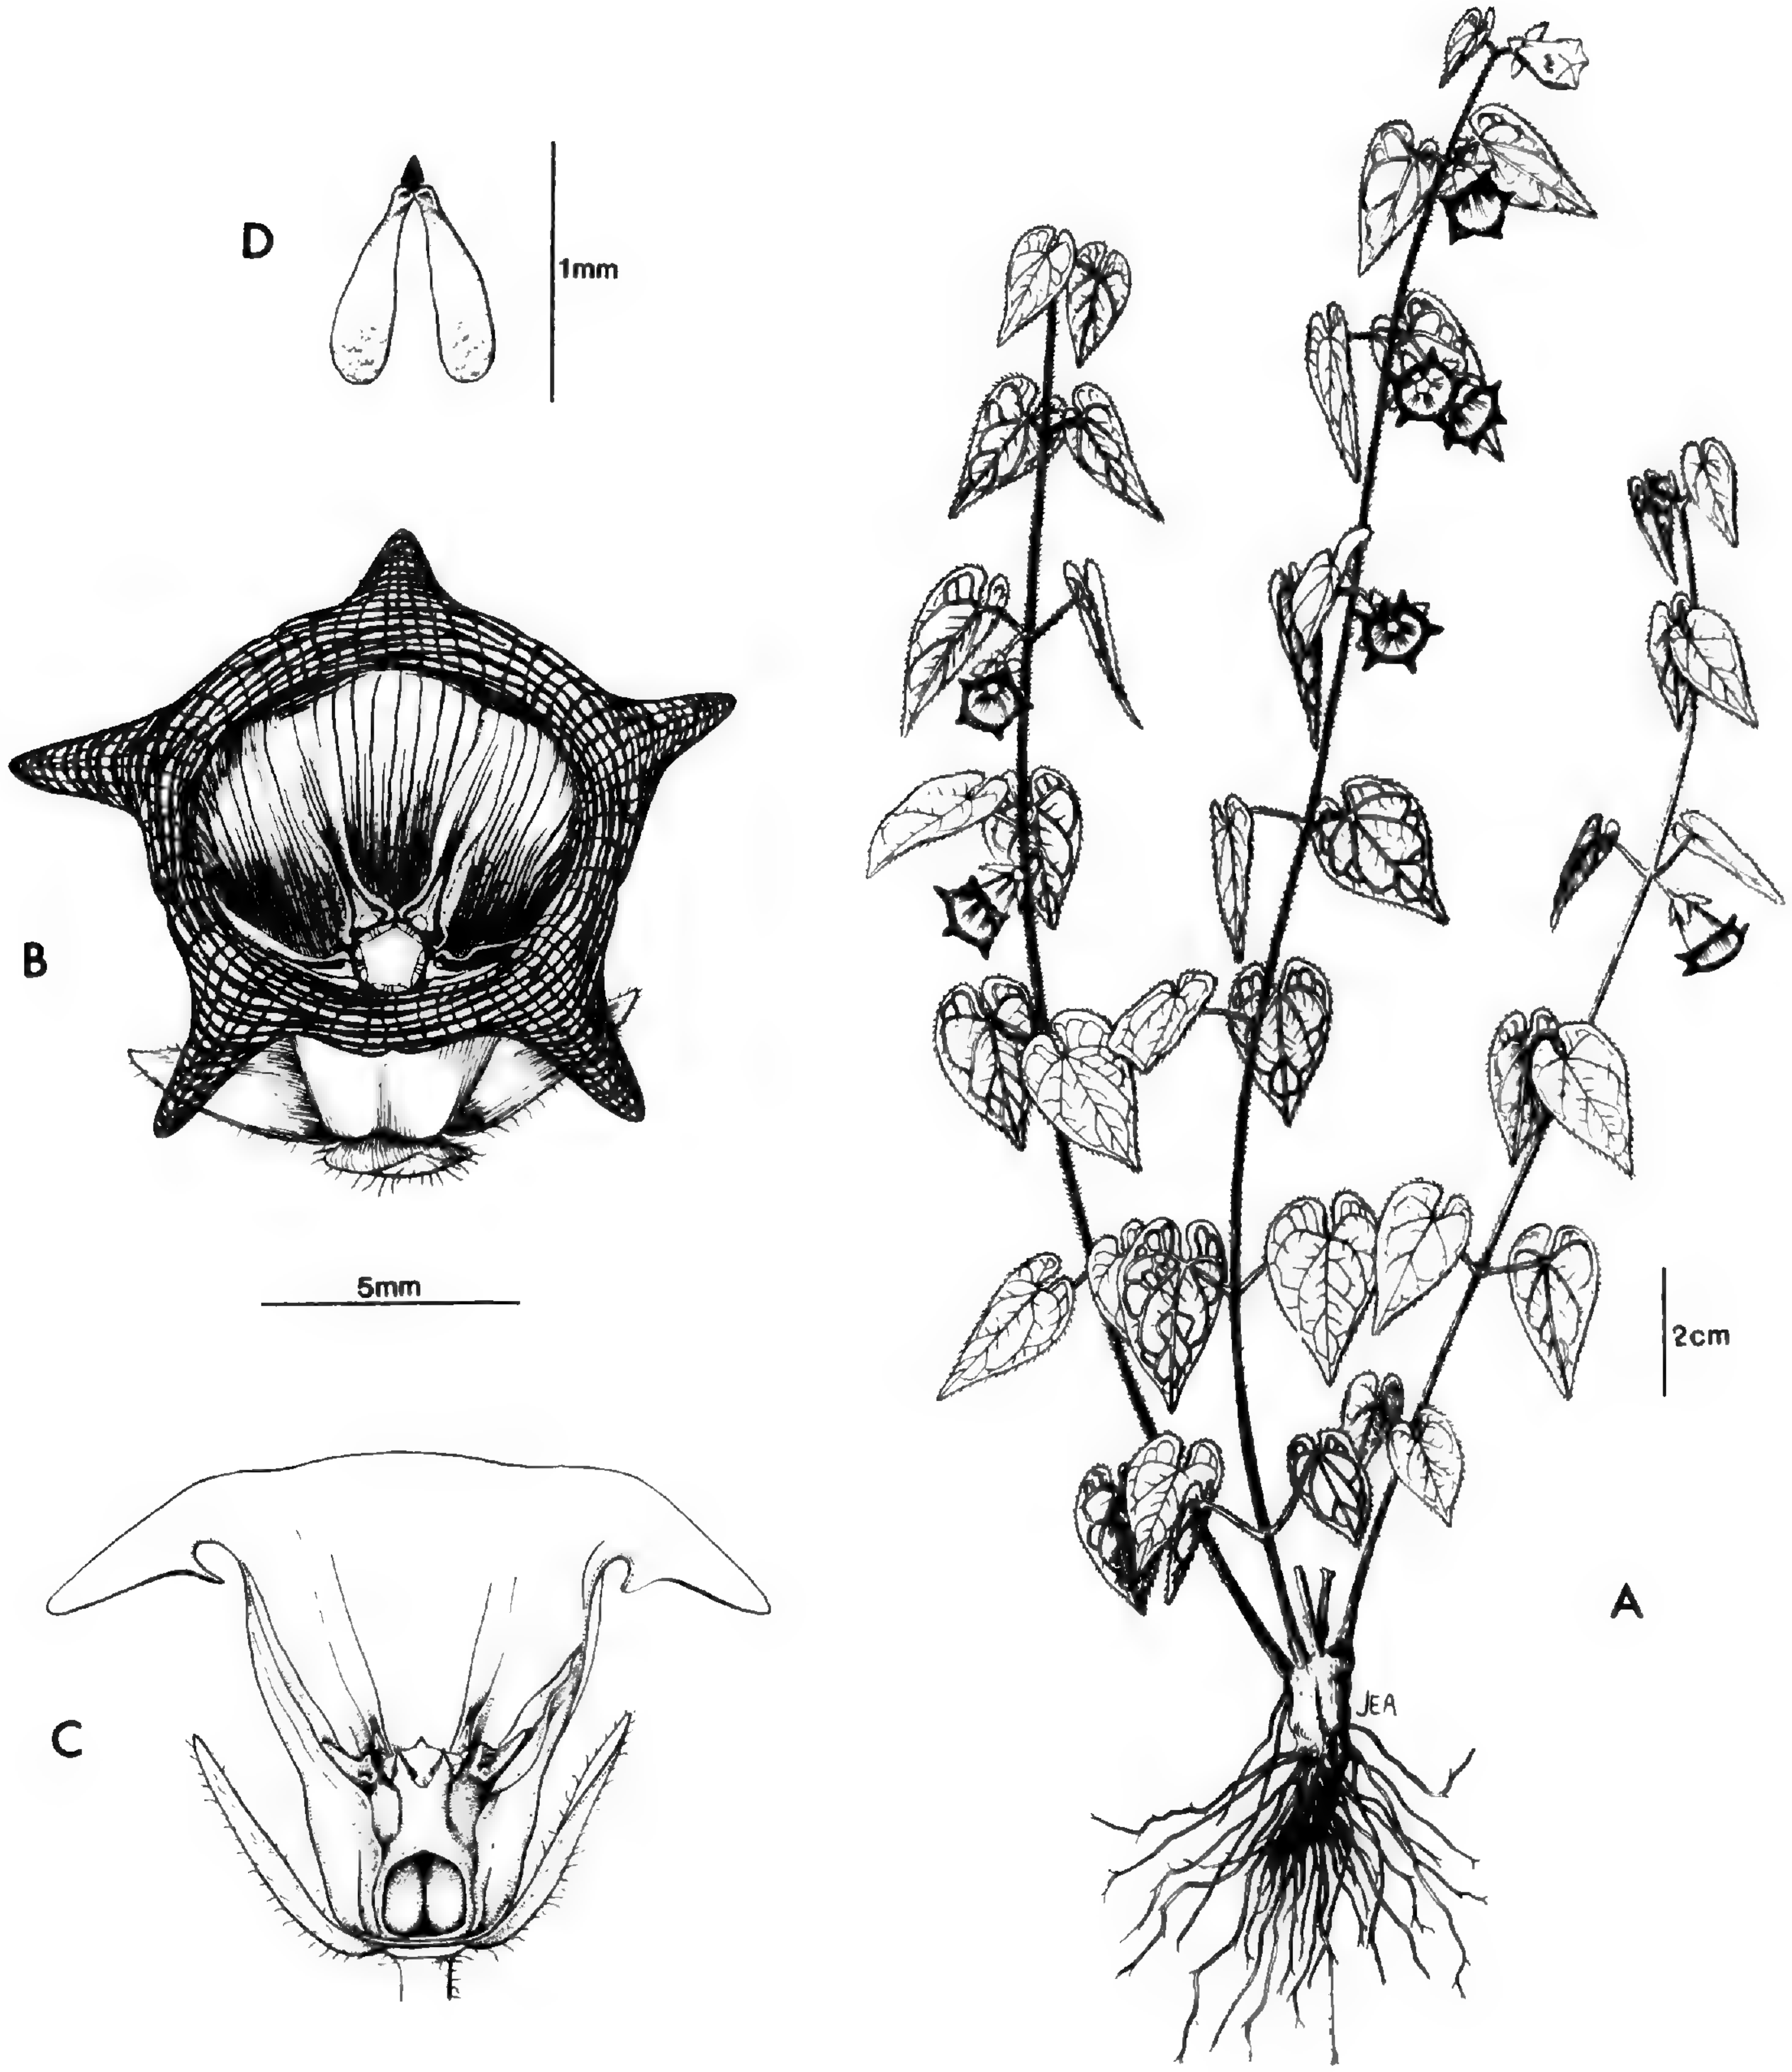

FIGURE 3. Matelea tuberosa (Stevens C-163 *and* C-164, *cultivated specimens of* Stevens 1458 *and* 1473, *respectively, and* Stevens 1473). *—A. Habit.—B, C. Flowers.—D. Bipollinium.*

lowly concave with the corpuscula as high points and slightly convex and bilobed in center. Corpusculum 0.14–0.22 mm long, 0.08–0.13 mm wide, pollinia 0.63–0.86 mm long, 0.29–0.37 mm wide. Follicles 55–65 mm long, 11–19 mm wide, mottled pale and dark green, with scattered short and long trichomes, with 50–110 arcuate projections to 2 mm long. Seeds nearly circular, 5.5–6 mm long, 4.5–5 mm wide, with a raised, radially grooved margin, this entire to shallowly toothed distally, inside this margin slightly convex and verrucate on both sides, one side with a narrow ridge from apex to near center, pale brown; coma ca. 25 mm long.

Collected from southern Sonora to southern Jalisco (Fig. 2) at elevations of 500–1,600 m, in open oak and pine–oak forests and adjacent grasslands, usually in shallow, red, clay soil. Flowering specimens have been collected from late July to early October, and the one specimen with mature seeds was collected in March.

The nearly tubular corolla of this species readily distinguishes it from the other species of this subgenus and is probably unique in the genus *Matelea*.

3. **Matelea hamata** W. D. Stevens, sp. nov. TYPE: México. Guerrero: La Unión, 50 m, 29 July 1898 (fl), *Langlassé 257* (holotype, US; isotypes, GH, P). Figure 4.

Matelea hamata W. D. Stevens; a speciebus ceteris subgeneris *Dictyanthi* pagina interiore corollae glabra et corona disciformi carnosa lutea lobis brevibus (circa 1 mm) corollae adnatis clare distinguenda.

Plants twining vines. Stems woody below, with corky bark, herbaceous stems with moderately dense short and glandular trichomes and sparse to very sparse straight or uncinate long trichomes to 1.5 mm long. Leaf blade narrow-ovate to wide-ovate, 52–113 mm long, 26–52 mm wide, with sparse to dense uncinate long trichomes, surface smooth to minutely pusticulate, apex acute to attenuate, base lobate, lobes slightly convergent to divergent, with 4–9 acropetiolar colleters, margin somewhat thickened and revolute; petiole 23–61 mm long, with moderately dense short and glandular trichomes and sparse, mostly uncinate long trichomes. Inflorescence relatively elongate; peduncle 14–40(–53) mm long, with indumentum of stem; bracts narrow-elliptic to elliptic or lanceolate to narrow-ovate, 4–10 mm long, with indumentum of leaf; pedicel 7–19 mm long, with indumentum of stem. Calyx lobes lanceolate to narrow-ovate or elliptic, 10–17 mm long, 4–6.5 mm wide, apex acute or acuminate, with one colleter below each sinus, abaxial surface with moderately dense, straight or uncinate long trichomes, adaxial surface glabrous. Corolla urceolate-campanulate, base to sinus length 11–16 mm, limb broad, patent; lobes 8–13 mm long, apex obtuse or rounded, slightly recurved, margin patent; glabrous within, indumentum on outside of dense short trichomes and of moderately dense long trichomes on limb and lobes; tube shallowly convoluted, with a pair of ridges opposite and a shallow pit alternate with each corona lobe; with fine, faint, reticulate lines within the tube, limb with fine, distinct circular lines, these becoming reticulate on lobes, these lines gray-brown on a pale yellow-green background. Corona lobes connate and forming a fleshy yellow disk ca. 6.5 mm wide, lobe tips subulate and extending ca. 1 mm above rim of disk, disk adnate to corolla base and lobe tips adnate to corolla between paired ridges, with a fleshy septum from each lobe to the gynostegium, each septum with a fleshy ornate hump. Gynostegium ca. 3 mm high and ca. 3 mm wide at apex, stipitate, apex broadly and shallowly concave with the corpuscula as high points and a slight hump in center. Corpusculum 0.22–0.24 mm long, 0.18–0.19 mm wide, pollinia 1.24–1.49 mm long, 0.41–0.48 mm wide. Fruit and seeds unknown.

Paratypes. MÉXICO. GUERRERO: near el Tuzal, ca. 3.9 mi. SE of Petatlán, ca. 80 m, 25 July 1976 (fl), *Stevens et al. 2538* (ARIZ, DS, DUKE, ENCB, F, G, GH, L, MICH, MO, MSC, NY, P, SD, SMU, TEX, UMO, US, WIS). OAXACA: Distrito de Pochutla, camino a la Bahía de Santa Cruz, 2 km al S de la desviación, 50 m, 25 July 1982 (fl), *Cedillo et al. 1697* (MEXU, MO).

Known only from near the coast (less than 100 m elevation) in Oaxaca and Guerrero (Figure 6), growing in clayey soil. Known flowering in July.

In many ways this is intermediate between *Matelea hemsleyana* and *M. tuberosa* on one hand and the other species of the subgenus on the other. The overall aspect of the plant, the general size and shape of the corolla, the connate corona lobes, and the size and shape of the bipollinia are essentially comparable to the larger group of species. The corona lobes, in this case the tips of the lobes, are more comparable in size, shape, and method of adnation to the corolla of *M. hemsleyana* and *M. tuberosa*. The fleshy corona disk is, however, unique. Also unique are the large, nearly foliaceous bracts, the large elliptic calyx lobes, the broad patent corolla limb, and the relatively short and blunt corolla lobes.

The holotype of this species previously had been tentatively determined as *Dictyanthus stapeliiflorus*; see the discussion of this name under *Matelea pavonii*.

4. **Matelea pavonii** (Decaisne) Woodson, Ann. Missouri Bot. Gard. 28: 237. 1941. *Dictyanthus pavonii* Decaisne in de Candolle, Prodr. 8: 605. 1844. TYPE: "Pavón" (Sessé, Mociño et al. *s.n.*) (holotype, FI, not seen; fragment of holotype, P). Figure 5.

Dictyanthus stapeliiflorus Reichenbach, ll.cc. *Matelea stapeliiflora* (Reichenbach) Woodson, Ann. Missouri Bot. Gard. 28: 237. 1941. TYPE: unknown.

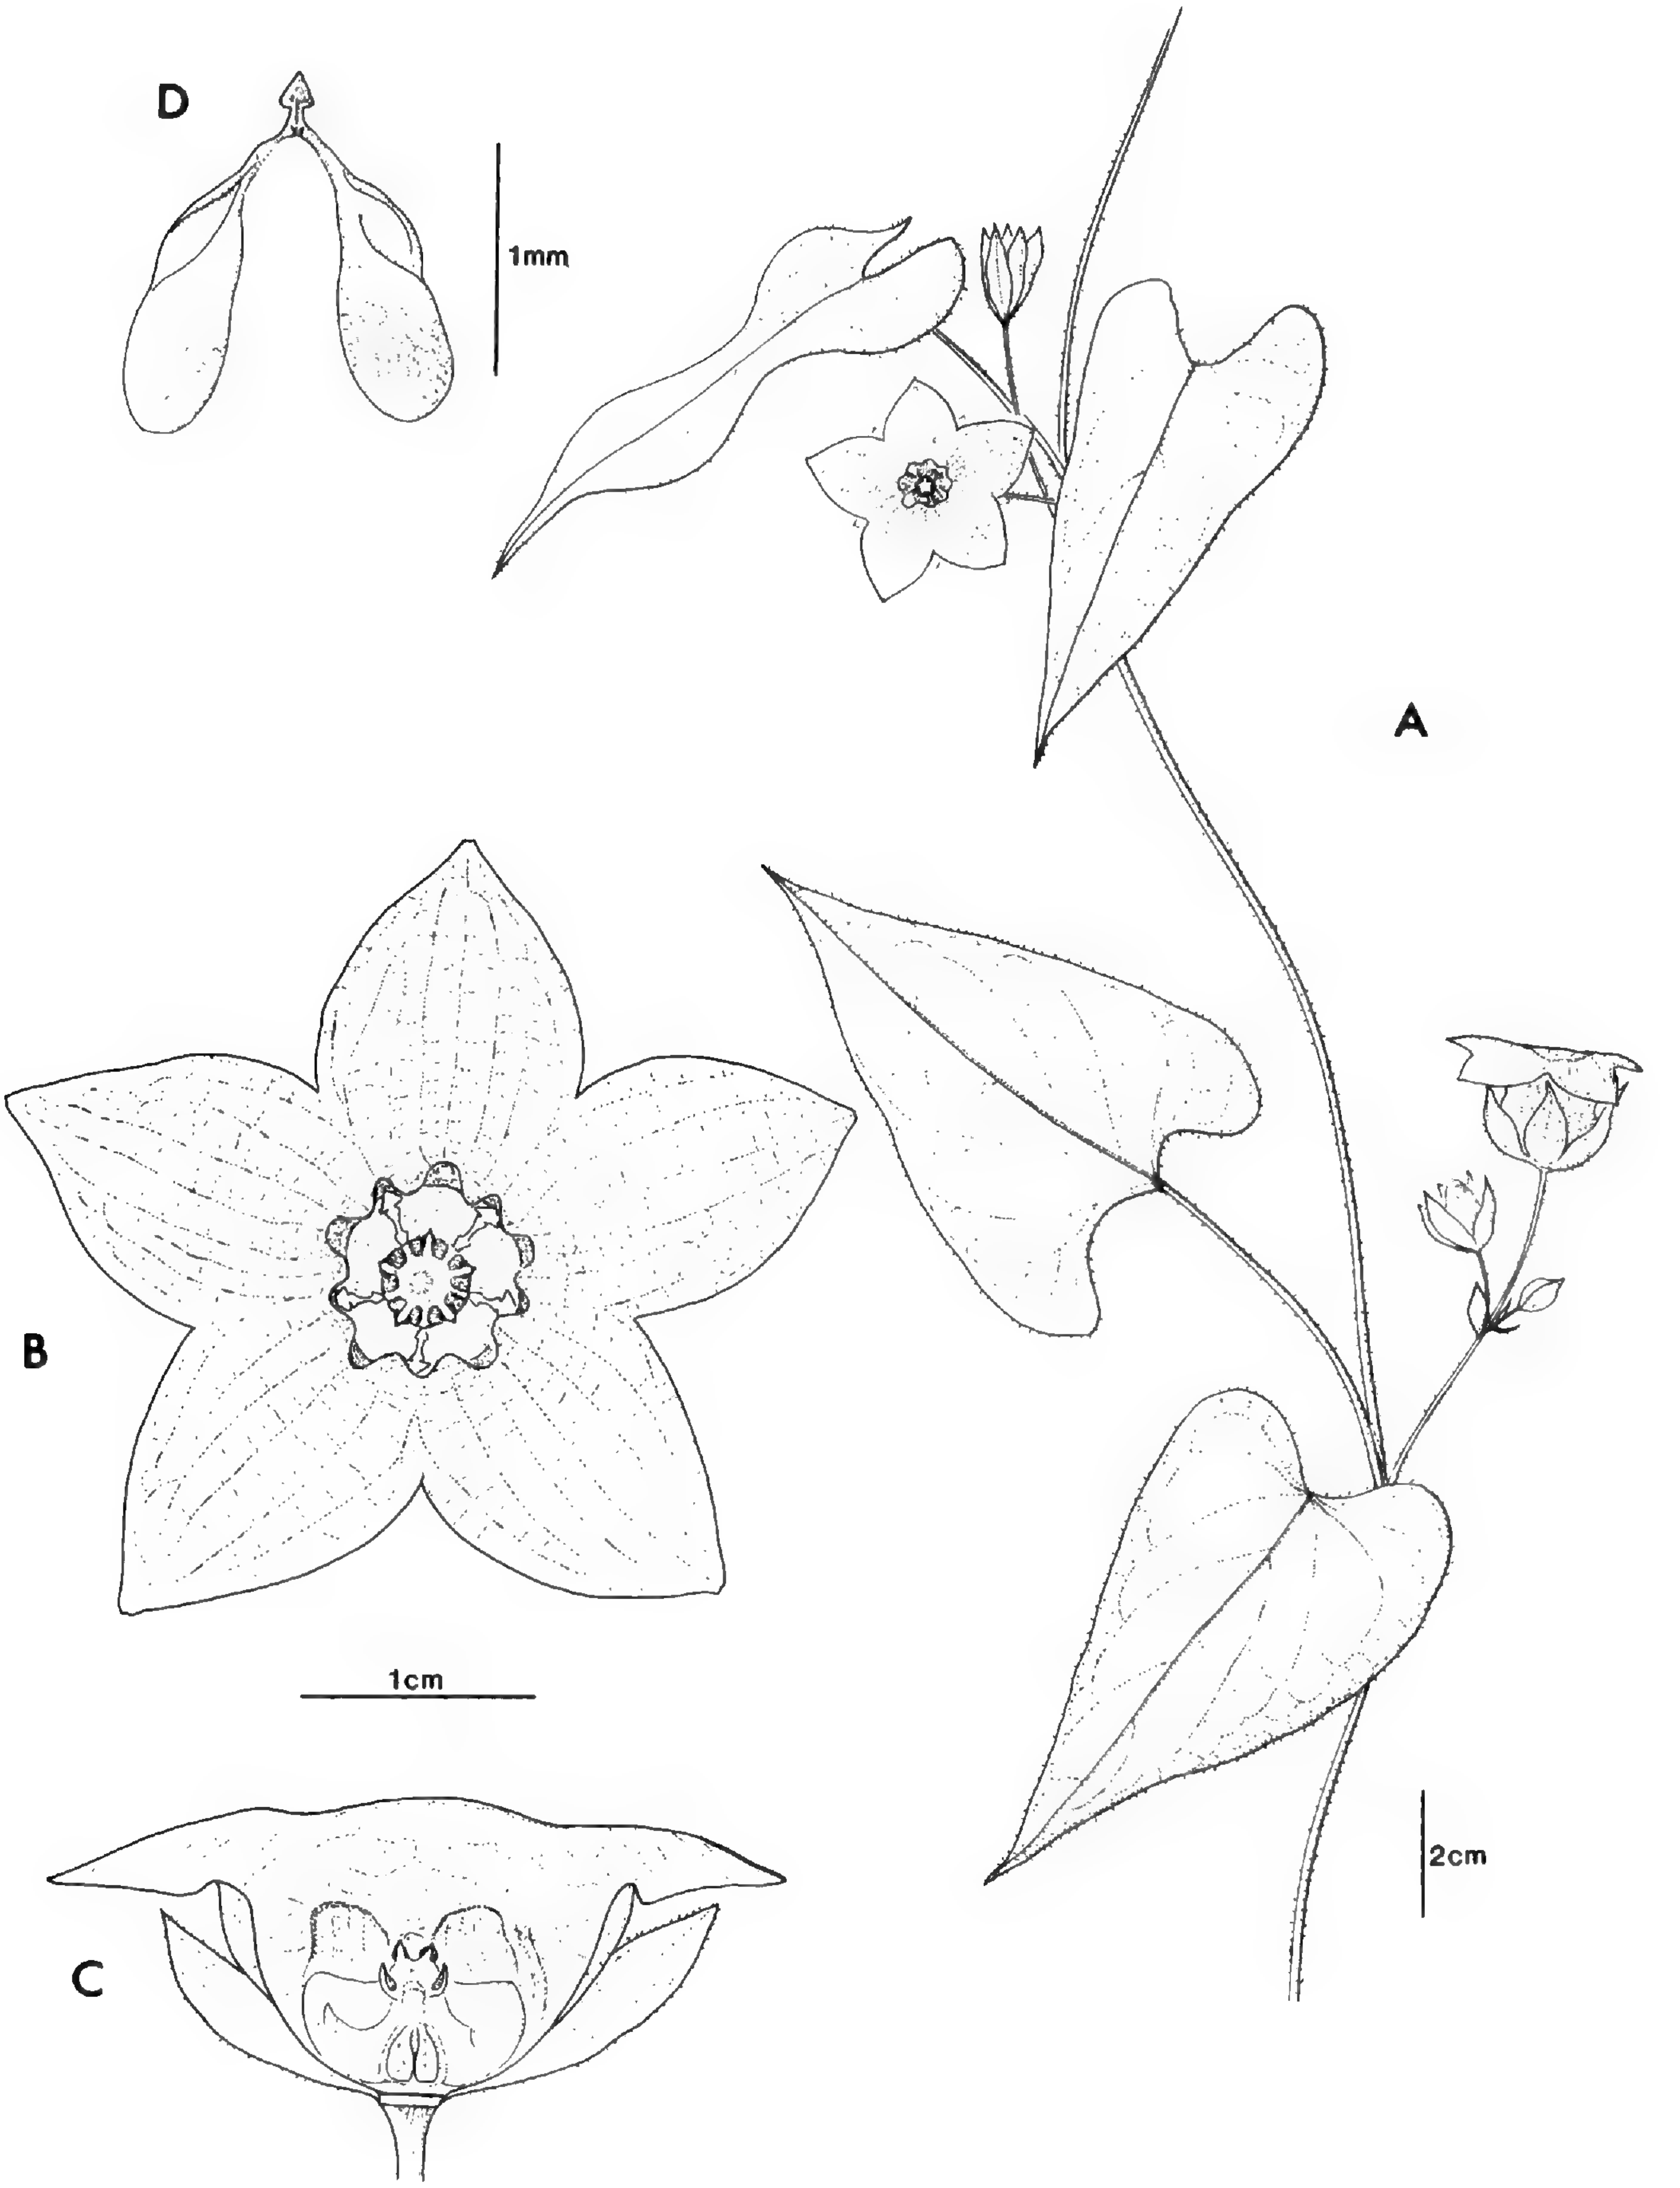

FIGURE 4. Matelea hamata (Stevens et al. 2538).—*A. Section of flowering stem.—B, C. Flowers.—D. Bipollinium.*

Stapelia campanulata Sessé & Mociño, Pl. Nov. Hisp. 41. 1888. TYPE: unknown (Sessé, Mociño et al. *s.n.*, from mountains of Mazatlán, Guerrero).

Plants twining vines. Stems woody below, with thick or occasionally thin corky bark; herbaceous stems with sparse to dense short and glandular trichomes and sparse to dense, straight or uncinate long trichomes to 1.5 mm long, these brittle and often missing from specimens. Leaf blade ovate to wide-ovate or rarely very wide-ovate, (49–)60–128 mm long, 29–100 mm wide, indumentum of sparse to dense uncinate long trichomes, surface pusticulate to minutely pusticulate or occasionally nearly smooth, smaller veins occasionally slightly raised below, apex acuminate to attenuate, base lobate or very rarely cordate, lobes mostly descending to widely divergent, with (0–)1–6(–11) acropetiolar colleters, margin often slightly thickened and revolute; petiole (16–)22–65(–81) mm long, with indumentum of stem. Peduncle 9–60 (–90) mm long, with indumentum of stem or occasionally long trichomes absent; bracts lanceolate or occasionally lorate, narrow-oblong, very narrow-elliptic, narrow-ovate, or ovate, 4–13 mm long, with sparse to dense short and uncinate long trichomes or sometimes nearly glabrous; pedicel (7–) 10–25(–32) mm long, with indumentum of stem or occasionally long trichomes absent. Calyx lobes lanceolate to narrow-ovate or rarely ovate, 9–18 mm long, 3–6(–9) mm wide, apex attenuate, with one colleter below each sinus, abaxial surface with sparse to moderately dense uncinate long trichomes, adaxial surface glabrous. Corolla campanulate, base to sinus length 13–25 mm, limb revolute; lobes 11–25 mm long, apex rounded or occasionally acute or obtuse, patent to slightly reflexed, margin revolute; glabrous within except with moderately dense short trichomes around corona lobes and on limb and lobes, indumentum on outside of very sparse to dense uncinate long trichomes except lobes distally to entirely glabrous; tube convoluted with the raised parts opposite the corona lobes and deep sacs formed between them; with brown, purple, or red vertical lines within tube, these lines becoming finer and circular on base of limb and finely to densely reticulate on distal part of limb and on lobes. Corona lobes 7–13 mm long, linear to linear-spathulate in outline, connate at base, adnate by a thin septum to gynostegium, this septum continuing as a narrow ridge nearly the length of the lobe and often with 1 or rarely 2 distinct teeth on upper margin. Gynostegium 3–6(–7) mm high and 3–4.5 mm wide at apex, stipitate, apex apiculate, the apiculum 0.5–1.5 mm long, slightly shorter than to slightly exceeding corpuscula, appearing to be papillate when dried. Corpusculum 0.31–0.38 mm long, 0.12–0.18 mm wide; pollinia 1.45–1.62 mm long, 0.42–0.48 mm wide. Follicles 70–106 mm long, 22–23 mm wide, green with pale green streaks, with dense short trichomes, bearing 18–54 projections, these thick, straight or slightly arcuate, to 4 mm long. Seeds ca. 6.5 mm long, ca. 3.5 mm wide, with a raised margin, this irregularly crenate distally, inside this margin slightly convex on one side and slightly concave on the opposite side, convex side tuberculate, concave side longitudinally verrucate, dark black-brown; coma ca. 25 mm long.

Collected from southernmost Sinaloa to Oaxaca (Fig. 6). Found mostly at elevations of 900–2,000 m, but also once at 2,500 m and three times at about 600–750 m. Mostly occurring in mountainous areas where pine–oak forests occupy the more exposed sites and tropical deciduous forests occupy the more protected slopes and barrancas. Found in either vegetation type but especially common in disturbed places. Apparently tolerant of a variety of substrates, including limestone, lava, weathered metamorphics, and alluvium. Flowering primarily July–September but also collected in June, October, and November. Mature fruits known only in cultivation (March).

Although there can be no question as to the proper name of this, the type species of *Dictyanthus*, the treatment of the Sessé & Mociño names and specimens has considerably complicated the synonymy. A summary of the Sessé & Mociño specimens relating to *Matelea pavonii* is provided in Table 1. A curious aspect of this summary is that two of the herbarium numbers, *3580* and *3581*, are mixtures of *Matelea pavonii* and *M. standleyana*. Since these species are not known to be sympatric, the mixing probably occurred at some stage of herbarium handling. After both Sessé and Mociño had died, Pavón apparently distributed specimens from their herbarium. It was upon one of these specimens that Decaisne based his genus *Dictyanthus*. The specimen was in the Webb herbarium, which at the time was in Paris (now at FI), but Decaisne kept a fragment which is now at P. I have not seen the specimen at FI, but Dr. Rogers McVaugh has examined it. Decaisne attributed the specimen and the label name, *Stapelia campanulata*, to Pavón. The name was probably actually the same Sessé & Mociño name that was published posthumously in their *Plantae Novae Hispaniae* (1888). In that publication a locality, mountains of Mazatlán, Guerrero, and a plate, "Fl. Mex. Ic. 255," are both cited, but these cannot be associated with any particular one of the Sessé & Mociño herbarium numbers nor with the specimen distributed by Pavón. The plate is apparently the same as the de Candolle plate 804, labeled "255," which is at G (F neg. 30763). A small line drawing taken from the flowers of the de Candolle plate 804 is also at G (F neg. 30406) and is labeled "*Eurybia stapeliaeflora*." This may or may not have been a Sessé & Mociño name, but was never published.

Reichenbach added to the proliferation of names

by describing *Dictyanthus campanulatus* and *D. stapeliiflorus.* The former, apparently as an early attempt to apply the idea of priority, is a superfluous name, since Reichenbach cited "*Stapelia campanulata* Pavón. *D. pavonii* DC. prodr. *Tympananthe suberosa* Haskarl." *Dictyanthus stapeliiflorus* is a most problematic name. Reichenbach described both of his species from plants growing at a botanical garden in Dresden from seeds collected in Mexico at the foot of the Sierra Madre, near Durango. Apparently no specimens were prepared and neither description is alone adequate for identifying the species, but both could apply to *Matelea pavonii* and the source area would be more appropriate for that species than for any of the other larger-flowered species of subgenus *Dictyanthus.* Partly on the basis of this weak evidence and partly because of a later reference (Anonymous, 1857), I have tentatively considered *D. stapeliiflorus* to be synonymous with *Matelea pavonii.* This Anonymous (1857) reference purports to provide the first illustration of *D. stapeliiflorus.* It is implied but not stated that the illustration, taken from a living plant, is from the original material. Considering that the plant was apparently also growing in a German botanical garden and that only seven years had passed since Reichenbach's description, it could well have been from original material. The illustration does not precisely fit any species of *Matelea,* but most resembles *M. pavonii.* It is conceivable that this represents a distinct species that has never been re-collected, but, in the absence of specimens, I consider it an atypical representative of the variable *M. pavonii.* Although Woodson (1941) made a new combination, *Matelea stapeliiflora,* one cannot be certain as to what he intended the name to apply. In some cases he annotated specimens of *M. tuberosa* with this name, probably following Gray's misapplication of the name (in Watson, 1887). In one other case, Woodson applied the name to a specimen of *M. yucatanensis,* a duplicate of which he properly determined. He also almost certainly had examined the specimen of *Langlassé 257* at US, which had been tentatively determined as *D. stapeliiflorus,* but which is here described as a new species, *Matelea hamata.* Standley (1924) apparently (but tentatively) described the equivalent of my *M. hamata* under *D. stapeliiflorus,* and this could also have accounted for Woodson's concept of the species.

In the late 1840s this species was introduced into European botanical gardens and was apparently a popular plant for about ten years. During this period, at least seven illustrations, mostly colored plates, were published in horticultural journals (Anonymous, 1852; Anonymous & Beaton, 1852; Morren, 1852; Planchon & Van Houtte, 1852–

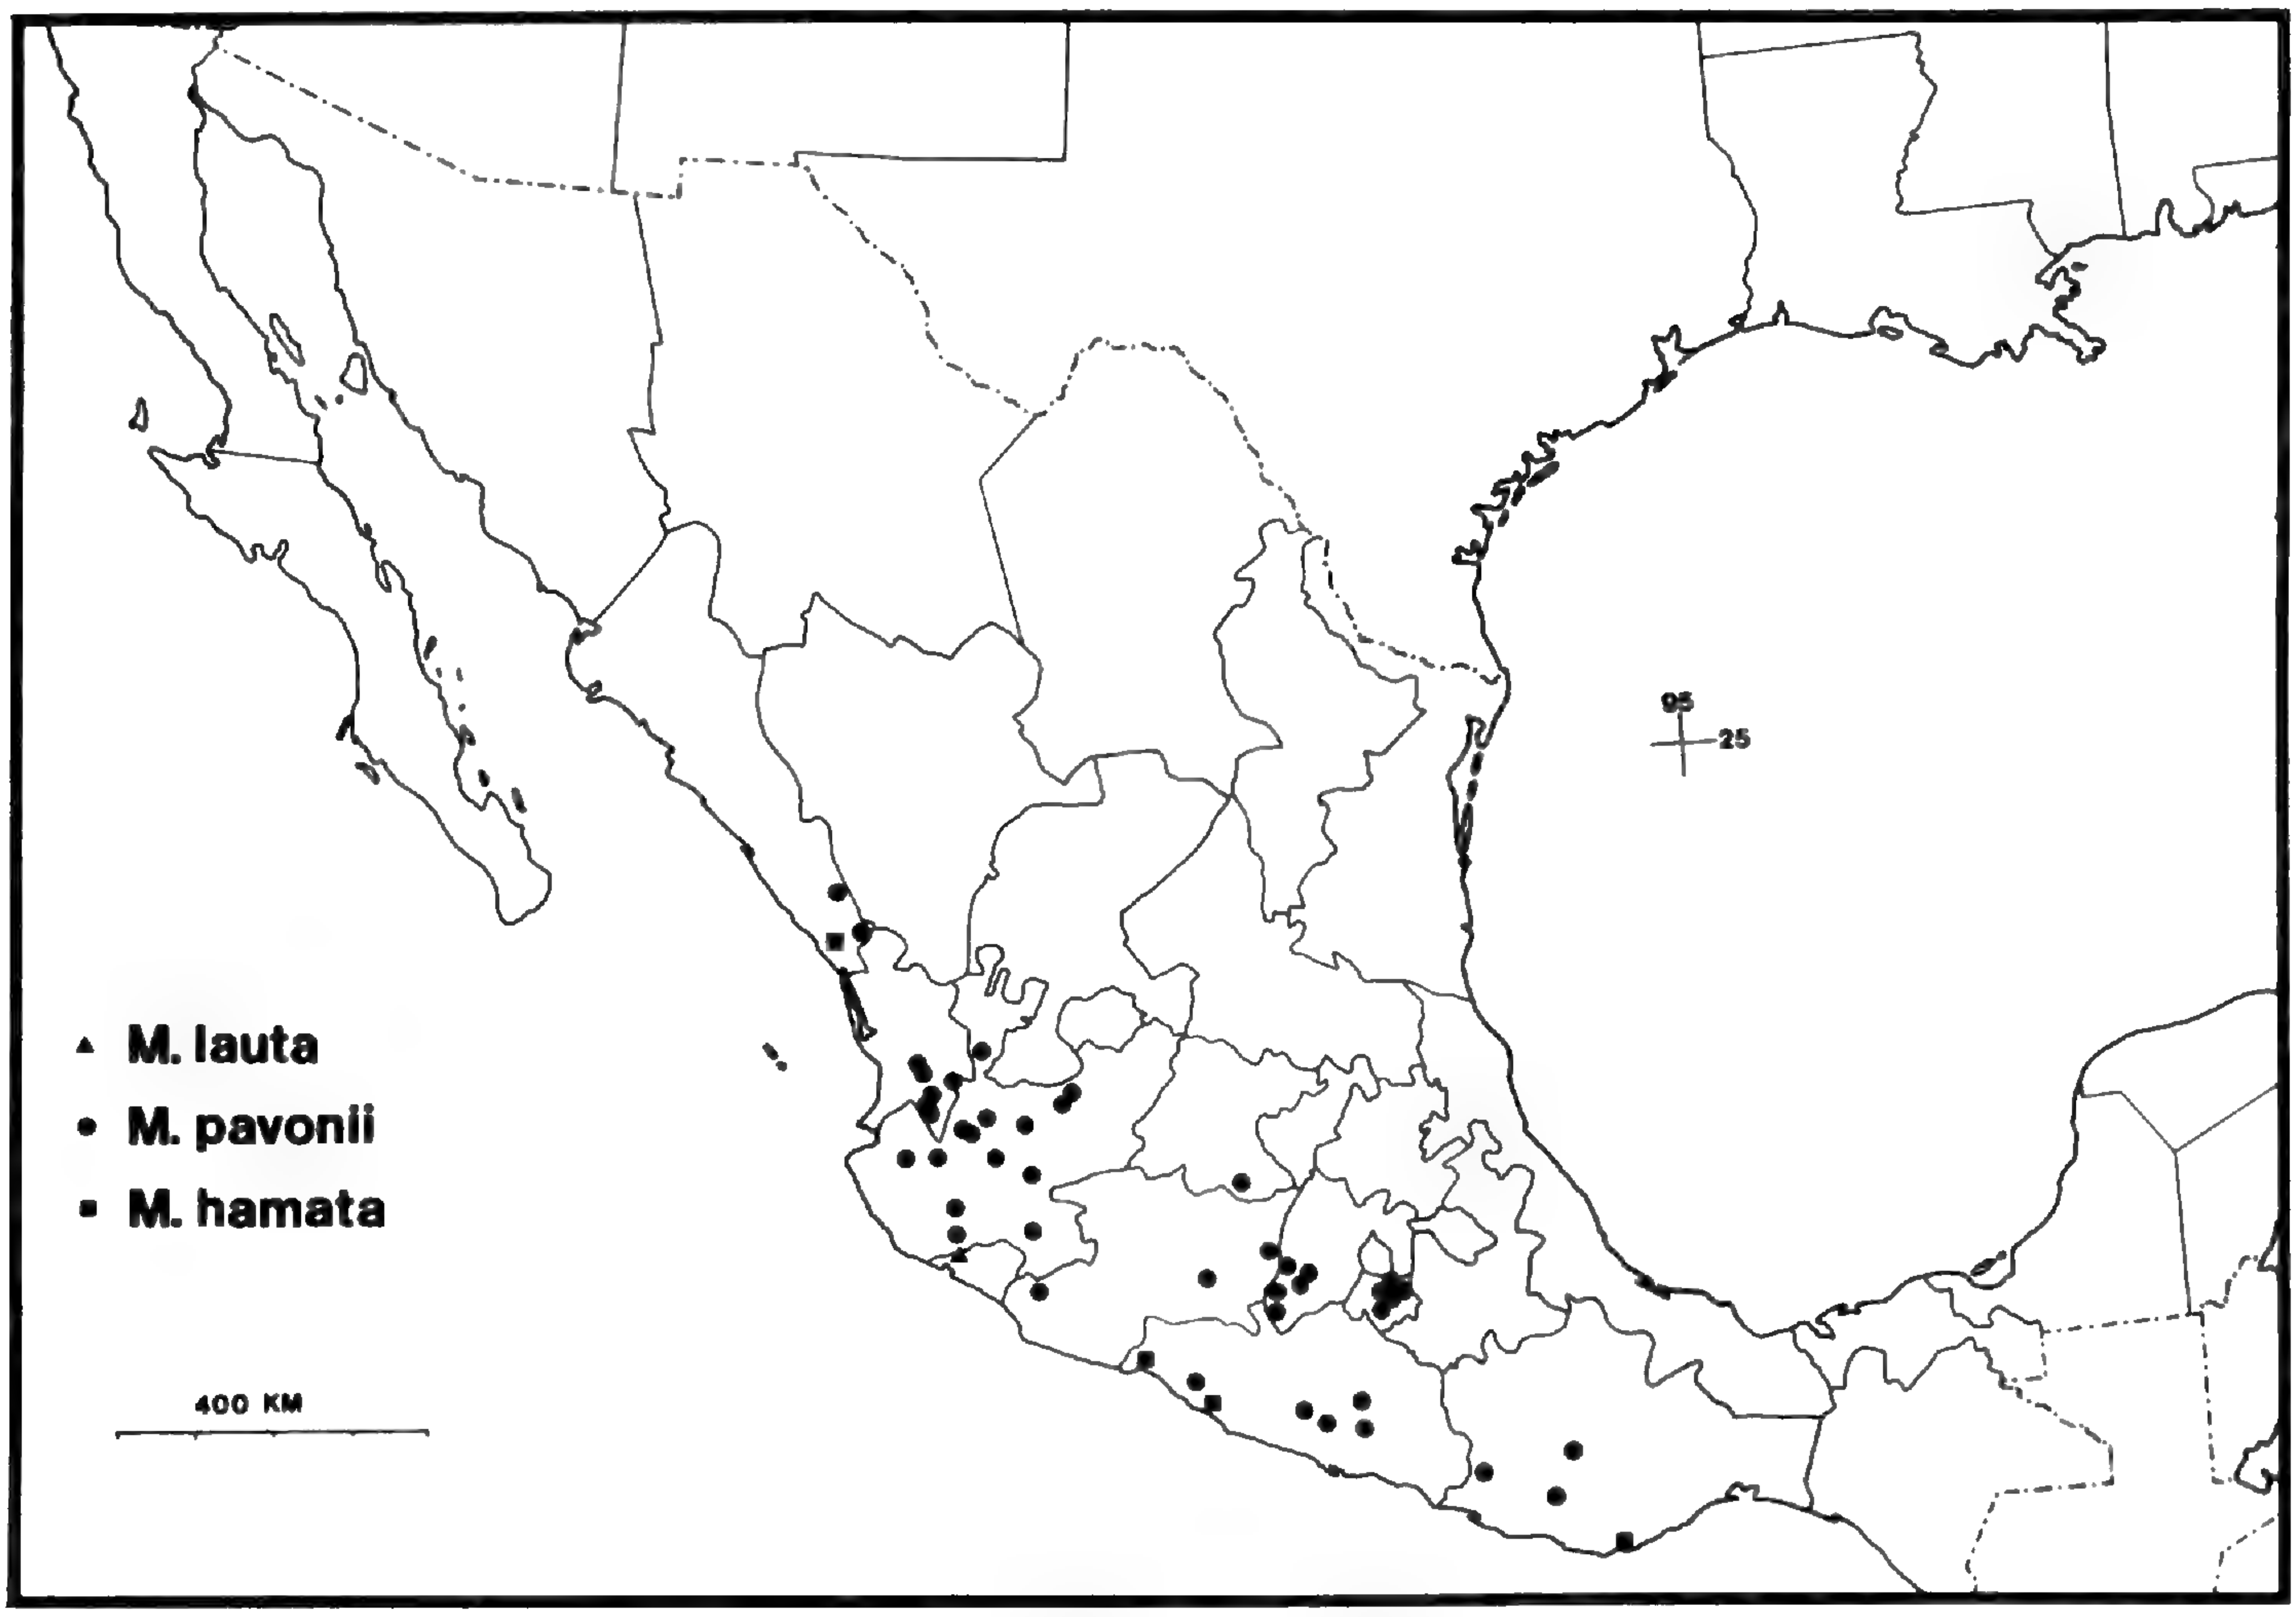

FIGURE 6. *Distributions of* Matelea lauta, M. pavonii, *and* M. hamata.

1853; Anonymous, 1853; Anonymous, 1857; Anonymous, 1862). The plants probably originated from one or two introductions, but little reliable information was provided.

This is the most common species of subgenus *Dictyanthus* and exhibits considerable floral variation throughout its range. The most conspicuous variation is in the background color of the corolla and in the color and density of corolla reticulations, but the basic color pattern is essentially constant. The presence or absence of teeth on the septum connecting the corona lobe to the gynostegium appears to have some geographical basis, all of the toothed specimens occurring from Jalisco and northward, but untoothed specimens occur throughout the range. In some populations, examples can be found with prominent teeth, with very small teeth, and with no teeth.

5. **Matelea macvaughiana** W. D. Stevens, sp. nov. TYPE: México. Jalisco: moist slopes near Guadalajara (between El Castillo and Juanacatlán, fide Davis, 1936, p. 199), 5 Aug. 1902 (fl), *Pringle 8629* (holotype, MSC; isotypes, ENCB, F, G(4), GH, L(2), MEXU, MO, NY, P, PH(2), POM, UC, US(2), VT, W). Figure 7.

Matelea macvaughiana W. D. Stevens; *M. pavonii* affinis, a qua imprimis differt caulibus annuis erectis vel leniter volubilibus et caudice perenni ligneo, pagina folii laevi, pedunculis plerumque brevioribus (0–16 mm), trichomatibus longis pedunculorum et pedicellorum rectis, tubo corollae breviore (9–12 mm e basi ad sinum), dentibus lateralibus loborum coronae duobus parvis et prominentiis folliculorum numerosioribus.

Plants erect to occasionally twining. Stems 20–85 cm long, with an herbaceous or woody caudex to 4 cm long and 2 cm wide, this with thin to moderately thick corky bark, occasionally with short woody stems above caudex, these with or without thin corky bark, herbaceous stems with dense short trichomes, sparse to dense glandular trichomes, and sparse to dense straight long trichomes to 3 mm long, these thin and often broken off on lower and older stems. Leaf blade ovate to wide-ovate or rarely narrow-ovate or very wide-ovate, 30–95 mm long, 21–72 mm wide, with sparse to dense uncinate long trichomes, surface smooth, smaller veins sharply raised below, apex acuminate to attenuate, base lobate, lobes mostly descending to widely divergent, with 2–6(–8) acropetiolar colleters, margin often somewhat thickened and revolute; petiole 9–37(–48) mm long, with dense short trichomes, sparse to dense glandular trichomes,

and sparse to dense uncinate long trichomes. Inflorescence often reduced to a single flower (then with or rarely apparently without a rudimentary peduncle); peduncle absent–16 mm long, with indumentum of stem or occasionally with long trichomes nearly absent; bracts linear to lorate or lanceolate, (2–)4–7 mm long, abaxial surface with dense short trichomes, sparse to dense glandular trichomes, and sparse to dense, straight or uncinate long trichomes, adaxial surface glabrous or with scattered short trichomes distally; pedicel (5.5–)8–20 mm long, with indumentum of peduncle. Calyx lobes lanceolate to narrow-ovate, 8–12 mm long, 3–4.5 mm wide, apex attenuate, with 1(2) colleter(s) below each sinus, abaxial surface with dense short trichomes, sparse to dense glandular trichomes, and sparse to dense, straight or uncinate long trichomes, adaxial surface glabrous. Corolla campanulate, base to sinus length 9–12 mm, limb revolute; lobes 9–17 mm long, apex rounded or occasionally obtuse, patent, margin revolute; glabrous within except limb and lobes with moderately dense to dense short trichomes, indumentum outside of dense short trichomes on tube and limb and sparse to moderately dense uncinate long trichomes on limb and lobes; tube convoluted with the raised parts opposite the corona lobes and sacs formed between them; with gray or black vertical lines within the tube, these becoming circular on base of limb and reticulate on distal part of limb and lobes. Corona lobes (6–)7–9(–10) mm long, linear to linear-spathulate in outline, connate at base, adnate by a thin septum to gynostegium, this septum continuing as a narrow ridge about half the length of the lobe and with a pair of small thick teeth lateral to the upper margin near center. Gynostegium (2.5–)3–4 mm high and (3–)4–5 mm wide at apex, stipitate, apex broadly convex or nearly apiculate, the center apparently slightly shorter than to equaling the corpuscula. Corpusculum 0.23–0.26 mm long, 0.12–0.15 mm wide, pollinia 1.46–1.68 mm long, 0.43–0.49 mm wide. Follicles ca. 83 mm long, ca. 20 mm wide, striped pale and dark green, with dense short and glandular trichomes, with 118–144 arcuate projections to 3 mm long. Seeds 5.5–6 mm long, ca. 4.5 mm wide, with a raised, faintly radially grooved margin, this entire or weakly toothed distally, inside this margin both sides flat or slightly convex, both sides verrucate to rugose, one side with a slight ridge from apex to near center, pale brown; coma 25–30 mm long.

Paratypes. MÉXICO. JALISCO: Huejotitán, July 1912 (fl), *Diquet s.n.* (MICH (2, one mixed with *Matelea pavonii*), P, US); ranch near Coyula (near Tonalá) ca. 12 mi. E of Guadalajara, July 1963 (fl), *Faberge s.n.* (TEX); wet seepage area 23 mi. S of Guadalajara on Hwy. 15, 5,300 ft., 13 July 1963 (fl), *Molseed & Rice 220* (ARIZ, MEXU, MICH, MO, NY, UC); wet meadows near Guadalajara (El Castillo, according to Davis, 1936, p. 118), 22 Aug. 1893 (fl), *Pringle 5431* (GH, VT). *Michoacán*: cultivated fields 6–7 km N of Jaripó, roadside thickets, 1,600 m, 1 Dec. 1970 (fr), *McVaugh 24934* (MICH, MSC).

The known collection localities are essentially centered in the region of Lago de Chapala at an elevation of about 1,600 m (Fig. 10). Apparently growing in seasonally wet meadows and grasslands; the erect or weakly twining habit and ground-level perennating parts are consistent with this open type of vegetation. Flowering July–August. Specimens with mature-sized fruit collected in December.

This species is named in honor of Dr. Rogers McVaugh for his extraordinary contributions to the flora of the part of Mexico in which this species is found, not the least of which are the many fine specimens of *Matelea*.

It is something of a quirk that this species requires description. Woodson recognized the species, but according to his annotation of the MO specimen of *Pringle 8629*, he considered it to be *Matelea dictyantha* Woodson, a new name based on *Rytidoloma reticulatum* Turcz. This apparently resulted from the fact that the two Pringle collections of this species were misdetermined as *Dictyanthus reticulatus* (Turcz.) Bentham & Hooker f. ex Hemsley (actually "*Dictyanthus reticulatus* Turcz. (ex char.)" in the case of *Pringle 5431* and "*Dictyanthus reticulatus* B. & H." in the case of *Pringle 8629*). Woodson, in providing the new name, cited both Turczaninow's name and type (*Jürgensen 692*), leaving no question as to the application of the name. *Jürgensen 692*, which Woodson apparently never examined, represents another species of *Matelea*, which according to his

←

FIGURE 7. *Representative features of* Matelea macvaughiana.—*A. Flower (*Pringle 8629, *US)*.—*B. Living flower, ca. same scale as A, negative taken from color positive, courtesy of Dr. Robert W. Cruden.*—*C. Fruit* (McVaugh 24934, *MICH)*.—*D. Inflorescence reduced to a single flower (past anthesis), without a bract to indicate the presence of a peduncle—contrast with more typical inflorescence of A (*Pringle 8629, *VT)*.—*E. Caudex (*McVaugh 24934, *MICH)*.

annotations he did not recognize, but which must nevertheless bear the name *M. dictyantha*. This left the species he did recognize without a description, type, or name, which are herewith provided.

Matelea macvaughiana is likely to be confused with *Matelea pavonii* because of the similarity of the shape and color pattern of the corolla but is amply distinct, most prominently by having a caudex, an erect or weakly twining habit, straight rather than uncinate long trichomes on several structures, smaller flowers on more reduced inflorescences, paired lateral teeth on the corona lobes, indumentum absent around the corona lobes, and more numerous and arcuate projections on the follicles.

6. Matelea lauta W. D. Stevens, sp. nov. TYPE: México. Colima: steep ravines in gorge of Río Cihuatlán, near bridge 13 mi. N of Santiago, 200–300 m, 27 July 1957 (fl), *McVaugh 15826* (holotype, MICH). Figure 8.

Matelea lauta W. D. Stevens; differt a *M. pavonii* ordinatione venationes corolla, habitatione, pedunculis pedicellisque brevioribus, bracteis floribusque parvioribus; a speciebus omnibus subgeneris *Dictyanthi* calyce et pagina exteriore corollae glabra facile dignoscenda.

Plants twining vines. Stems woody below, with thick corky bark, herbaceous stems with dense, short, sparse glandular trichomes and sparse straight or uncinate long trichomes to 1 mm long. Leaf blade ovate to wide-ovate, 107–130 mm long, 71–88 mm wide, indumentum of sparse uncinate long trichomes above and dense uncinate long trichomes below, surface pusticulate along the veins, apex acuminate, base lobate, lobes descending to widely divergent, with 4–6 acropetiolar colleters; petiole 47–81 mm long, with indumentum of stem. Peduncle 1–4 mm long, with moderately dense short and glandular trichomes; bracts lanceolate, 2.5–5 mm long, with sparse short trichomes abaxially, adaxially glabrous; pedicel 3–4.5 mm long, with moderately dense short and glandular trichomes. Calyx lobes lanceolate, 8–9.4 mm long, 2–3 mm wide, apex acute, with one colleter below each sinus, glabrous. Corolla campanulate, base to sinus length 15–18 mm, limb patent; lobes 14–18 mm long, apex acute, patent, margin revolute; glabrous within except with sparse short trichomes on lobes and in a line around corona lobes, glabrous without; tube convoluted with the raised parts opposite the corona lobes and deep sacs formed between them; with gray-brown vertical lines within tube, these becoming ± angularly and uniformly reticulate on limb and lobes. Corona lobes 7–8 mm long, linear-spathulate in outline, connate at base, adnate by a thin septum to gynostegium. Gynostegium ca. 4.5 mm high and 3 mm wide at apex, stipitate, apex apiculate, the apiculum ca. 0.5 mm long, equaling corpuscula, shriveled and apparently papillate when dried. Corpusculum ca. 0.33 mm long, 0.20 mm wide, pollinia ca. 1.27 mm long, 0.40 mm wide. Fruit and seeds unknown.

Known only from the type collection in lowland Colima (Fig. 6), flowering in July.

This new species appears to be closest to *M. pavonii* but can be immediately distinguished by the pattern of reticulations of the corolla. Most inflorescence and floral measurements of this species are notably smaller than the corresponding measurements of *M. pavonii*, and the glabrous calyx and outer surface of the corolla are unique in the subgenus. Additionally, the single collection was made at a significantly lower elevation than any known collection of *M. pavonii*.

7. Matelea standleyana Woodson, Ann. Missouri Bot. Gard. 28: 237. 1941, based on *Dictyanthus tigrinus* Conzatti & Standley. *Dictyanthus tigrinus* Conzatti & Standley in Standley, Contr. U.S. Natl. Herb. 23: 1183–1184. 1924, not *Matelea tigrina* (Grisebach) Woodson. TYPE: México. Oaxaca: Dist. Tuxtepec, Laguna de Ojitlán, 350 m, 31 Oct. 1919 (fl), *Conzatti 3760* (holotype, US; isotype, GH). Figure 9.

Plants twining vines. Stems herbaceous and lacking bark, or sometimes rhizomes slightly woody and with thin corky bark; rhizomes thin, horizontal; stem indumentum of sparse to dense short and glandular trichomes and sparse to very sparse straight long trichomes to 1.5 mm long, these very brittle and mostly missing from specimens. Leaf blade wide-ovate to very wide-ovate or occasionally ovate, 48–104 mm long, 36–102 mm wide, indumentum of sparse uncinate long trichomes above and dense uncinate long trichomes below, surface smooth, apex acuminate to attenuate, base lobate, lobes mostly convergent to descending, with 1–7 acropetiolar colleters; petiole 35–112 mm long, with sparse to dense short and glandular trichomes and sparse to very sparse, straight or uncinate long trichomes. Peduncle 5–18(–25) mm long, with indumentum of stem or often with long trichomes absent; bracts linear to lanceolate, 2–6 mm long, with dense short and sparse straight long trichomes; pedicel 7–16 mm long, with indumentum of stem. Calyx lobes narrow-ovate or occasionally lanceolate

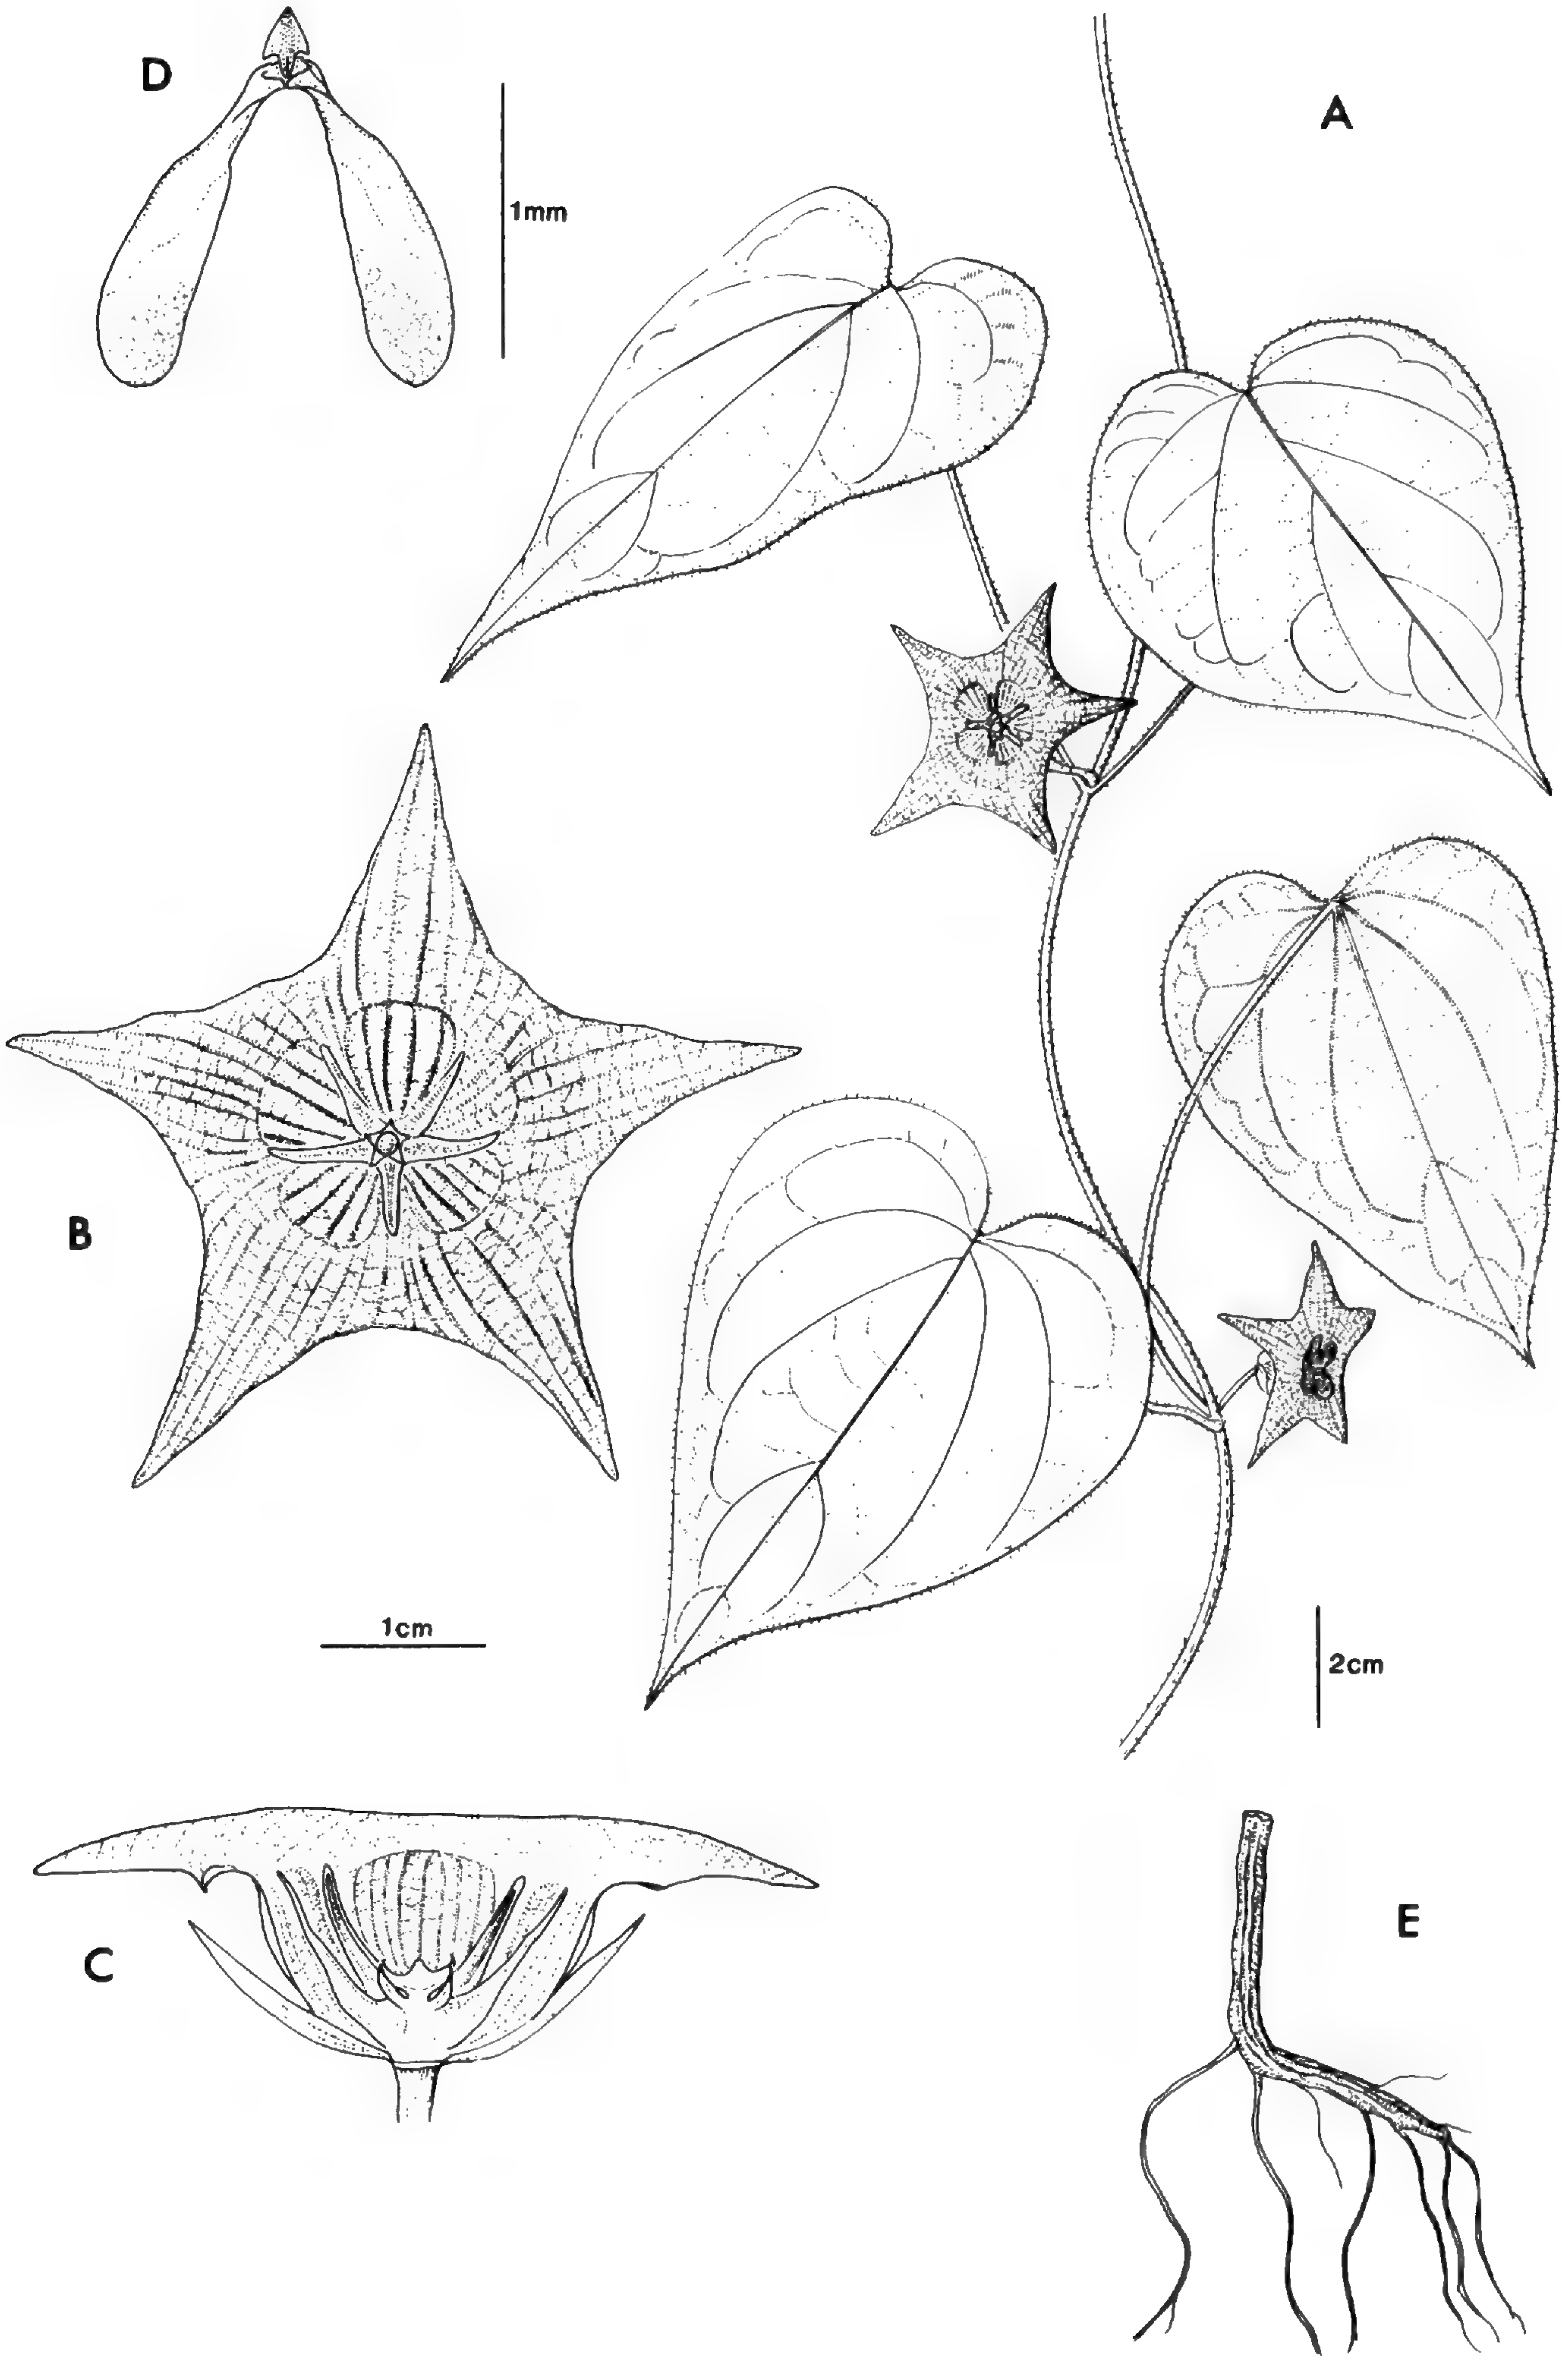

FIGURE 8. Matelea lauta (McVaugh 15826).—*A. Section of flowering stem.—B, C. Flowers.—D. Bipollinium.—E. Base of stem.*

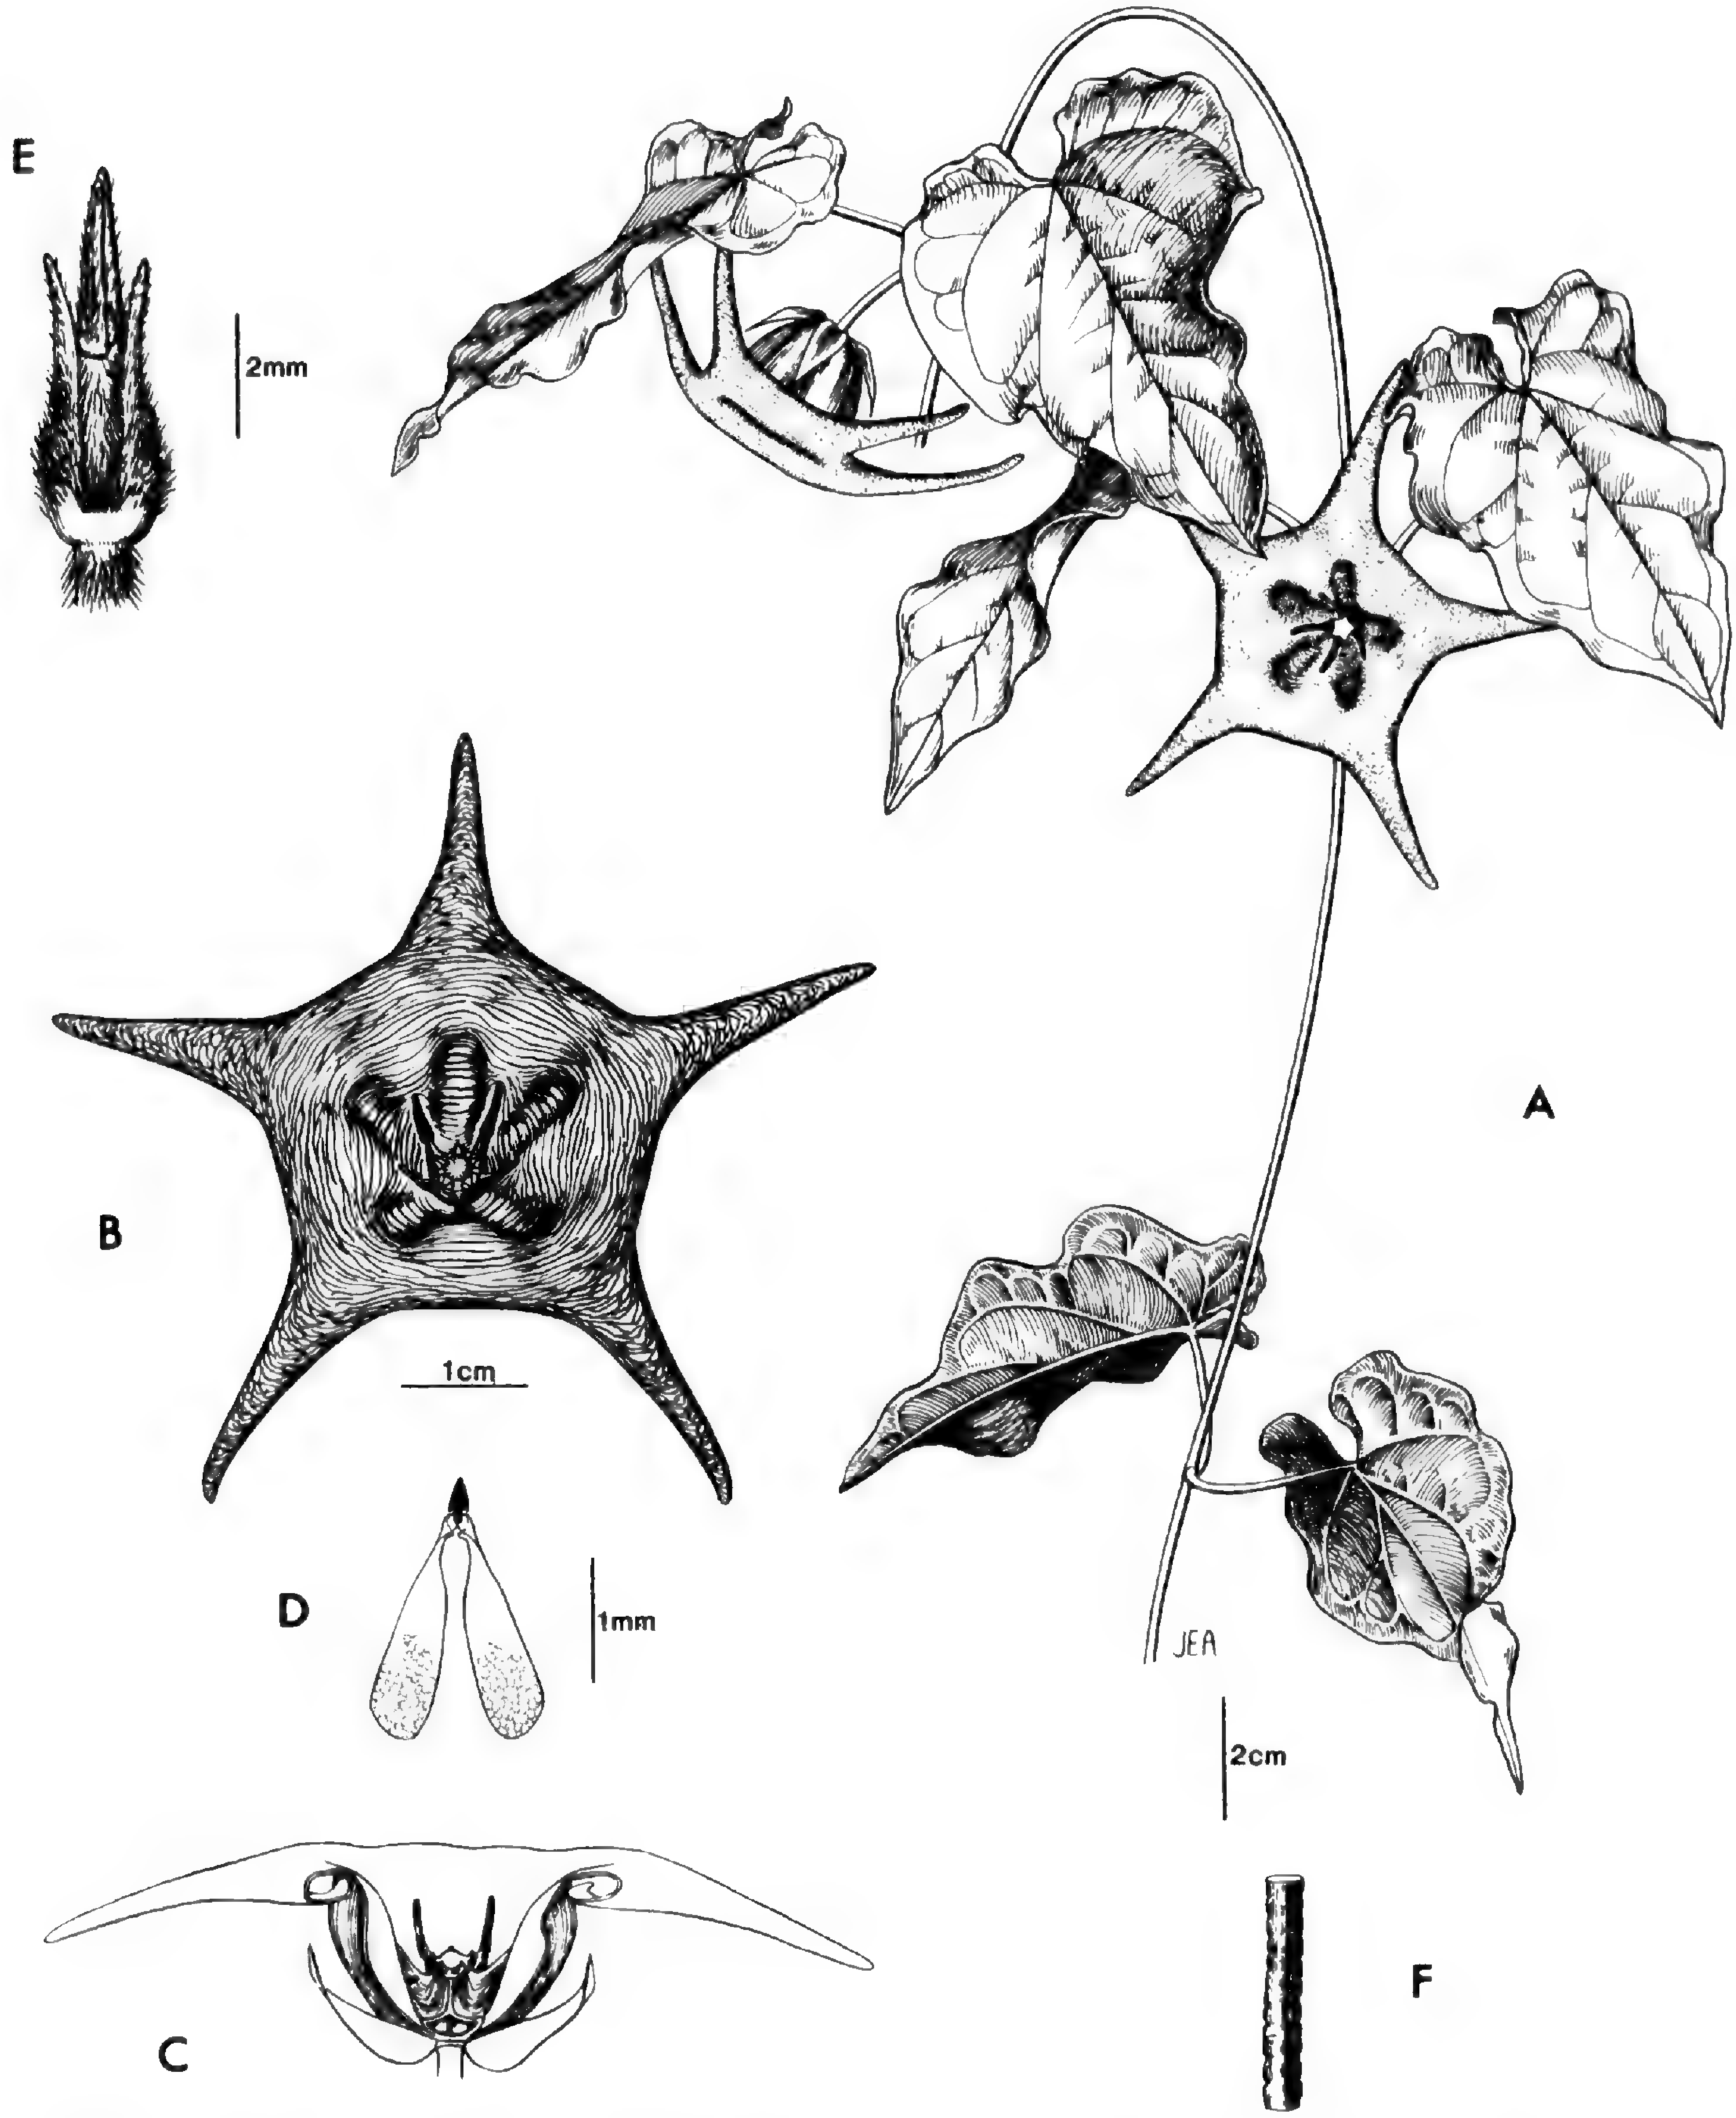

FIGURE 9. Matelea standleyana (Stevens C-161, *a cultivated specimen of* Stevens 1392*).—A. Section of flowering stem.—B, C. Flowers.—D. Bipollinium.—E. Base of stem.—F. Base of adaxial surface of leaf blade,*

or ovate, (8.5–)12–18 mm long, 4–6.5 mm wide, apex attenuate, with one colleter below each sinus, abaxial surface with dense short trichomes, margin with sparse straight or uncinate long trichomes, adaxial surface glabrous. Corolla deeply campanulate, base to sinus length (14–)17–31 mm, limb revolute; lobes 17–28 mm long, apex acute, patent to reflexed, margin revolute; glabrous within except with moderately dense to dense short trichomes on lobes, limb, and around corona lobes, indumentum on outside of sparse to dense short trichomes; tube convoluted with the raised parts opposite the co-

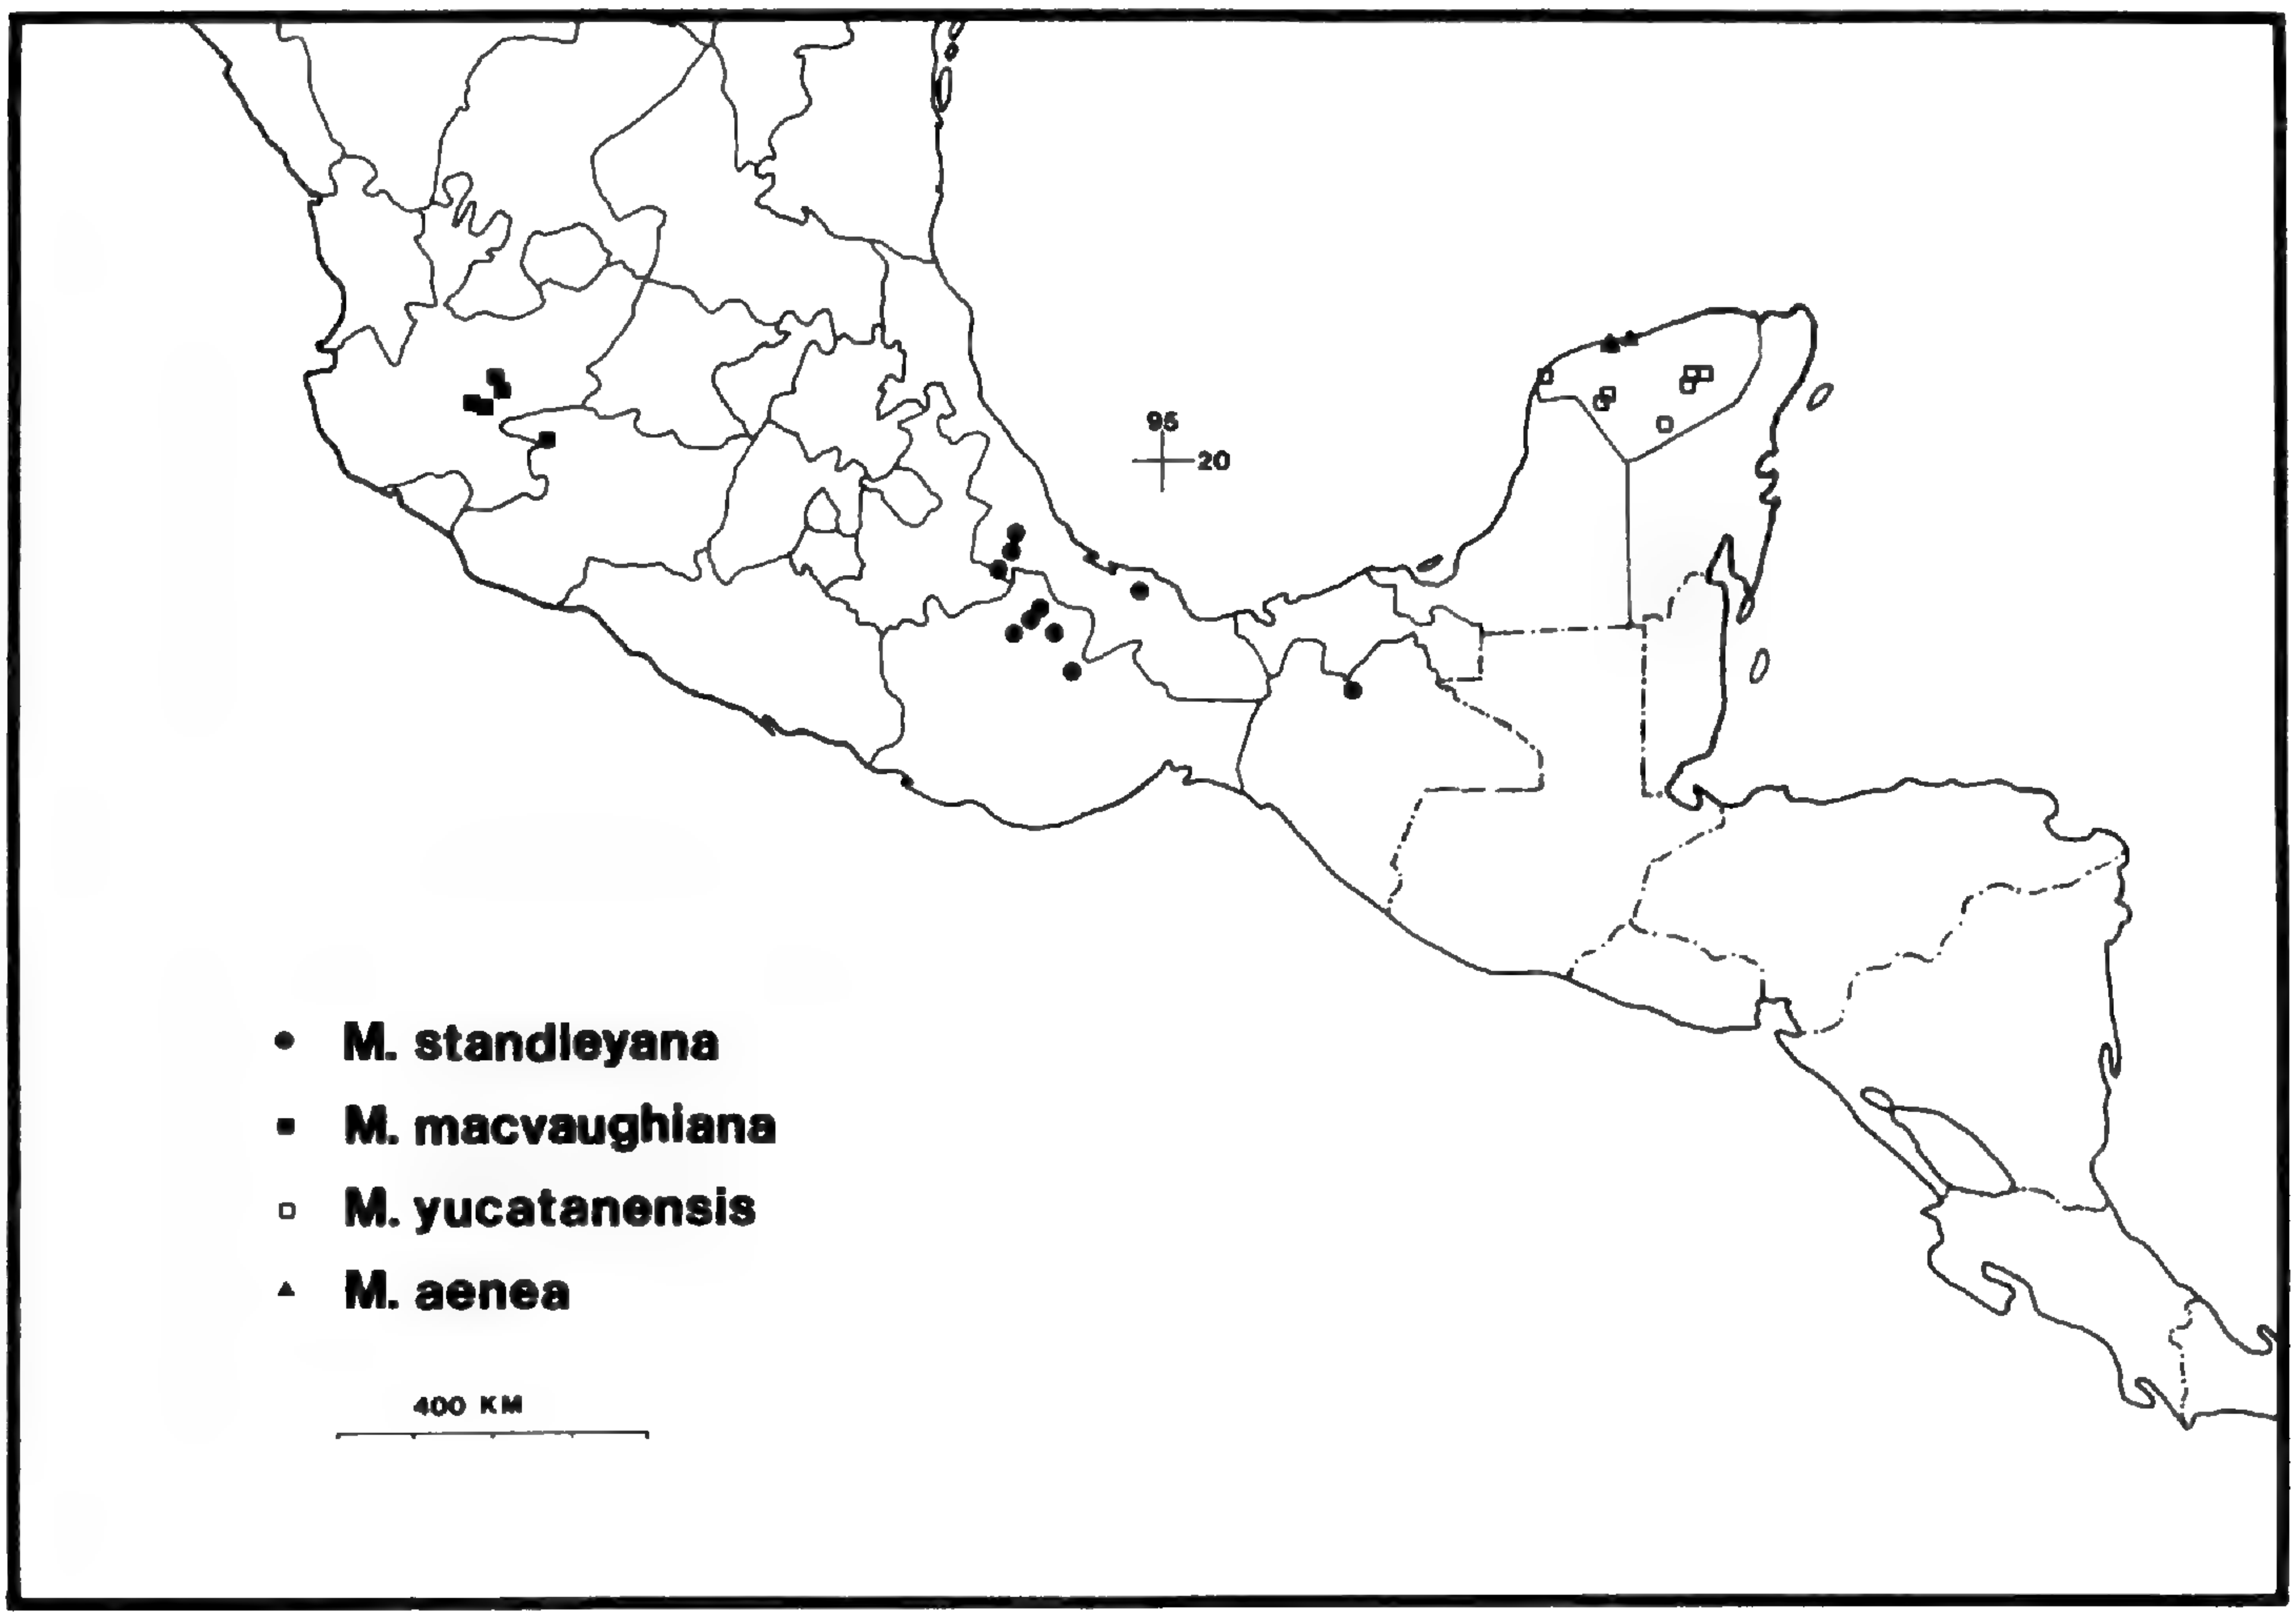

FIGURE 10. *Distributions of* Matelea standleyana, M. macvaughiana, M. yucatanensis, *and* M. aenea.

rona lobes and sacs formed between them; with thick, brown-red, circular lines within tube, these becoming thinner and reticulate on distal part of limb and lobes. Corona lobes 9–13 mm long, linear in outline, connate at base, adnate by a thin septum to gynostegium. Gynostegium (3–)4–5 mm high and 3–4.5 mm wide at apex, stipitate, apex with a blunt projection (formed from apices of anther wings) below each corpusculum and exceeding them laterally, apex convex with tip flattened and slightly bilobed and slightly exceeding corpuscula, terminal anther appendages covering ca. 1/3 of apex. Corpusculum 0.48–0.55 mm long, 0.23–0.28 mm wide, pollinia 1.54–1.88 mm long, 0.45–0.63 mm wide. Mature follicles unknown, immature follicles fusiform, to 85 mm long, to 28 mm wide, apparently green, with dense short trichomes, with ca. 50 very thick, straight projections to 7 mm long. Seeds unknown.

Apparently a plant of moist thickets restricted to northern Oaxaca and adjacent Veracruz, with one collection in northern Chiapas (Fig. 10), at elevations up to 1,220 m. Flowering specimens collected mainly in July and August, but also once each in June and late October. The one immature fruit was collected in August. Flowers of a greenhouse-grown specimen were noticed to produce a faint foetid odor in late afternoon.

This species is readily identifiable because of the large, deeply campanulate corolla with circular markings within the tube. It is likely the largest-flowered New World asclepiad. Well-formed leaves of this species are, along with those of *Matelea pavonii*, the largest of the subgenus and have a uniquely angular sinus.

For a discussion of the Sessé & Mociño collections of this species, see *Matelea pavonii.*

8. **Matelea ceratopetala** (J. D. Smith) Woodson, Ann. Missouri Bot. Gard. 28: 236. 1941. *Dictyanthus ceratopetalus* J. D. Smith, Bot. Gaz. (Crawfordsville) 18: 208. 1893. TYPE: Guatemala. Santa Rosa: Santa Rosa, 3,000 ft., Aug. 1892 (fl), *Heyde & Lux ex J. D. Smith 3999* (holotype, US; isotypes, G, GH, K, NY, US). Figure 11.

Plants twining or occasionally trailing or erect, frequently rooting at lower nodes. Stems 25–55 cm long when erect, woody and with thin to thick corky bark below or occasionally entirely herbaceous, herbaceous stems with dense short trichomes, lacking to dense glandular trichomes, and very sparse to moderately dense, mostly straight long trichomes to 2 mm long. Leaf blade ovate to very wide-ovate, 25–63 mm long, 15–55 mm wide, indumentum above of sparse to occasionally dense straight or uncinate long trichomes and occasionally also sparse short trichomes, or rarely glabrous, indumentum below of sparse to dense mostly uncinate long trichomes, glandular trichomes lacking to sparse, surface smooth, smaller veins often moderately to sharply raised below, apex acute to attenuate, base lobate, lobes mostly convergent, with 1–4(–7) acropetiolar colleters, margin often somewhat thickened and revolute; petiole 13–60(–70) mm long, with dense short trichomes, sparse to dense glandular trichomes, and very sparse to moderately dense, mostly uncinate long trichomes. Inflorescence sometimes reduced to a single flower but with a distinct peduncle; peduncle 1–15(–27) mm long, with dense short trichomes, sparse to dense glandular trichomes, and very sparse to moderately dense, straight or uncinate long trichomes; bracts linear to lanceolate, 3–5(–7) mm long, abaxial surface with short, glandular, and long trichomes, adaxial surface with short and occasionally also scattered long trichomes; pedicel 3–12(–15) mm long, sometimes accrescent in fruit, with indumentum of peduncle. Calyx lobes narrow-ovate or occasionally lanceolate, 9–13 mm long, 3.5–6 mm wide, apex acute or attenuate, with one colleter below each sinus, abaxial surface with scattered straight or uncinate long trichomes, adaxial surface glabrous. Corolla campanulate, base to sinus length 12–20 mm, limb revolute; lobes 11–18 mm long, apex acute, patent to reflexed, margin revolute; glabrous within except with scattered short trichomes on lobes, on limb (on veins only), and around corona lobes, indumentum on outside of sparse to dense short and scattered long trichomes; tube convoluted with the raised parts opposite the corona lobes and deep sacs formed between them; brown- or red-purple-reticulate, reticulations wider within tube. Corona lobes 8–11 mm long, linear-spathulate in outline, connate at base, adnate by a thin septum to gynostegium, this septum with a distinct tooth near center of upper margin. Gynostegium 3.5–5.5 mm high and 3–4.5 mm wide at apex, stipitate, apex apiculate, the apiculum 1–2 mm long and exceeding corpuscula. Corpusculum 0.41–0.46 mm long, 0.18–0.22 mm wide, pollinia 1.52–1.63 mm long, 0.40–0.49 mm wide. Follicles 75–90(–103) mm long, 20–27 mm wide, striped dark green and pale green or white, with short and glandular trichomes, with (36–)48–60 straight or occasionally arcuate projections to 7 mm long. Seeds ca. 4.5 mm long and 2.5–3.5 mm wide, with a raised, radially grooved margin, this weakly toothed distally, inside this margin convex and verrucate on one side, concave and verrucate to rugose on the opposite side, concave side with a slight ridge extending ca. 1 mm from apex; coma 20–30 mm long.

Collected from southern Guatemala to southern Nicaragua (Fig. 13), mostly at elevations of 800–1,000 m but occasionally up to 1,400 m and down to near sea level, both extremes occurring in Nicaragua. Apparently not found on forests but rather in moist or dry fields, thickets, fencerows, streamsides, and roadsides. Mostly associated with rocky volcanic soils but once noted as occurring on a salt flat. Flowering mostly mid July to early October but as early as June and as late as November. Collected with mature-sized fruit from mid September to December.

Until now, the plants here considered to be *Matelea dictyantha* have been included in this taxon. The two species are actually quite distinct, and *M. ceratopetala* has its closest affinities with *M. pavonii*. This problem is further discussed under *M. dictyantha*.

9. **Matelea eximia** W. D. Stevens, sp. nov.

TYPE: México. Chiapas: Fca. Fuarez, Esc. (Finca Unión Juárez, fide M. Sousa S., pers. comm.), 12 Aug. 1937 (fl), *Matuda 1778* (holotype, MICH; isotype, MEXU). Figure 12.

Matelea eximia W. D. Stevens; differt a *M. ceratopetala* ordinatione venationis super limbo corollae ordinate circulari (in illa irregulater reticulata), trichomatibus super limbo corollae aequaliter distributis (in illa limitatis ad reticulum), septis coronae integris, apiculo styli breviore, floribus ubique grandioribus.

Plants twining or trailing, rooting at lower nodes. Stems slightly woody below and with thin corky bark, herbaceous stems with dense short trichomes and very sparse straight long trichomes to 0.5 mm long. Leaf blade ovate, 45–58 mm long, 36–41 mm wide, indumentum above of sparse straight or uncinate long trichomes, indumentum below of dense uncinate long trichomes, surface smooth, apex acuminate to attenuate, base lobate, lobes convergent, with 1–4 acropetiolar colleters, margin somewhat thickened and revolute; petiole 44–65 mm long, with dense short trichomes, sparse glandular trichomes, and sparse to dense (only distally) uncinate long trichomes. Peduncle 3–8 mm long, with dense short trichomes; bracts lanceolate to narrow-ovate, 2–3 mm long (probably larger, primary bracts unknown), with dense short and sparse long trichomes; pedicels 7–9 mm long, with dense

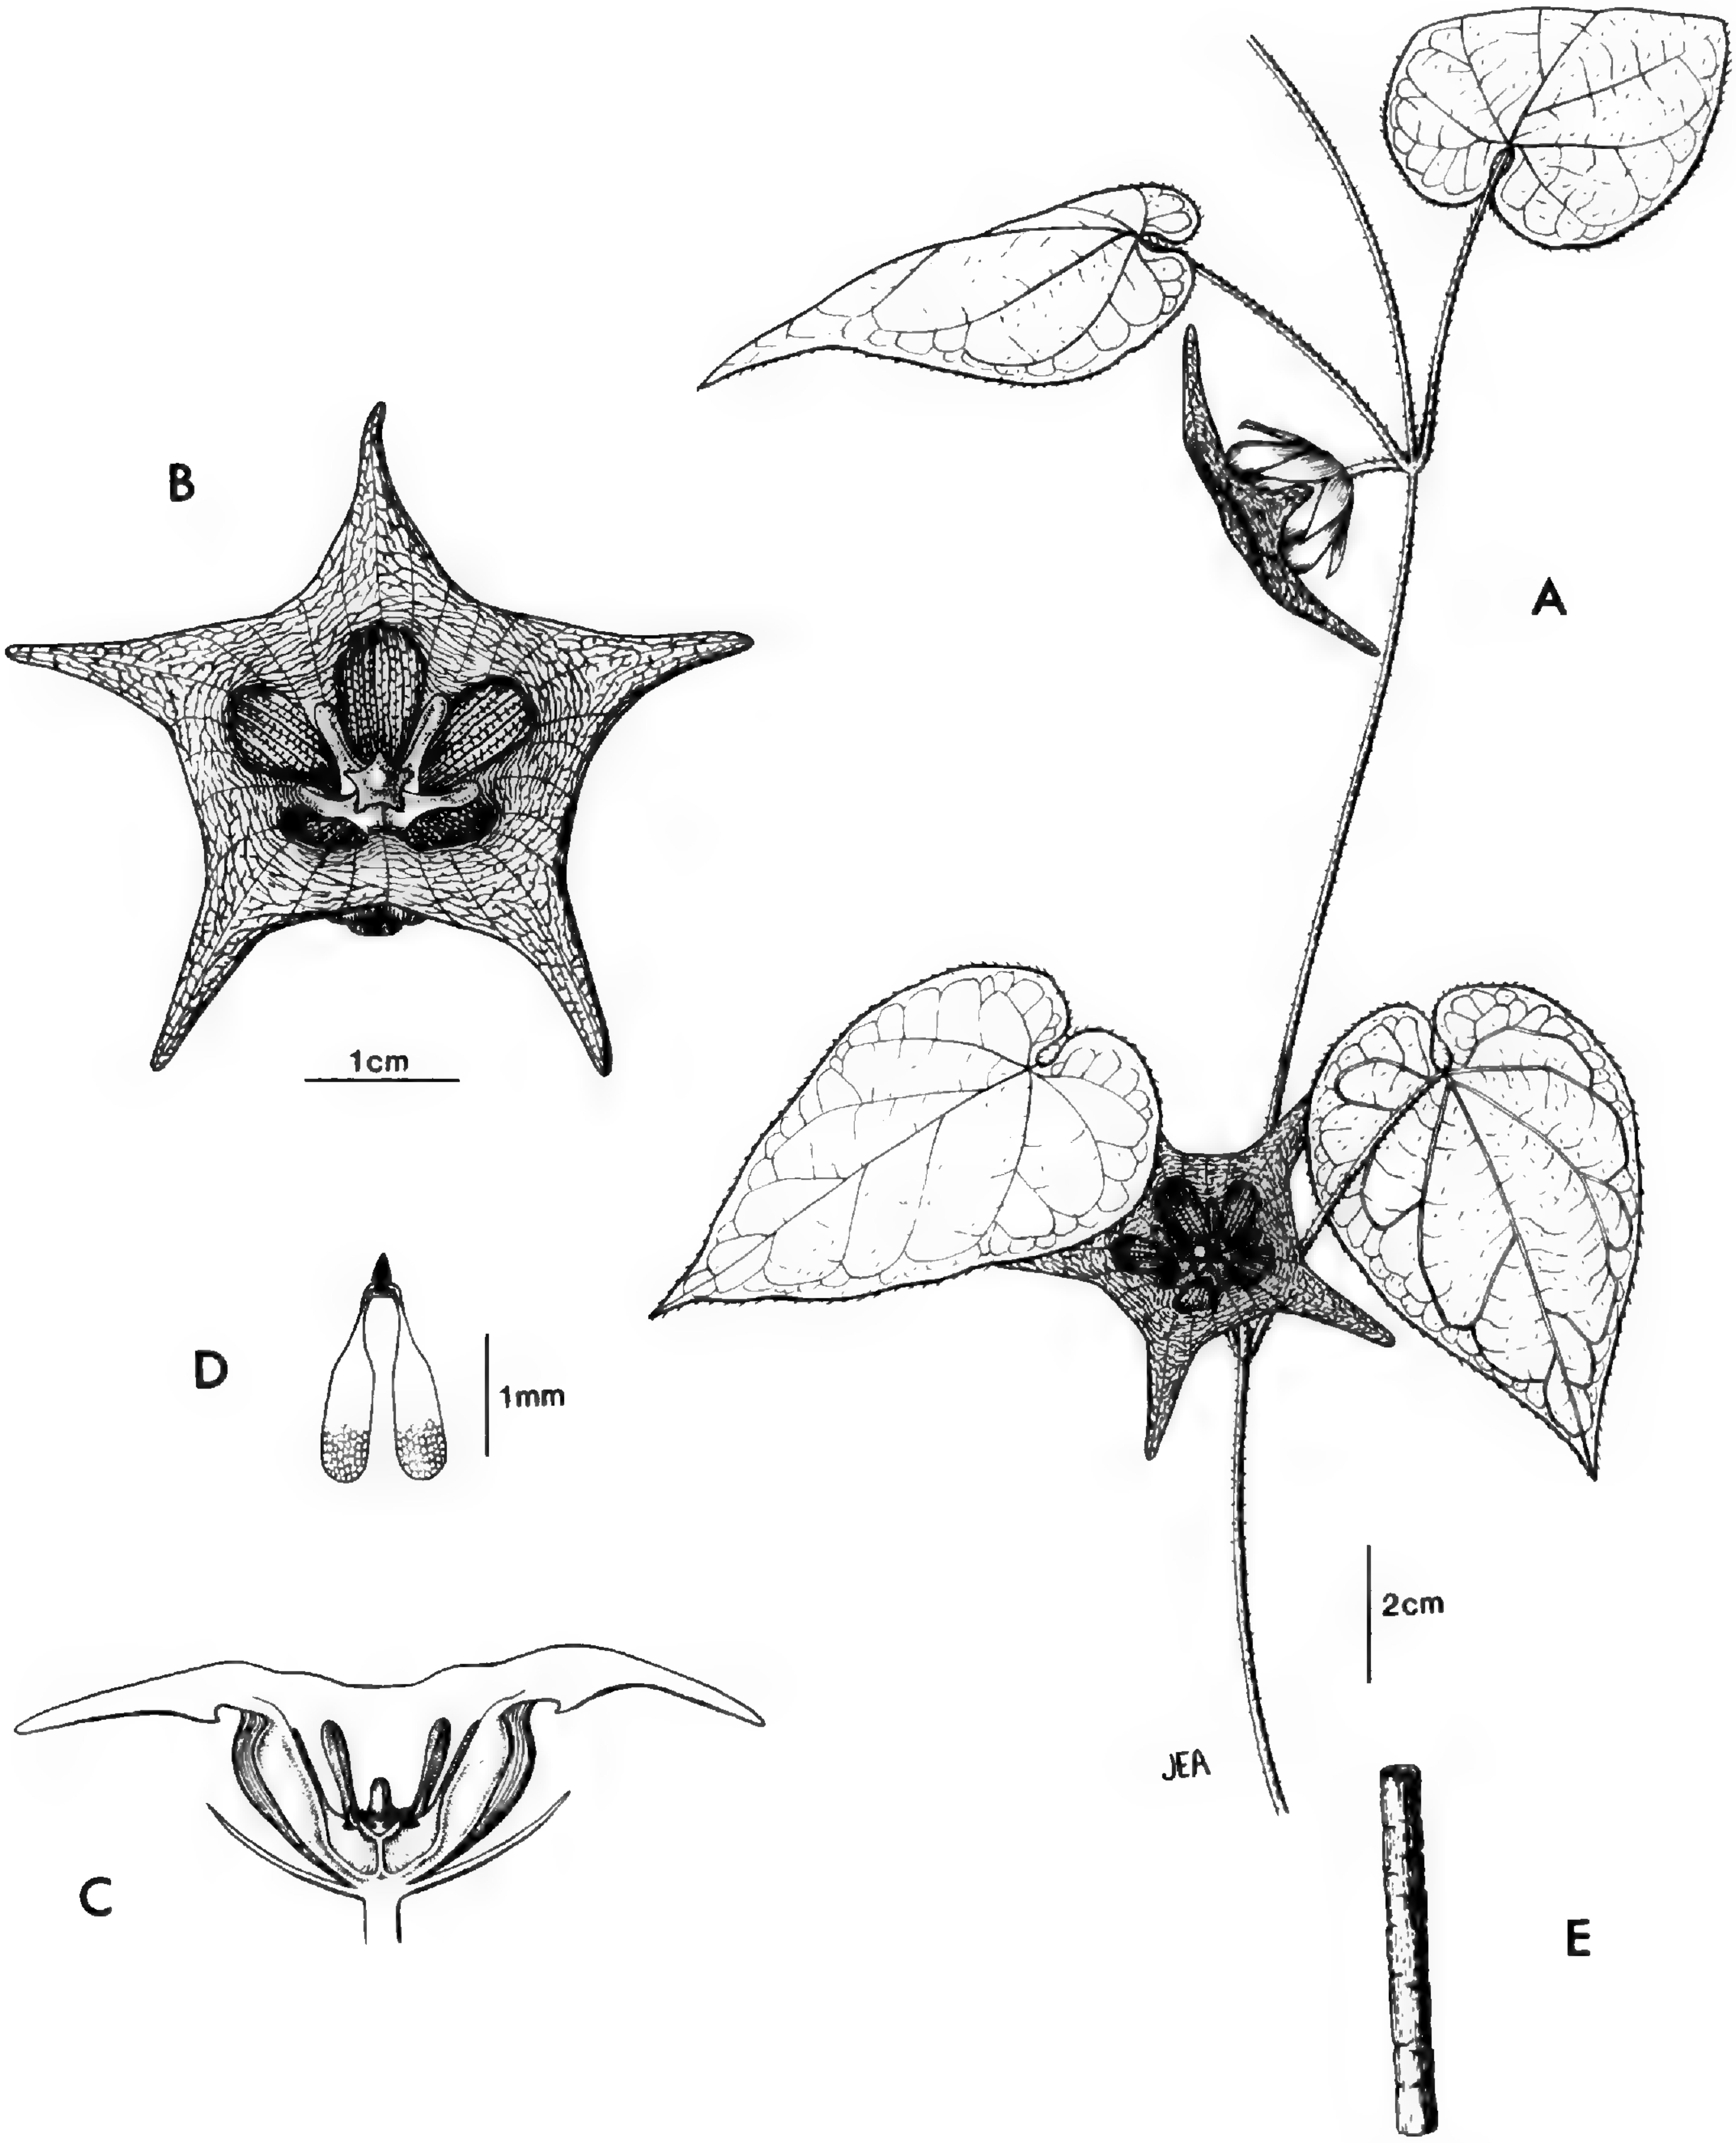

FIGURE 11. Matelea ceratopetala (Stevens 1245).—*A. Section of flowering stem.—B, C. Flowers.—D. Bipollinium.—E. Section of old stem.*

short trichomes and sparse straight long trichomes (only distally). Calyx lobes narrow-ovate to ovate, 9–15 mm long, 6–7.2 mm wide, apex acute or attenuate, with 1 colleter below each sinus, abaxial surface with scattered short trichomes and sparse straight or uncinate long trichomes, adaxial surface glabrous. Corolla campanulate, base to sinus length 16–20 mm, margin apparently revolute; lobes 14–23 mm long, apex acute, apparently reflexed with margin revolute; with uniformly distributed, moderately dense short trichomes within except glabrous in tube between corona lobes, indumentum outside of dense short trichomes; tube convoluted with the raised parts opposite the corona lobes and

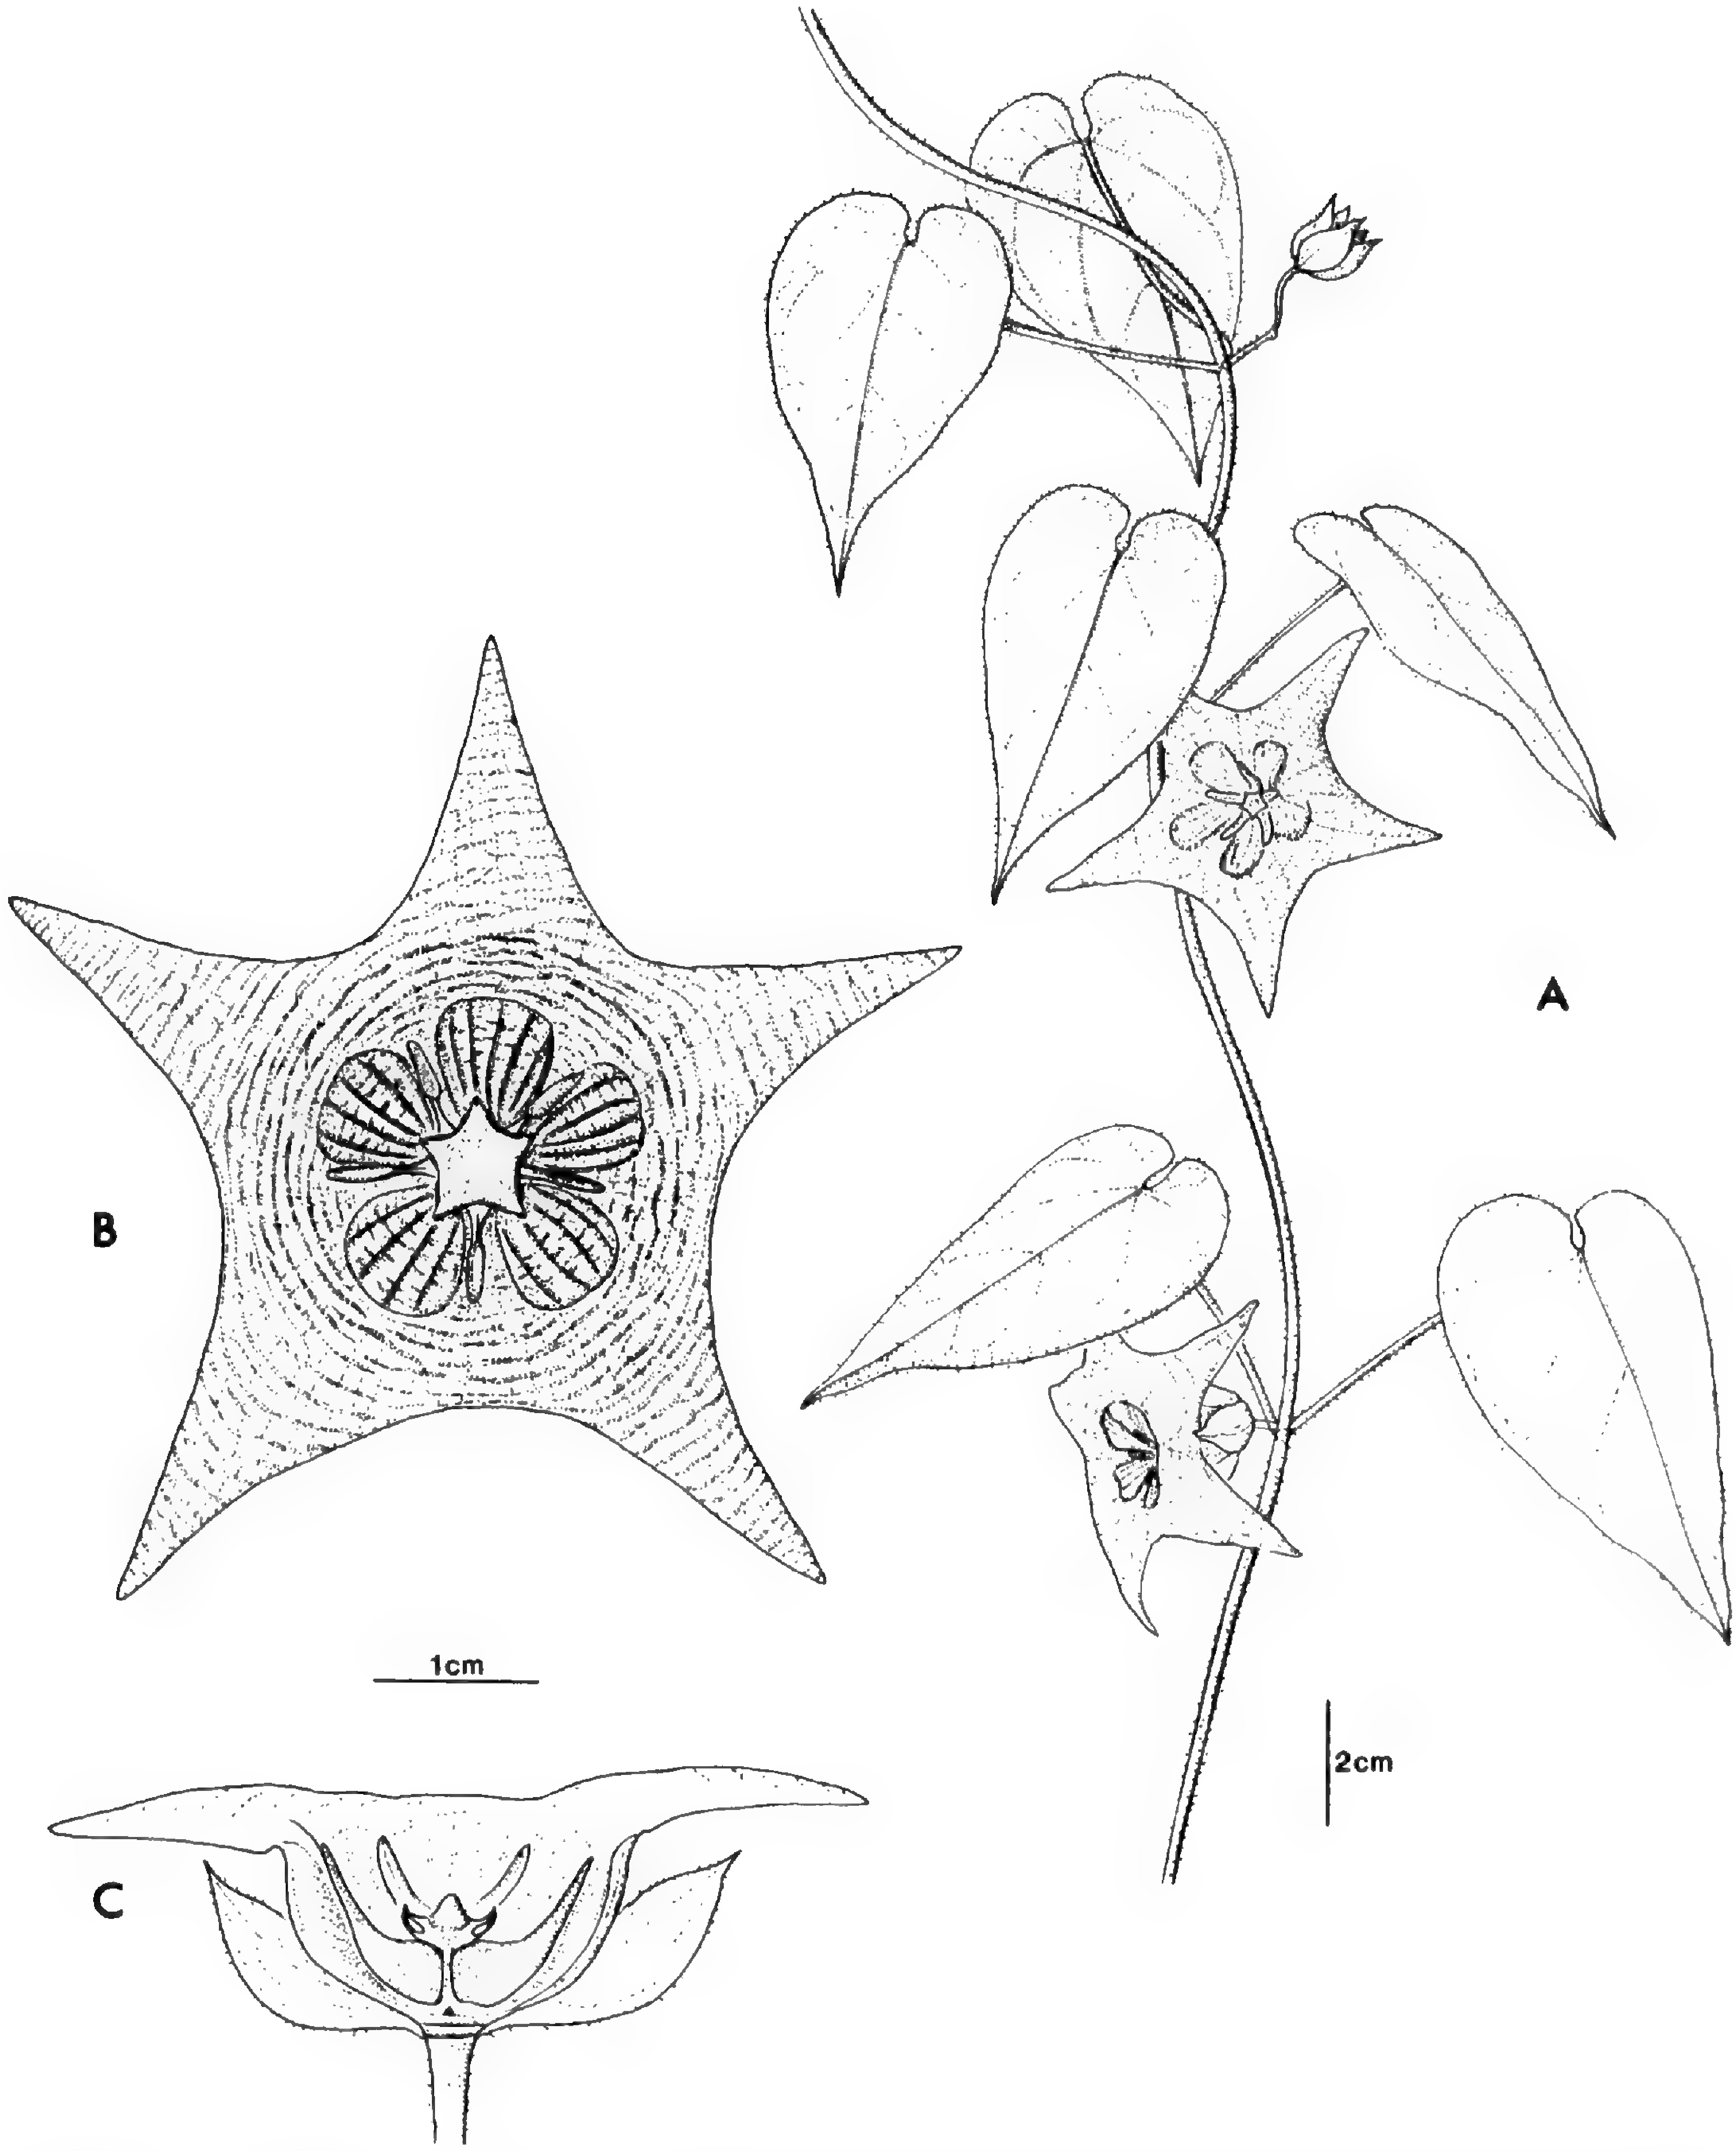

FIGURE 12. Matelea eximia *(*Breedlove 28682 *and* Matuda 1778*).—A. Section of flowering stem.—B, C. Flowers.*

deep sacs formed between them; apparently purple-reticulate. Corona lobes 6–7 mm long, linear-spathulate in outline, connate at base, adnate by a thin, entire septum to gynostegium. Gynostegium 4.5–5 mm high and 2.7–3 mm wide at apex, stipitate, apex apiculate, the apiculum ca. 0.8 mm long and exceeded by corpuscula. Corpusculum ca. 0.37 mm long, 0.23 mm wide, pollinia ca. 1.17 mm long, 0.30 mm wide. Fruits and seeds unknown.

Paratype. MÉXICO. CHIAPAS: Mpio. de Motozintla de Mendoza, 25–27 km NE of Huixtla along road to Mo-

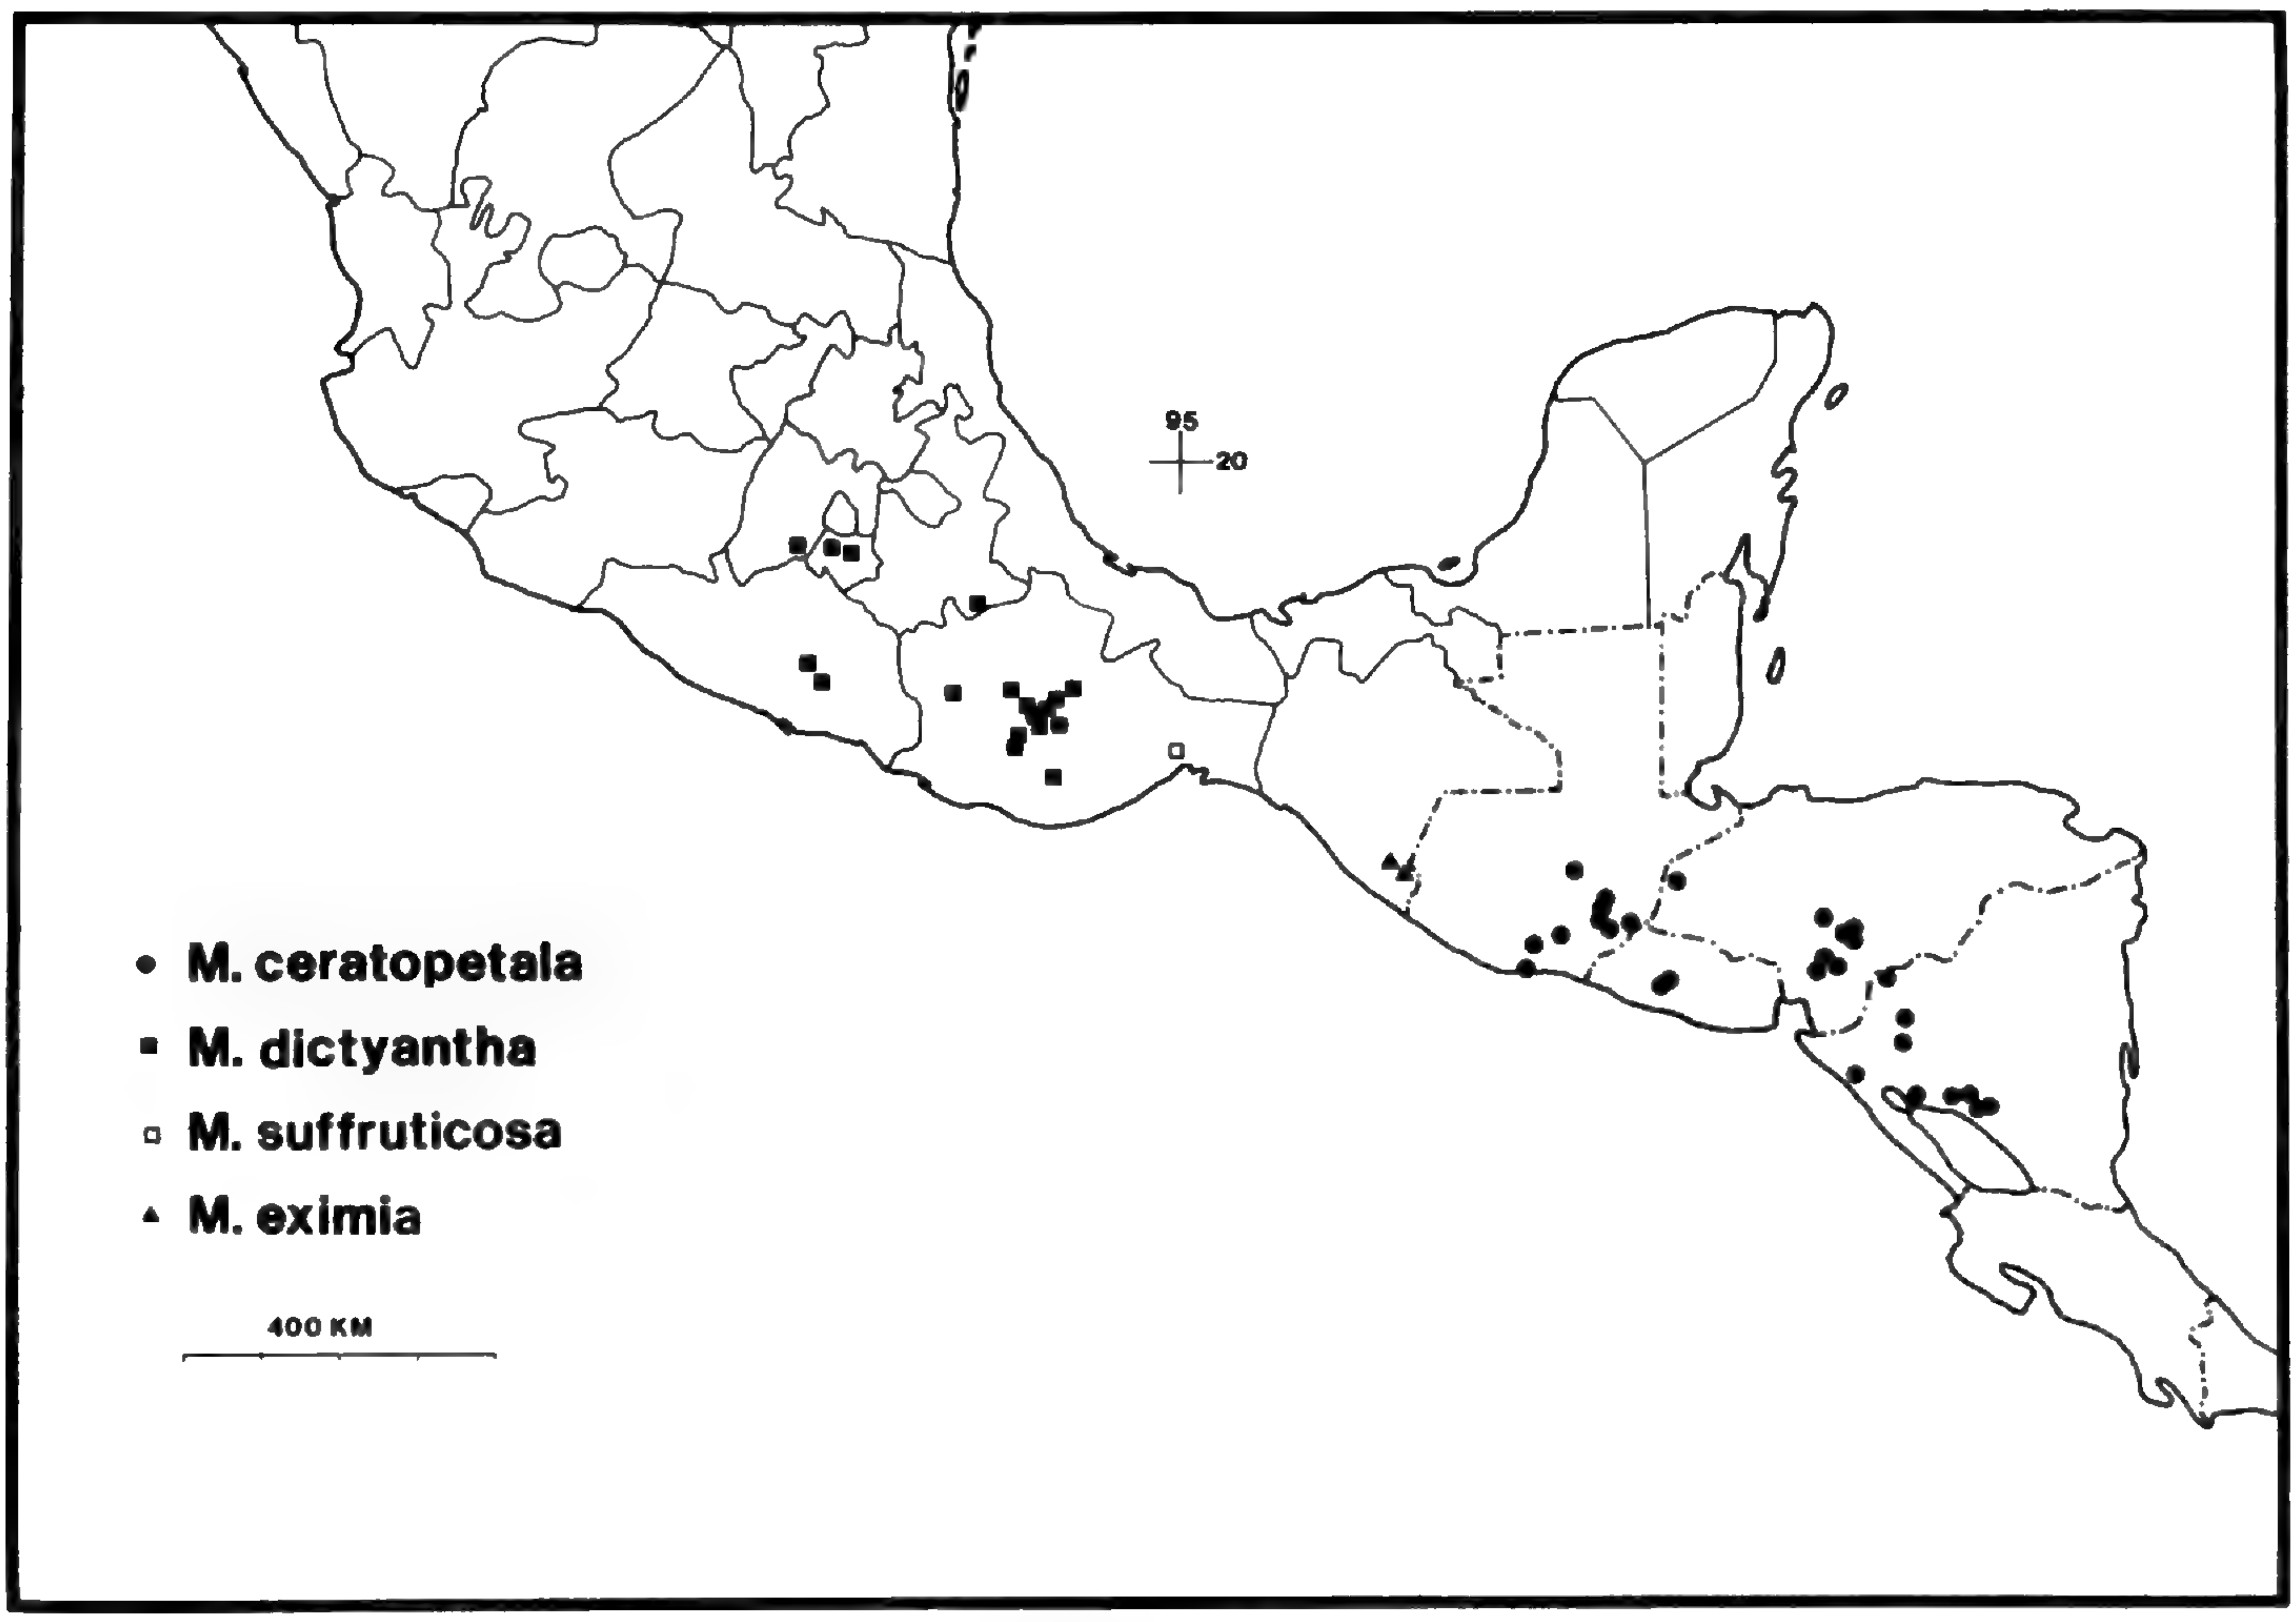

FIGURE 13. *Distributions of* Matelea ceratopetala, M. dictyantha, M. suffruticosa, *and* M. eximia.

tozintla SW of Toliman, 700 m, 7 Oct. 1972 (fl), *Breedlove 28682* (DS).

Known only from the type collection and one other, both from the southern corner of Chiapas (Fig. 13).

This new species is clearly related to *Matelea ceratopetala,* with which it has a contiguous but apparently allopatric range. These two species are quite similar in general aspect and are the only ones in the subgenus where the trailing stems typically root at the nodes. The flowers of the two known collections of *M. eximia* are rather different in appearance, perhaps because the Matuda collection was bleached of corolla coloration during preservation. The Matuda collection thus has a corolla limb with the regular circular veins intersecting the vertical veins and producing a regular angular reticulation; the Breedlove collection has the same pattern of veins but the circular veins are pigmented while the vertical are not, resulting in a circular pattern. Both are different, however, from the irregular roundish pigmented reticulations of *M. ceratopetala.* The additional differences in limb indumentum, corona septa, and style apex apiculum leave little doubt that neither collection pertains to *M. ceratopetala,* nor to any other species of subgenus *Dictyanthus*; but until *M. eximia* is better known, there must remain some doubt that the two collections are properly associated.

10. Matelea dictyantha Woodson, Ann. Missouri Bot. Gard. 28: 236. 1941, based on *Rytidoloma reticulatum* Turczaninow. *Rytidoloma reticultum* Turczaninow, Bull. Soc. Imp. Naturalistes Moscou 25(2): 319–320. 1852, not *Matelea reticulata* (Engelmann ex A. Gray) Woodson. *Dictyanthus reticulatus* (Turczaninow) Bentham & Hooker f. ex Hemsley, Biol. Cent.-Amer., Bot. 2: 329. 1882. TYPE: México. Oaxaca: "Sierra San Pedro Nolasco, Talea, etc.," 1843–1844 (fl), *Jürgensen 692* (holotype, KW, not seen; isotype, K). Figure 14.

Plants erect to trailing or twining. Stems 15–70(–150+) cm long, with a woody caudex to 5 cm long and 3 cm wide, this with thin to thick corky bark, or occasionally with an elongate woody rhizome, also often with woody stems above caudex or rhizome, these usually with thin corky bark and up to ca. 5 cm long but occasionally up to 20 cm long, herbaceous stems with dense short and glandular trichomes and sparse to dense, mostly straight long trichomes to 3 mm long. Leaf blade wide-ovate to very wide-ovate, 26–62(–103) mm long, 24–52(–76) mm wide, with long uncinate trichomes and also often glandular trichomes on veins below, surface smooth, smaller veins sharply raised below, apex acute to attenuate or rarely obtuse, base lobate, lobes mostly convergent to descending, with 1–6(–8) acropetiolar colleters, margin often somewhat thickened and revolute; petiole (11–)14–34(–57) mm long, with dense short and glandular trichomes and sparse to dense uncinate long trichomes. Inflorescence sometimes reduced to a single flower with or apparently without a rudimentary peduncle; peduncle absent–10 mm long, with indumentum of petiole; bracts linear to lanceolate, 2.5–7 mm long, abaxial surface with indumentum of stem, adaxial surface glabrous; pedicel 5–12 (–16) mm long, sometimes markedly accrescent in fruit, with indumentum of stem. Calyx lobes narrow-ovate or occasionally lanceolate or ovate, 6–11 mm long, 2.5–6 mm wide, apex acute to attenuate, with one colleter below each sinus or occasionally these somewhat above sinus near margin of lobe, abaxial surface with indumentum of stem, adaxial surface glabrous. Corolla campanulate, base to sinus length (7–)9–16 mm, limb revolute; lobes 8–14 mm long, apex acute or sometimes rounded, patent to strongly reflexed, margin revolute; glabrous within except with sparse to dense short trichomes around corona lobes and on limb and bases of lobes or sometimes over whole surface of lobes, indumentum on outside of short trichomes and occasionally also with long trichomes on limb and bases of lobes, or occasionally tube and tips of lobes nearly glabrous; tube convoluted with the raised parts opposite the corona lobes and deep sacs formed between them; faintly to densely gray-purple-reticulate, reticulations wider within tube. Corona lobes (5–)6–8 mm long, linear in outline with a raised margin, connate at base, adnate by a thin septum to gynostegium, this septum continuing as a narrow ridge nearly the length of lobe. Gynostegium 3–4 mm high and 3–3.5 mm wide at apex, stipitate, apex broadly and shallowly concave with corpuscula as high points. Corpusculum 0.22–0.35 mm long, 0.09–0.17 mm wide, pollinia 1.17–1.45 mm long, 0.29–0.38 mm wide. Follicles (45–)55–70 mm long, 10–22 mm wide, pale green with a few dark green stripes, with short and glandular trichomes, with (30–)50–110 straight to arcuate projections to 3 mm long. Seeds ca. 5.5 mm long and 4–4.5 mm wide, with a raised, radially grooved margin, this weakly toothed distally, inside this margin flat or slightly concave and verrucate on one side, convex and verrucate on the opposite side, the flat side with a slight ridge from apex to near center, pale brown to brown; coma 25–30 mm long.

Collected in the mountains of four more or less discrete areas: around Cuernavaca (Morelos and adjacent state of Mexico), around Chilpancingo (Guerrero), around Oaxaca (Oaxaca), and in southwestern Puebla (Fig. 13). Found at elevations of ca. 1,500–2,500 m. About a third of the collections are noted as being on or associated with limestone, and many of the other localities are in limestone areas, but whether or not *Matelea dictyantha* is restricted to limestone is uncertain. Mostly in low, open oak, pine, or pine–oak forests, especially where disturbed. Flowering mid June to mid September. Mature-sized fruits collected August–December, mature seeds only in December.

As mentioned under *Matelea macvaughiana*, Woodson provided the epithet for *M. dictyantha* quite by accident. He did not distinguish it from *M. ceratopetala*, to which it bears some resemblance in the shape and color pattern of the corolla and the size and shape of the leaves. The major characteristics distinguishing *M. dictyantha* from *M. ceratopetala* include the woody caudex and predominantly shorter habit, the smaller flowers, the lack of a tooth on the septum connecting the corona lobe to the gynostegium, the concave rather than apiculate gynostegium apex, and the smaller follicles with smaller and more numerous projections. The geographic ranges of the two species are also distinct. The distinctiveness of *M. dictyantha* from *M. ceratopetala* has been noted on two specimens, *Conzatti 2168* at F (unsigned and undated) and *Pringle 4768* at GH (J. M. Greenman, 18 Sep. 1890). Standley (1924) considered *Rytidoloma reticulatum* to be synonymous with *Matelea pavonii*.

The form of Turczaninow's protologue (1852) has led to some confusion. The apparent generic description is actually a description of the genus and its single species and cites *Jürgensen 692*. Immediately following the genus–species description is the entry "18. *R. reticulatum*. Altera species hujus generis, quantum e flore unico, Ptino corrupto, dijudicare possum, adest in collectione Galeottiana ex Oaxaca sub n. 1563." This led Langman (1964: 748) to state that *Rytidoloma reticulatum* was based on a Galeotti collection. Turczaninow was actually indicating that he recognized another

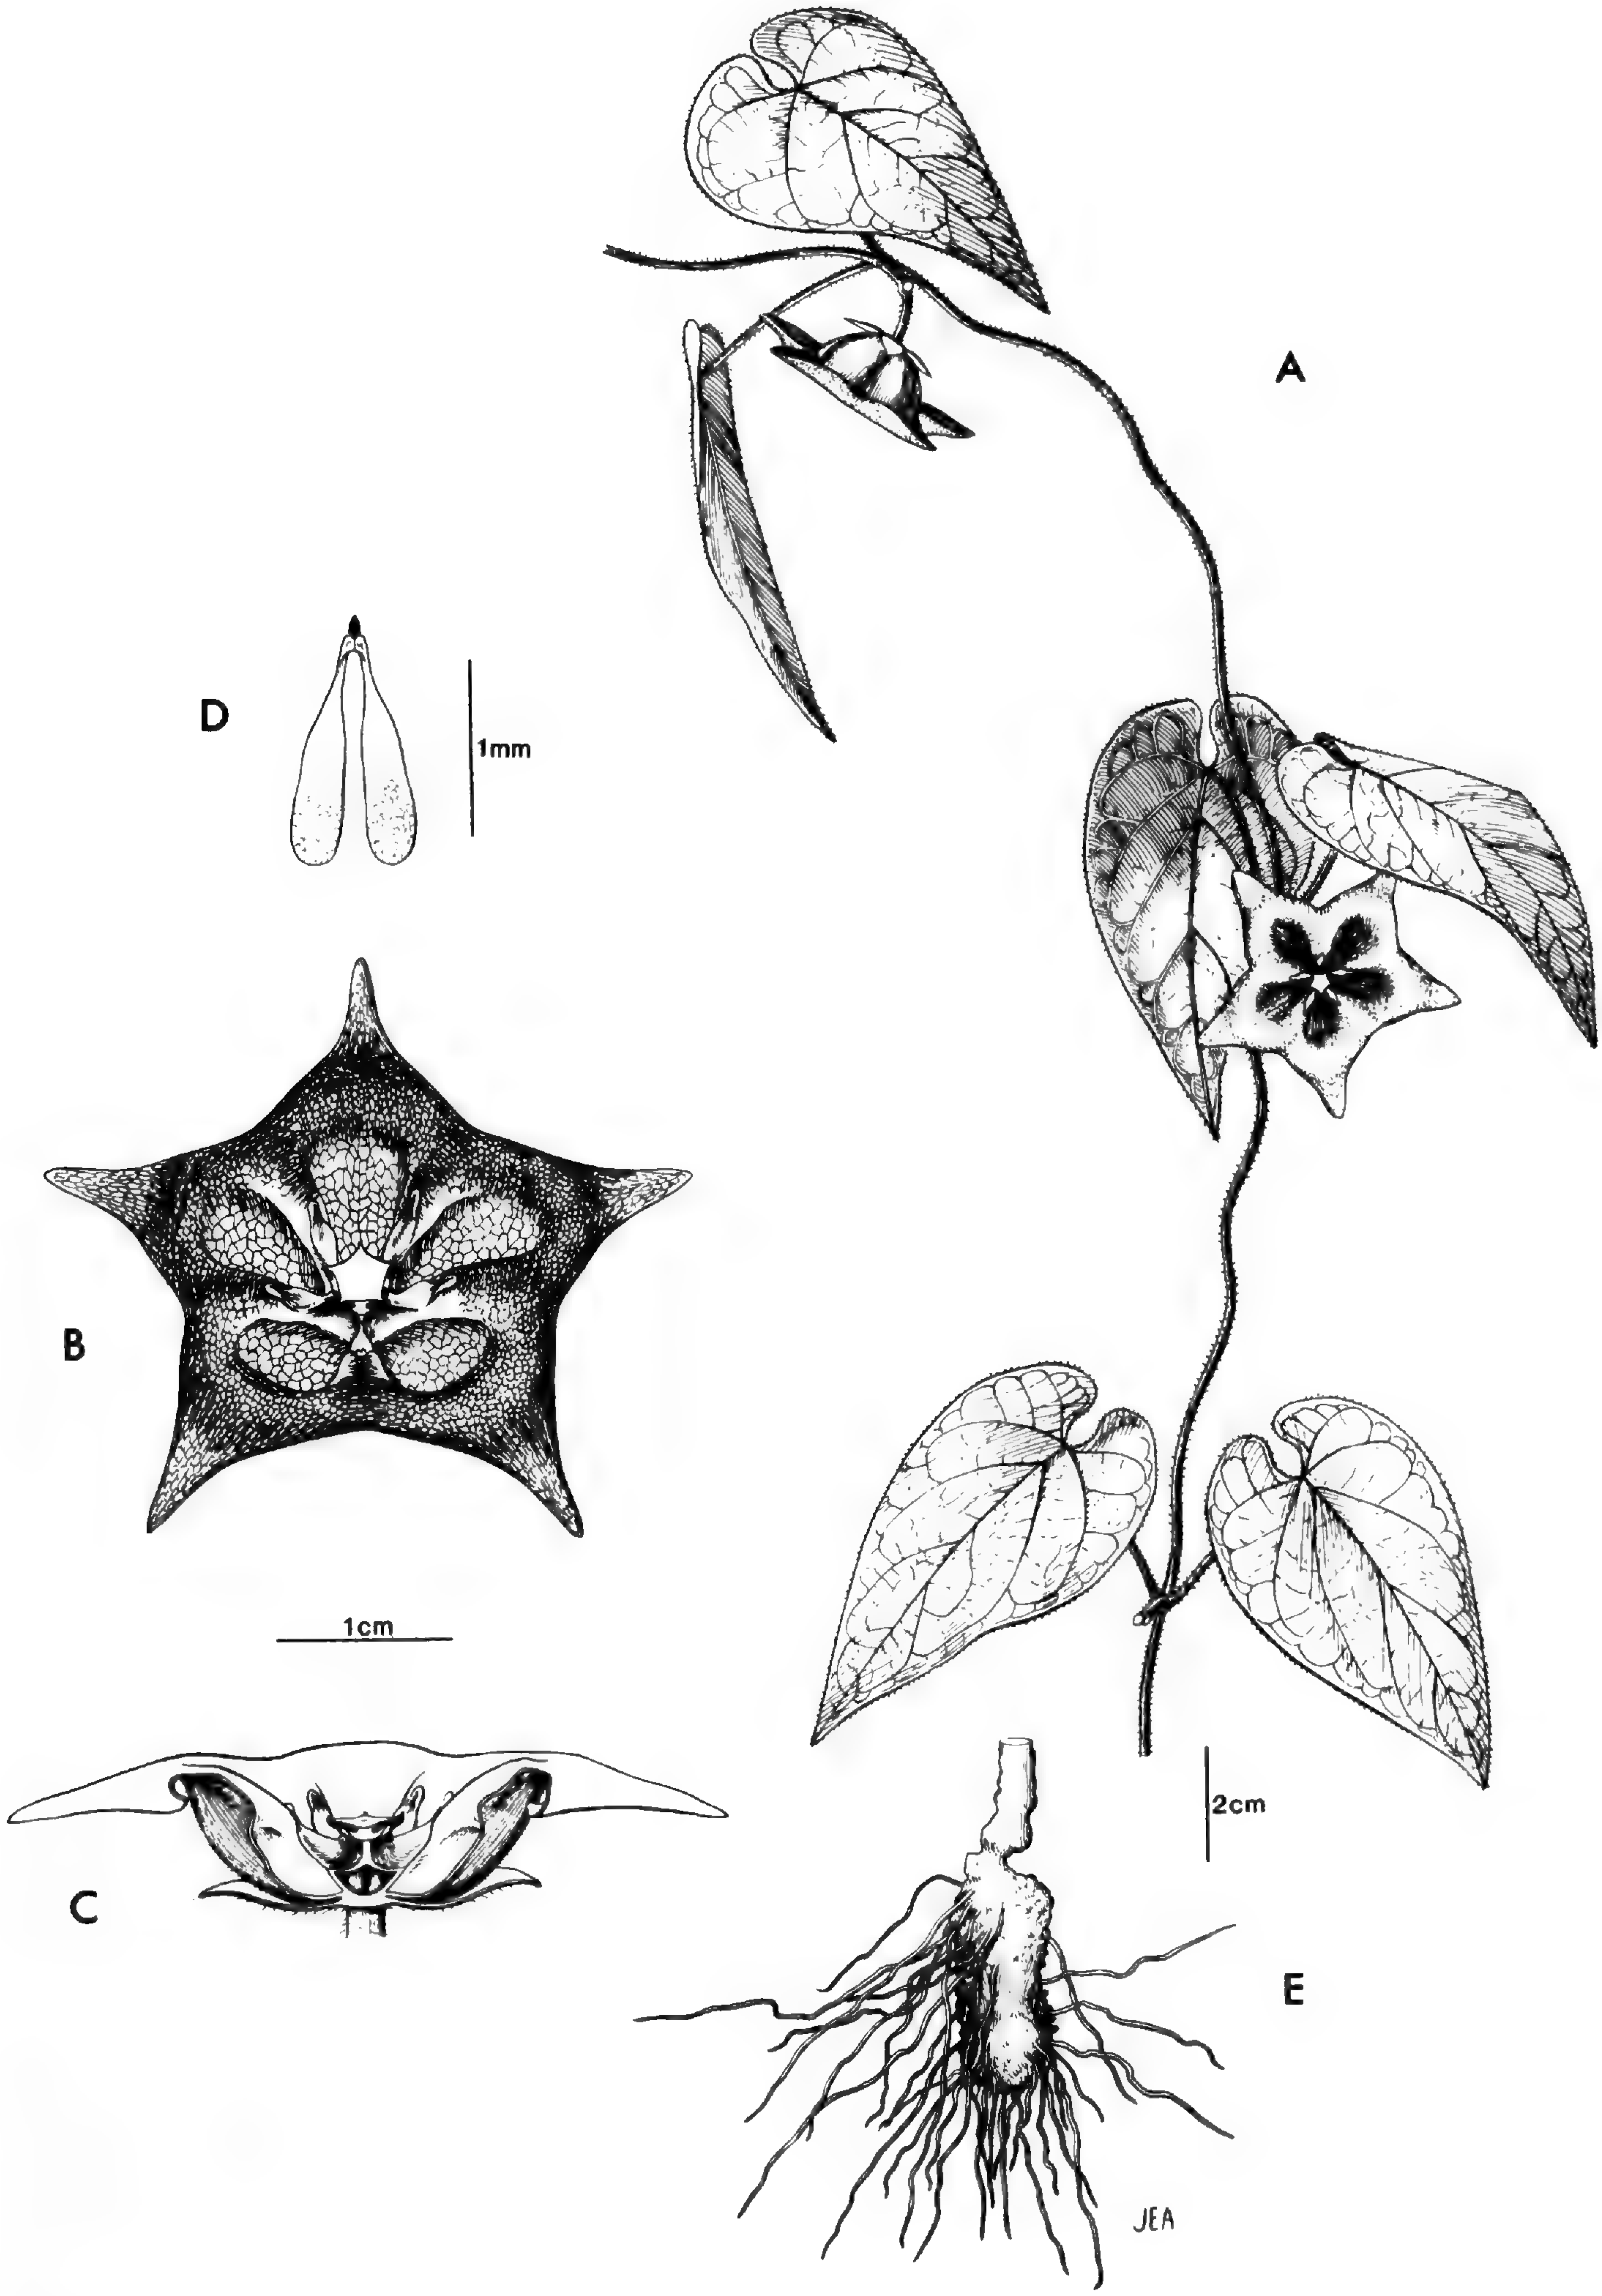

FIGURE 14. Matelea dictyantha *(A–D from* Stevens C-105, *a cultivated specimen of* Graham 1231; *E from* Stevens 1311*)*.—*A. Section of flowering stem.*—*B, C. Flowers.*—*D. Bipollinium.*—*E. Caudex.*

species in his new genus, but he neither named nor described it. *Galeotti 1563* is indeed a different species, *Matelea standleyana.*

As with *M. hemsleyana,* two somewhat distinctive elements of *M. dictyantha* can be recognized, but it does not seem that they warrant taxonomic recognition on the basis of currently available material. The flowers of the Morelos and Guerrero element tend to be larger, more shallowly campanulate, and much lighter in color than the Puebla-Oaxaca element. In this case the ranges are apparently distinct, but I have found no objective way of describing the difference in dried specimens. Perhaps with additional field study their separation will become more feasible. In this connection, it is most likely that the specimens of *Ghiesbreght s.n.* from "province d'Oaxaca" were actually collected at Cuernavaca, Morelos; such mixing of labels apparently often occurred with Ghiesbreght specimens.

11. Matelea suffruticosa W. D. Stevens, sp. nov. TYPE: México. Oaxaca: 4 mi. W of junction of Mex. 185 with Mex. 190, near La Ventosa, 17 Aug. 1971 (fl), *Wunderlin, Dwyer, Spellman & Vaughn 800* (holotype, MO; isotype, MEXU). Figure 15.

Matelea suffruticosa W. D. Stevens; *M. yucatanensis* atque *M. aeneae* affinis coronae apicibus propriis sed inter species subgeneris *Dictyanthi* forma corollae (tubo anguste campanulato, limbo in sinibus abrupte reflexo, lobis erectiusculis) notabilis.

Plants apparently suffrutescent with twining tips. Woody stems with thin corky bark, herbaceous stems with dense short and glandular trichomes and moderately dense uncinate long trichomes to 1.5 mm long. Leaf blade ovate to wide-ovate, 40–51 mm long, 27–39 mm wide, indumentum of short and glandular trichomes on and near major veins and moderately dense (above) to dense (below) uncinate long trichomes, surface smooth, apex acuminate, base lobate, lobes descending, with 5–7 acropetiolar colleters, margin somewhat thickened, revolute, and crispate; petiole 36–53 mm long, with indumentum of stem. Inflorescence sometimes with a smaller adjacent cyme apparently produced lateral to the axillary bud, that is, originating between the axillary bud and the normal extra-axillary inflorescence; peduncle to 1 mm long, with dense short and glandular trichomes; bracts linear to lorate, margins mostly revolute, 1–2 mm long, with short, glandular, and uncinate long trichomes abaxially, glabrous adaxially; pedicel 1.5–2.5 mm long, with indumentum of stem. Calyx lobes decurrent on pedicel, elliptic to wide-elliptic, 3.3–4.5 mm long, 1.6–1.7 mm wide, apex acute, with one colleter below each sinus, abaxial surface with dense short, glandular, and uncinate long trichomes, adaxial surface glabrous. Corolla narrowly campanulate, base to sinus length 5.5–6.5 mm, limb sharply reflexed at each sinus; lobes 4–5 mm long, apex rounded, apparently erect, margins revolute; tube glabrous within, limb and lobes with stiff, erect, glassy, apparently unicellular trichomes 0.1–0.2 mm long, outer surface of corolla with dense short, glandular, and uncinate long trichomes; tube apparently suffused with deep purple, becoming purple-reticulate on limb and lobes. Corona lobes 3–3.5 mm long, linear-spathulate with tip deeply convoluted, glistening purple-black, separate to base, base (below style apex) yellow and glistening. Gynostegium ca. 2 mm high and 1.5 mm wide at apex, short-stipitate, apex nearly plane with corpuscula forming high points and center slightly convex, terminal anther appendages covering about half of apex. Corpusculum ca. 0.25 mm long, 0.17 mm wide, pollinia ca. 0.53 mm long, 0.37 mm wide. Fruits and seeds unknown.

Known only from the type collection, from the south side of the Isthmus of Tehuantepec (Fig. 13), probably below 100 m elevation.

This new species has some striking innovations but nonetheless fits easily into the subgenus and, despite its distinctive appearance, is probably closely related to the two species from the Yucatan. The exaggerated development of the corolla limb at the sinuses, which even at the bud stage is obvious as the sinuses have the appearance of recurved horns, causes the modified tips of the corona lobes to be presented in a unique fashion, at the distal margin of the limb, with which they contrast in color, between the erect and revolute corolla lobes. The hairs on the inside of the corolla, the occasional subsidiary inflorescences, and the roundish (rather than pentagonal) style apices appear to be unique in the subgenus but not in the genus as a whole. The highly modified tips of the corona lobes suggest a link between this species and the two Yucatan species, as does similarity in indumentum.

12. Matelea aenea (Woodson) W. D. Stevens, comb. nov. *Dictyanthus aeneus* Woodson, Amer. J. Bot. 22: 691, pl. 1, fig. 4. 1935. TYPE: México. Yucatán: Progreso, 11–15 Aug. 1932 (fl), *Steere 3005* (holotype, MO; isotype, MICH). Figure 16.

Plants twining vines. Stems woody below, with thin to thick corky bark, herbaceous stems with

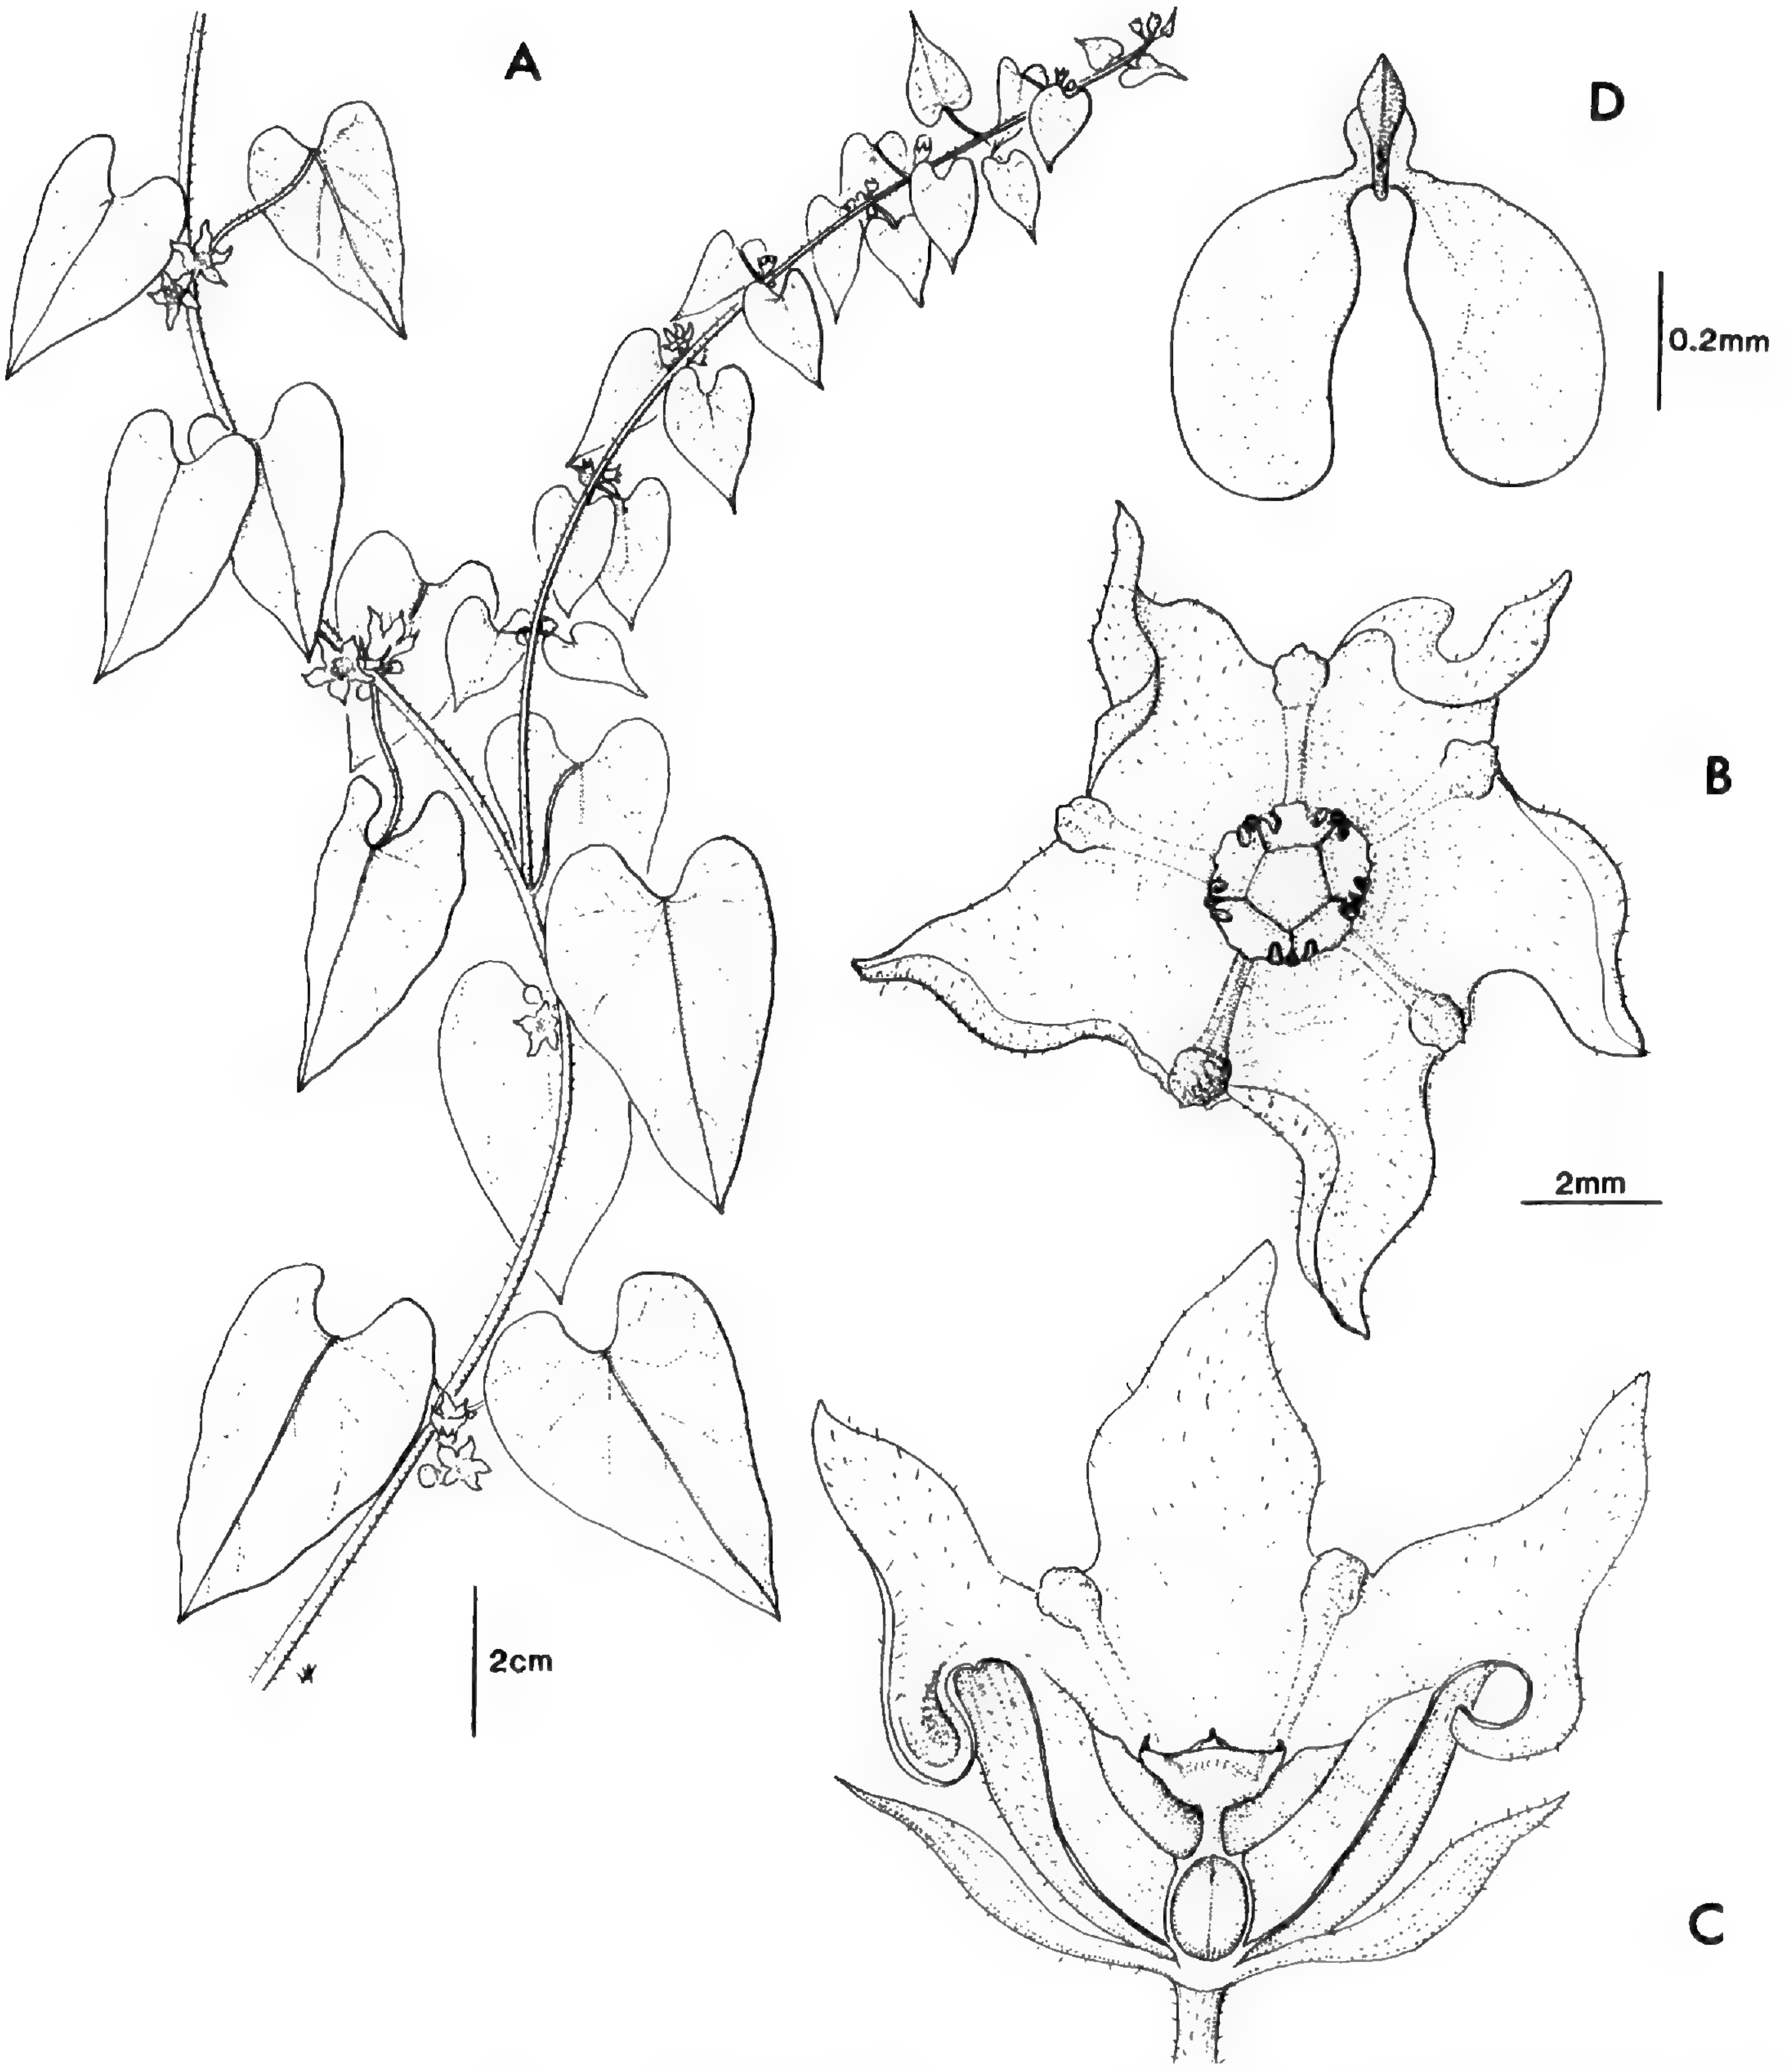

FIGURE 15. Matelea suffruticosa (Wunderlin et al. 800).—*A. Section of flowering stem.—B, C. Flowers.— D. Bipollinium.*

dense short and glandular trichomes and dense uncinate long trichomes to 2.5 mm. Leaf blade wide-ovate to very wide-ovate or occasionally ovate, 35–98 mm long, 26–70 mm wide, indumentum of uncinate long trichomes and of glandular trichomes on veins below, surface smooth, apex acute to acuminate, base lobate, lobes convergent to widely divergent, with 4–11 acropetiolar colleters, often crispate; petiole 21–62 mm long, with indumentum of stem. Peduncle 4–11 mm long, with indumentum of stem; bracts linear to lanceolate, 3–4 mm long, with indumentum of stem or occasionally glabrous on adaxial surface; pedicel ca. 4 mm long, with indumentum of stem. Calyx lobes lanceolate to narrow-ovate, 6–9 mm long, 2–4.5 mm wide, apex acute to attenuate, with 1(2) colleter(s) below each sinus, abaxial surface with dense short, glandular, and uncinate long trichomes, adaxial surface

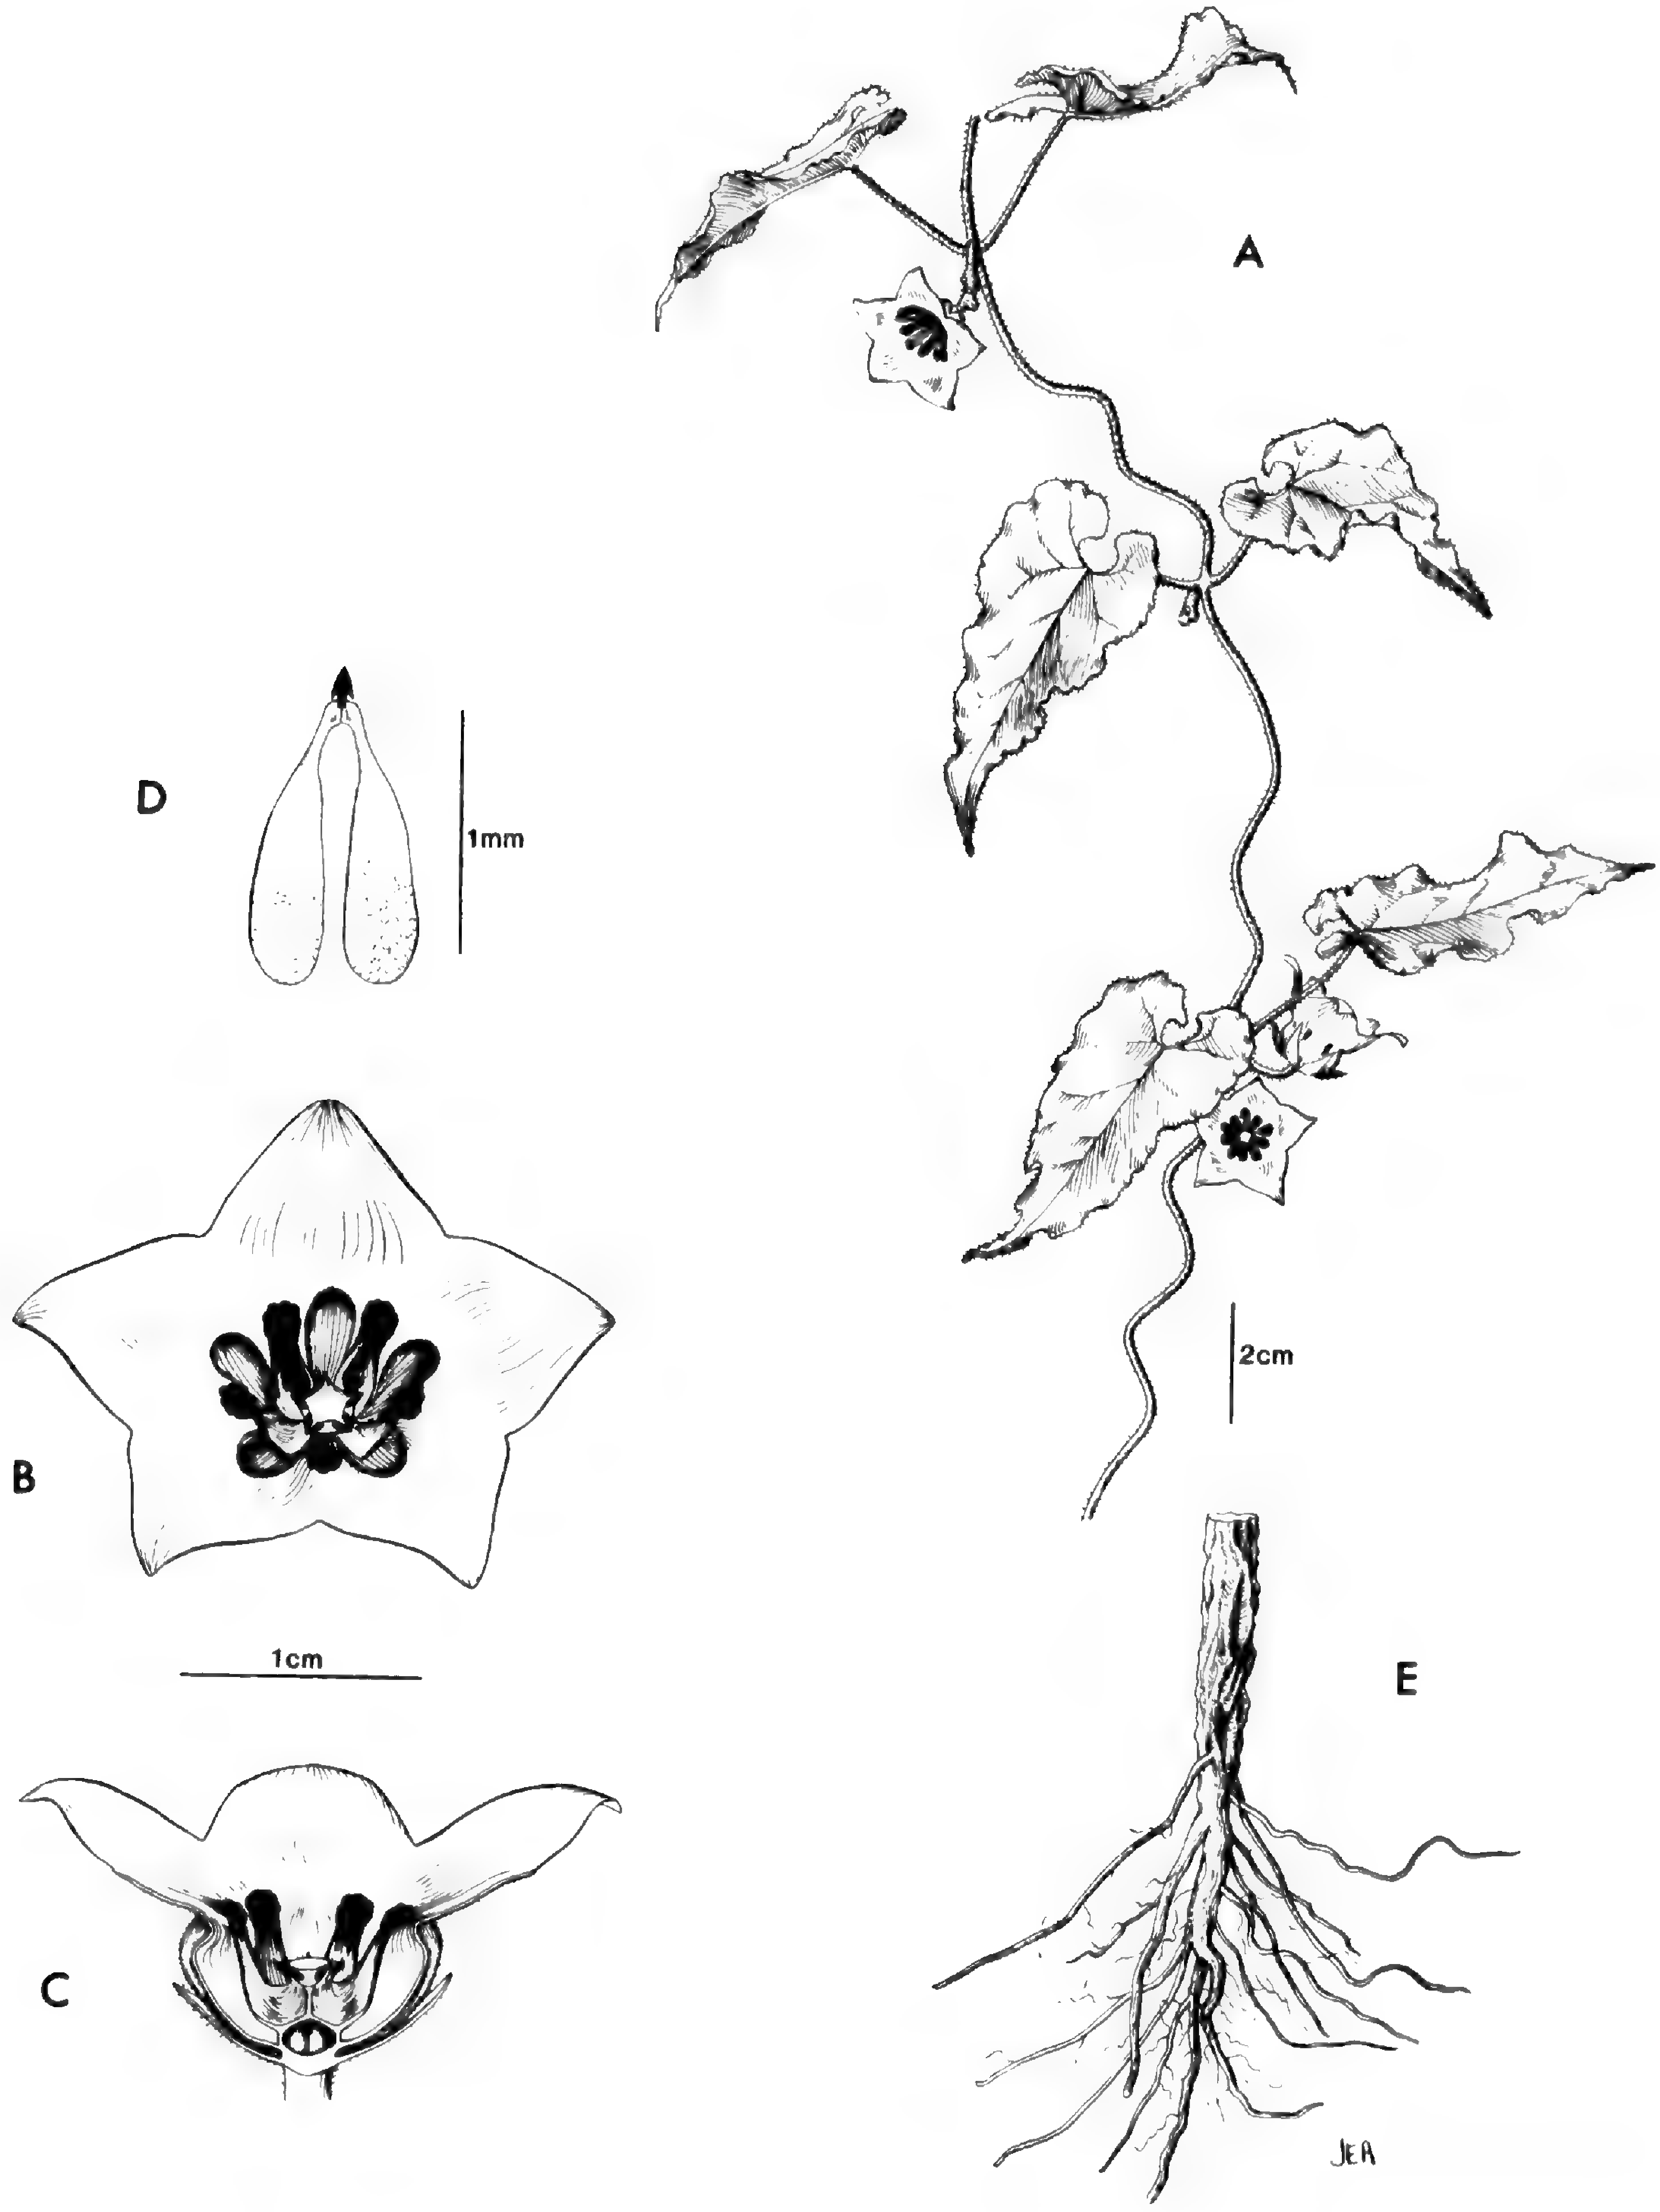

FIGURE 16. Matelea aenea *(A–D from* Stevens C-157, *a cultivated specimen of* Stevens 1145; *E from* Stevens 1145*).—A. Section of flowering stem.—B, C. Flowers.—D. Bipollinium.—E. Base of stem.*

glabrous. Corolla campanulate, base to sinus length (6–)8–12 mm, limb ascending to nearly patent, not revolute; lobes 5–9 mm long, length to width (sinus–sinus) ratio 0.67–0.78, apex acute or rounded, ascending to slightly reflexed at tip, margin not revolute; glabrous within except with dense short trichomes on limb and lobes, indumentum on outside of short, glandular, and uncinate long trichomes; tube convoluted with raised parts opposite corona lobes and forming deep sacs between them; pale yellow-green, sometimes with faint reticulations, these often drying darker. Corona lobes 6–8 mm long, linear-spathulate in outline with tip deeply rugose and glistening purple-black, otherwise yellow-green or tinted purple, connate at base, adnate by a thin septum to gynostegium, this septum continuing as a narrow ridge nearly the length of the lobe. Gynostegium ca. 3 mm high and ca. 2.5 mm wide at apex, stipitate, apex broadly and shallowly concave with corpuscula as high points and occasionally also slightly convex in center, terminal anther appendages hardly covering margin of apex. Corpusculum 0.21–0.28 mm long, 0.12–0.15 mm wide, pollinia 1.08–1.18 mm long, 0.35–0.37 mm wide. Follicles ca. 95 mm long, ca. 20 mm wide, finely mottled, probably green and white, with scattered short and glandular trichomes, with ca. 40 thick projections to 2 mm long. Seeds ca. 4.5 mm long and 3 mm wide, with a raised, radially grooved margin, this essentially entire, inside this margin essentially flat on one side and convex on the other, both sides deeply verrucate to deeply rugose, dark brown; coma ca. 40 mm long.

Collected only in the vicinity of Progreso, on the tip of the Yucatan Peninsula (Fig. 10), at near sea level. Growing in low scrub vegetation in thin, limestone-derived soils, apparently where not particularly saline. Collected flowering June–August and in December.

In describing *Dictyanthus aeneus*, Woodson (1935) summarized the differences as follows: "*T. aeneus* differs from *T. yucatanensis* Standl. [sic] superficially in the smaller and more shortly petiolate leaves with paler color and hispidulous or strigillose surfaces, and smaller, paler corollas with a more pronounced campanulate tube. Structural differences of the corolla and corona are conspicuous as well." Later, Woodson (1941) considered *Dictyanthus aeneus* to be a synonym of *Matelea yucatanensis* (Standley) Woodson and so annotated the type specimen. I concur with his original recognition of *Dictyanthus aeneus*, but unfortunately his characters are not very diagnostic and, in fact, his drawing of the flower (Woodson, 1935; pl. 1, fig. 4a) has the shape of *Matelea yucatanensis* and the size of *M. aenea*. The best characters for separating the two species are most easily observable in fresh flowers. The corolla limb and lobes of *Matelea yucatanensis* form essentially a right angle with the tube and have revolute margins, while those of *M. aenea* are ascending and do not have revolute margins. This difference can often still be seen in dried specimens when not carefully pressed. The corolla color is also strikingly different in fresh flowers, being yellow-green with faint reticulations in *M. aenea* and densely gray-purple-reticulate in *M. yucatanensis*. Unfortunately, *M. aenea* sometimes darkens in drying and this difference is partially obscured. The most dependable floral characters in pressed specimens are the size and shape of the corolla lobes, but even with these the flowers often require boiling to be measured accurately. As noted in the descriptions, *M. aenea* has shorter and proportionately wider corolla lobes. There seem to be certain vegetative differences as well, but the variation within each species is large and there are too few specimens to make possible any meaningful conclusions. *Matelea aenea* tends to have denser long trichomes on the vegetative parts and smaller, wider, more crispate, and less purple-pigmented leaves. Although obviously very closely related and the only two species of the subgenus *Dictyanthus* occurring on the Yucatan Peninsula, *M. aenea* appears to be restricted to the coastal area immediately around Progreso, while *M. yucatanensis* is found at scattered, mostly inland, localities. Both species are too poorly collected, however, to support much conjecture on their relative distributions.

13. Matelea yucatanensis (Standley) Woodson, Ann. Missouri Bot. Gard. 28: 237. 1941. *Dictyanthus yucatanensis* Standley, Publ. Field Columbian Mus., Bot. Ser. 8: 37. 1930. TYPE: México. Yucatán: without precise locality or date (fl), *Gaumer 933* (holotype, F; fragment of holotype, G). Figure 17.

Plants twining vines. Stems woody below, with thin to thick corky bark, herbaceous stems with dense short and glandular trichomes and dense uncinate long trichomes to 2.5 mm long. Leaf blade ovate to wide-ovate or occasionally very wide-ovate, (39–)45–95 mm long, 24–81 mm wide, indumentum of uncinate long trichomes and also glandular trichomes on veins below, surface smooth, apex acuminate to attenuate, base lobate, lobes mostly

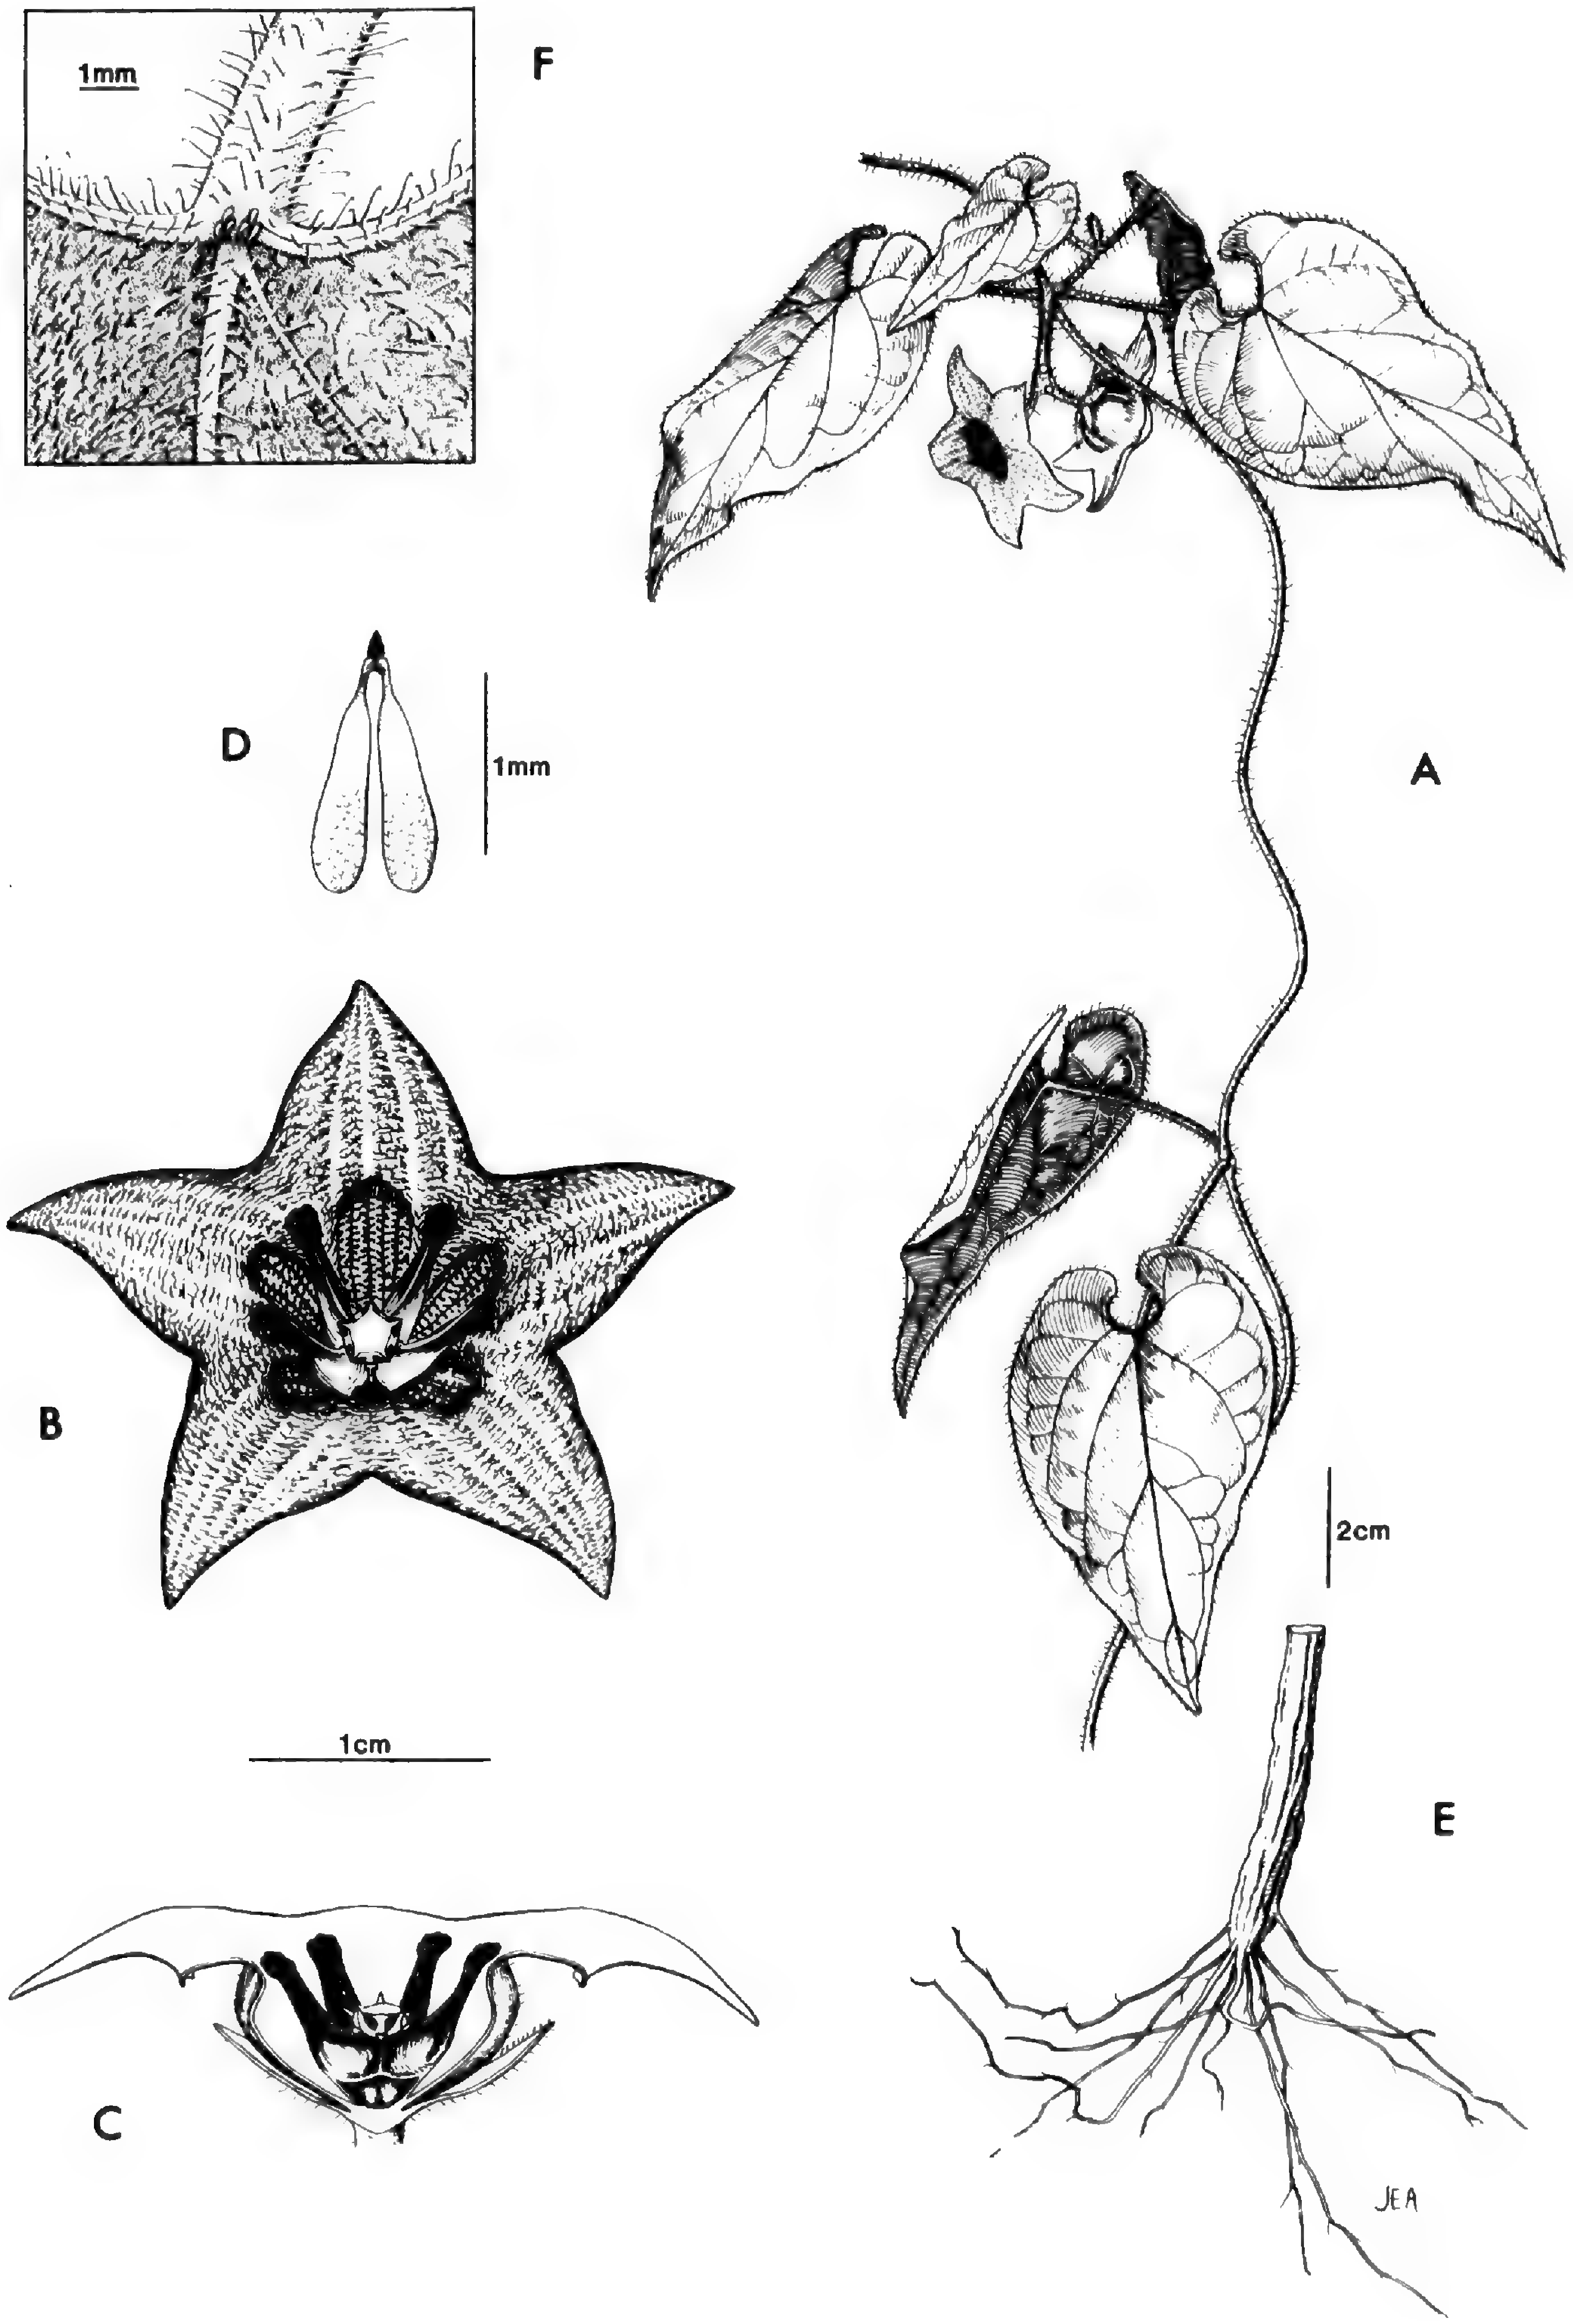

FIGURE 17. Matelea yucatanensis (Stevens C-158, *a cultivated specimen of* Stevens 1168).—*A. Section of flowering stem.—B, C. Flowers.—D. Bipollinium.—E. Base of stem.—F. Base of adaxial surface of leaf blade, showing acropetiolar colleters.*

convergent to descending, with 4–10 acropetiolar colleters, margin often crispate; petiole (22–)42–57(–82) mm long, with indumentum of stem. Peduncle 2–9 mm long, with indumentum of stem; bracts linear to lanceolate, 3–5 mm long, with indumentum of stem or sometimes with long trichomes on margin only and glabrous on adaxial surface; pedicel 3–5(–7) mm long, with indumentum of stem. Calyx lobes lanceolate to narrow-ovate, 7–10 mm long, 2–3.5 mm wide, apex acute to attenuate, with 1(2) colleter(s) below each sinus, abaxial surface with scattered short trichomes, dense glandular trichomes, and scattered uncinate long trichomes or occasionally nearly glabrous, adaxial surface glabrous. Corolla campanulate, base to sinus length (7–)10–11 mm, limb patent, revolute; lobes 7–12 mm long, length to width (sinus–sinus) ratio 0.83–1.20, apex acute, patent or slightly reflexed at tip, margin revolute; glabrous within except with sparse to dense short trichomes on limb and lobes, indumentum on outside of short, glandular, and uncinate long trichomes; tube convoluted with raised parts opposite corona lobes and forming deep sacs between them; densely gray-purple-reticulate, reticulations wider in tube. Corona lobes (4–)5–7 mm long, linear-spathulate in outline with tip deeply rugose and glistening purple-black, otherwise deep purple, connate at base, adnate by a thin septum to gynostegium, this septum continuing as a narrow ridge nearly the length of lobe. Gynostegium 3–3.5 mm high and 2.5–3 mm wide at apex, stipitate, apex broadly and shallowly concave with corpuscula as high points and occasionally also slightly convex in center, terminal anther appendages hardly covering margin of apex. Corpusculum 0.24–0.26 mm long, 0.12–0.15 mm wide, pollinia 1.11–1.26 mm long, 0.28–0.35 mm wide. Follicles ca. 95 mm long, ca. 15 mm wide, finely mottled green and white, with scattered short and glandular trichomes, with ca. 55 thick projections to 4 mm long. Seeds ca. 4.5 mm long and 3.5 mm wide, with a raised, faintly radially grooved margin, this entire, inside this margin essentially flat on one side and convex on the other, both sides deeply verrucate to deeply rugose, dark brown; coma ca. 35 mm long.

The identifiable collection localities are scattered in the state of Yucatan (Fig. 10), at elevations probably well below 200 m. Almost certainly to be expected in the adjacent areas of Campeche and Quintana Roo. Growing in low forests and second growth and probably always in limestone-derived soils. Collected flowering in June, July, and October and fruiting in October.

Most closely related to *Matelea aenea*; for comparison see discussion under that species. These two species form a distinct unit morphologically and are geographically isolated from the other species of subgenus *Dictyanthus*. They are obviously related to *M. suffruticosa* and the several species grouped with *M. pavonii* but have clear affinities only with the former. Their most conspicuous innovation, besides occupying a unique region and a unique environment (karst limestone), is the highly modified tip of the corona lobe. These tips glisten as if they are wet but apparently produce no secretion. They may function as "pseudonectaries." It should be noted, however, that the sides of the corona lobes are secretory in apparently the same manner as the species grouped with *M. pavonii*. These two species, along with *M. suffruticosa*, are also unique in having predominantly uncinate long trichomes on the internodes, the other species considered here having either entirely straight or only occasionally a few uncinate long trichomes on the internodes.

FLORA OF THE VENEZUELAN GUAYANA—VI[1]

Julian A. Steyermark[2]

ABSTRACT

Studies in the genus Sloanea *(Elaeocarpaceae) for the* Flora of the Venezuelan Guayana *have yielded changes in nomenclature and taxonomic concepts in addition to the following new taxa:* Sloanea bolivarensis, S. cataniapensis, S. davidsei, S. longiaristata, S. merevariensis, S. parvifructa, S. sipapoana, S. steyermarkii *subsp.* autanae, S. steyermarkii *subsp.* jauaensis, S. subpsilocarpa, *and* S. wurdackii. *Notes pertaining to the families Rapateaceae, Bombacaceae, and Theaceae are included.*

RAPATEACEAE

In preparing the treatment of Rapateaceae for the *Flora of the Venezuelan Guayana*, a number of discrepancies have been noted in the previous treatments by Maguire (1958, 1982). In the interest of placing these observations on record before the publication of the flora, the following data are presented.

AMPHIPHYLLUM

Amphiphyllum rigidum Gl.

Maguire (1982: 105) gave the length of the involucral bracts as 3–4 cm long. On the three specimens in VEN they measure 2–2.5 cm long.

CEPHALOSTEMON

Cephalostemon vs. *Duckea*

Maguire (1958) separated *Duckea* on the basis of the exappendiculate seeds. I am unable to separate *Duckea* from *Cephalostemon* on gross morphological characters. They merge as noted in such species as *Duckea squarrosa* and *Cephalostemon gracilis* and should be combined under the earlier-published *Cephalostemon*.

Duckea flava becomes *Cephalostemon flavus* (Link) Steyerm., a new combination.

Cephalostemon flavus (Link) Steyerm., comb. nov. *Duckea flava* (Link) Mag., Mem. New York Bot. Gard. 10(1): 43. 1958.

Cephalostemon junciformis (Mag.) Steyerm., comb. nov. *Duckea junciformis* Mag., Mem. New York Bot. Gard. 10(1): 43, fig. 1. 1958.

Cephalostemon flavus vs. *Cephalostemon junciformis*

The bracteole apex is acute in *C. junciformis* and obtuse to rounded in the commoner *C. flavus*. Maguire (1958) distinguished them on the basis of the globose inflorescence 1–1.4 cm long of *C. junciformis* contrasted with the oblong inflorescence 2–4 cm long of *C. flavus*. This difference does not hold true: several collections of *C. flavus* have short globose inflorescences 1 cm long. Measurements show the following intergradation:

C. junciformis: heads 0.8–1.5 cm high, broadly hemispherical or subhemispherical.

C. flavus: heads 1–4 cm high, depressed subglobose to cylindric-oblong.

The depressed or subglobose short inflorescences of *C. flavus* are represented by the collections of *Maguire et al. 30800, 37662, 30487*; *Huber 4860, 3115, 3129*; and *Vareschi & Magdefrau 6718, 6590.*

Cephalostemon cyperaceoides vs. *Cephalostemon squarrosus*

In general, heads in *C. cyperaceoides* are 1–1.5 cm broad and smaller than in *C. squarrosus* with heads 2–2.5 cm broad. Yet heads in *C. cyperaceoides* vary in size and may reach 2 cm wide in such collections as *Huber & Medina 5905*. In others, such as *Maguire 29276* (identified as *C. squarrosus*), the heads are 2.5 cm wide, while the mature bracteoles are nerved and long attenuate or subulate but not squarrose. Although the bracteoles of *Steyermark 75323* are strongly nerved, they show varying degrees of squarroseness, some

---

[1] *This work was supported by National Science Foundation Grant BSR-85152085.*

[2] *Deceased, October 15, 1988.*

ANN. MISSOURI BOT. GARD. 75: 1565–1586. 1988.

scarcely or not at all squarrose, others only slightly so.

Also in *C. squarrosus*, specimens are found with strongly nerved squarrose bracteoles, but with small heads only 1.3 cm broad, as in *Vareschi & Magdefrau 6611* (VEN), so that overlapping appears in the sizes of the heads and in the degree of squarroseness. In *Maguire et al. 30799* (identified as *C. squarrosus*), the bracteoles are strongly nerved but are mainly ascending at maturity.

Moreover, *C. squarrosus* and *C. cyperaceoides* do not differ in the type of apex of the bracteole between as described by Maguire in his keys (1958: 42): "bracteoles . . . , apex strongly aristate" in *Duckea cyperaceoides* vs. "bracteoles . . . , apex merely acuminate" in *Duckea squarrosa*. Both have attenuate apices, and no fine distinction can be drawn: the two taxa may have to be merged eventually.

KUNHARDTIA

Kunhardtia rhodantha Mag., Mem. New York Bot. Gard. 10(1): 32, figs. 5, 6. 1958.

Schoenocephalium sipapoanum Mag., Acta Bot. Venez. 14(3): 17. 1984.

Schoenocephalium sipapoanum was based on a collection (*Steyermark et al. 124534*) from the summit of Cerro Sipapo. Although Maguire (1984—see above) noted that it had a general similar aspect to that of *Kunhardtia*, he placed the specimen in *Schoenocephalium* on the basis primarily of its anthers opening by four apical pores instead of being two-celled as in *Kunhardtia*. Other differences thought by Maguire to distinguish the two genera were the conspicuous exsertion of the porrect corollas and depressed-subglobose heads of *Kunhardtia* contrasted with the included corollas and sphaeroidal heads with the mature flowers radiate of *Schoenocephalium*.

These gross morphological characters were observed by the author at the time the type collection was made, and having already seen thousands of individuals of *Kunhardtia rhodantha* on the summit of the nearby Cerro Autana (Steyermark, 1974), the Sipapo collection was noted to be in all respects the same as the common *Kunhardtia rhodantha*. The depressed-subglobose, deep red heads with red, conspicuously exserted porrect flowers, and strongly imbricated leaf sheaths abruptly narrowed at their summits of the Sipapo collection match perfectly the numerous specimens in the colonies of *Kunhardtia rhodantha* seen on the summit of Cerro Autana.

Reexamination and careful comparison of the type collection of *Schoenocephalium sipapoanum* and *Kunhardtia rhodantha* does not reveal any further difference between them. Reexamination of the anthers in the type material of *Schoenocephalium sipapoanum* and *Kunhardtia rhodantha* shows no difference between the two. Moreover, the other characters pertaining to *Kunhardtia* as emphasized by Maguire, together with an examination of additional herbarium specimens, emphasizes the conspecifity of the two taxa.

MONOTREMA

Monotrema aemulans vs. *M. affine*

The key difference separating *M. aemulans* from *M. affine* in Maguire (1958: 46) is that in the former the primary bracts of the inflorescence do not exceed the head or do so only inconspicuously, whereas in *M. affine* they conspicuously exceed the head. However, specimens cited by Maguire, such as *Maguire et al. 30491* from Yapacana savanna, have the bracts somewhat exceeding the heads and are 13 mm long. Thus, *Maguire et al. 30491* could be placed in *M. affine* instead of *M. aemulans*. *Monotrema affine* may have the primary bracts only 10–15 mm long. The isotype of *M. affine*, from Yapacana at VEN, has the longest bracts only 15–16 mm long and barely exceeding the head. The leaves of *M. affine* vary in width from 5–9 mm up to 16 mm in *Huber 5939*, those of *M. aemulans* from 6 to 10(–15) mm. In *M. bracteatum* var. *bracteatum* the leaves are only 2–4(–5) mm wide except in var. *major*, where they are 6–12 mm wide.

Some specimens of *M. aemulans* have bracts usually 8–12 mm long, but in early stages preceding anthesis, as in *Steyermark et al. 130334* from Cerro Vinilla (VEN), they are only 1–5.5 mm long and equal the head, or they are slightly shorter to only slightly longer than the head. The two taxa are otherwise similar vegetatively and occur in the same Yapacana savanna.

The collections *Huber & Tillett 2965* (identified by Huber as *M. xyridoides*) and *Huber & Medina 5939* (identified by Maguire as "*M. affine* with broad leaf blades *vel valde aff.*") are forms with leaves 1.4–1.5 cm wide and leaf sheaths 14–15 cm long, whereas other collections of *M. affine* vary in leaf width from only 0.5 to 0.9 cm. The broadly ovoid heads are also longer than broad as in *M. xyridoides* and are 17–21 mm long × 12 mm broad at the middle. The outer involucral bract is 21 mm long and barely longer than the head. Perhaps these represent introgressive collections of *M. xyridoides* and *M. affine*. *Huber 1640*, identified as *M. bracteatum*, has the shorter broader outer bracts of *M. affine* and the shorter secondary bracts of *M. affine*.

A third species, *M. bracteatum*, with all the bracts elongated, occurs in the Yapacana savanna and occasionally is confused with *M. affine* which has shorter, broader outer bracts.

A fourth species, *M. xyridoides*, with heads usually longer than broad having bracteoles rounded or obtuse, likewise occurs in the Yapacana savanna.

Monotrema bracteatum may be confused with *Cephalostemon cyperacoides* on account of the outer bracts, which in *C. cyperacoides* are reflexed, whereas those of *M. bracteatum* and *M. affine* are spreading to ascending.

Monotrema bracteatum subsp. *bracteatum*

Huber 3268 from W of Serranía El Tigre (identified as *M. affine* by Maguire) represents *M. bracteatum* subsp. *bracteatum* with the bracts and bracteoles long pointed.

Monotrema arthrophyllum (Seub.) Maguire, Mem. New York Bot. Gard. 10(3): 47. 1958. *Schoenocephalium arthrophyllum* Seub. in Mart., Fl. Bras. 3(1): 131. 1847.

This species was originally described from Arara-Coara, Río Caquetá, Colombia. *Maguire et al. 44109* from scrub savanna, Araracuara, identified by Maguire as *M. aemulans* Körnicke, is a topotype of *Schoenocephalium arthrophyllum*. In his English key (1958, p. 46) Maguire gave "5–10-flowered" for *M. arthrophyllum*, as contrasted with "numerous" and "50–75-flowered" for *M. aemulans* in both his English (1958) and Spanish (1982) treatments. This collection matches the photo of the type of *M. arthrophyllum* in shape and width of leaf, abrupt contracted leaf sheath summit at the base of the leaf blade, and much shorter leaves compared with the peduncle length. The leaf blades are strongly 11-nerved on the lower side, 13–14 mm wide, 14–22 cm long, and show the leaf sheath strongly 7–8 nerved. This compares well with the type photo of *M. arthrophyllum*. Although *Maguire et al. 44109* has strongly nerved leaf sheaths, they do appear, although not very sharply, on the type photo of *Schoenocephalium arthrophyllum*.

A specimen from Yavita, Territorio Federal Amazonas (*Williams 14086*, VEN), originally identified by Maguire in 1950 as *M. arthrophyllum*, was later identified by him as *M. aemulans*. Although never cited by Maguire (1958, 1982), this specimen partly agrees with the description and key characters assigned by him (1958) to *M. arthrophyllum* in having fewer spikelets with heads which are not subdidymous. However, the linear leaves are only 3.5–7 mm wide, whereas in the photo of the type of *Schoenocephalium arthrophyllum* they are broader. The *Williams 14086* specimen from Yavita does not match either the photo or the *Maguire et al.* collection from Colombia. Its much narrower leaves 3.5–7 mm wide merge, but not abruptly, at the base into the leaf sheath, which is 6 cm long and 4 mm wide. Also, the leaf blade and sheath are not strongly nerved as in the Colombian collections and are 21–25 cm long. The head is 8 mm wide and hemispheric as in *M. aemulans*, but the head is too small and few-flowered to be placed in *M. aemulans*. Probably, as Huber concluded, the specimen represents a depauperate inflorescence form of *M. xyridoides* rather than a form of *M. aemulans*, as *M. arthrophyllum* was interpreted by Maguire.

PHELPSIELLA

Phelpsiella ptericaulis Maguire

The genus is described in Maguire's (1958) generic key as having yellow petals, but the *Hoyos & Morillo 518* collection from Laguna Asisa, Cerro Asisa, Serranía Parú indicates that the flowers are white. The winged strongly compressed stem and narrow leaf blades are strongly reminiscent of *Stegolepis breweri* Mag.

SCHOENOCEPHALIUM

Schoenocephalium cucullatum vs. *coriaceum*

The distinctions made between *S. cucullatum* and *S. coriaceum* (in Maguire's key, 1958: 37) were based on the relative distance separating the upper bracteoles and the tip of the sepals (in *S. coriaceum* the sepals exceed "the upper bracteoles by (3)4–5 mm in length," whereas in *S. cucullatum* the sepals exceed the upper bracteoles "2(3) mm or less in length." Also, the width of 14–16 mm is given for the leaf blades of *S. coriaceum* contrasted with that of "2.0–3.5 cm" for *S. cucullatum*. These differences have been found inconstant. It should be noted that although Maguire described the leaves of *S. cucullatum* in his key as "2.0–3.5 cm broad," none of the specimens from VEN, including the paratype (*Maguire et al. 37631*) and the isotype (*Maguire et al. 30486*) of *S. cucullatum* have leaf blades exceeding 1 cm.

Moreover, of all the specimens examined at VEN of *S. cucullatum* determined by Maguire, the leaf blades vary from 0.8 to 1.7 cm broad, those in *S. coriaceum* varying from 0.5 to 1.3 cm. With the material at hand, the specimens cannot be separated on either of these characters and, in combining them as conspecific, I am employing the binomial *Schoenocephalium cucullatum.*

It should also be noted that in *S. teretifolium* the sepals exceed the upper bracteoles by distances of 6–10 mm instead of, as stated, by "(3–)4–5 mm" (1958). The same error occurs in *S. cucullatum,* where the sepals exceed the upper bracteoles by 2–4 mm and in *S. coriaceum* by 2–6 mm.

Schoenocephalium martianum Seub.

It is probable that *S. martianum* Seub. may eventually be considered synonymous with *S. cucullatum,* in which case *S. cucullatum* has priority. However, differences in sepal length in relation to the bracteoles, leaf sheaths, and leaf blades appear to justify their separation for the present. The leaf sheaths in *S. cucullatum* are shorter and terminate more abruptly at the base of the leaf blade, whereas in *S. martianum* the leaf sheaths are more elongated and merge at their summit more directly with the leaf blade. In *S. martianum* the sepals exceed the upper bracteoles by 7–10 mm. Also, the leaves are longer in *S. martianum* than in *S. cucullatum* and *S. coriaceum.* I have seen a topotype of *S. martianum* from Colombia (*Maguire et al. 44179* VEN, scrub savanna Araracuara, Vaupés).

SAXOFRIDERICIA

Saxofridericia duidae vs. *S. grandis*

The separation of *S. grandis* from *S. duidae* on the basis of the presence of a petiole between the base of the leaf blade and the summit of the leaf sheath is not evident on some specimens. In his (1958) key, Maguire differentiated them as follows:

Petioles absent, the leaf passing directly from the summit of the leaf sheath to the leaf blade . . *S. duidae*
Petioles 10–15 cm long, uniting the summit of the leaf sheath with the leaf blade proper . . . . . *S. grandis*

However, in *Huber 4426,* a topotype of *S. grandis* from Serranía Parú, the length of the petiolar portion varies from only 1 to 2 cm long to as much as 8.5 cm long in *Huber 4347,* also from Parú. Although the description of *S. grandis* gives 10–15 cm as the length of the petiolar portion, the isotype (*Cowan & Wurdack 31115*) at VEN has the petiolar portion only 4 cm long. Maguire (1958) stated that *S. grandis* is the only species of subgenus *Saxofridericia* to have developed a distinct petiole. In Huber's specimens the summit of the peduncle beneath the head is sharply angled, flattened, glaucous, and broadened to 2–2.7 cm. The leaf blades in *S. grandis* vary from 3.5 to 4.5 cm wide (4–5.5 cm wide according to Maguire). The sheath in *S. grandis* is strongly indurated and 4–7 cm wide.

Saxofridericia duidae, confused with *S. grandis,* does not possess a petiolar portion between the summit of the sheath and the base of the leaf blade, the sheath is narrower (2–3 cm wide), less indurated, conspicuously carinate dorsally, the peduncle below the head narrower (1.2–1.7 cm wide), less conspicuously ampliated, with stronger ribbing, and the leaf blades mainly narrower (2.5–3.5–4) cm, but overlapping the measurements of *S. grandis.* However, although the other specimens of *S. duidae* lack petiolar interruptions between the leaf sheath and the leaf blade, the VEN paratype of *S. duidae* (*Maguire & Maguire, Jr. 29122*) has an elongated petiolar portion 10–18 cm long, although it has the narrower leaf blades, narrower leaf sheath with dorsal keel, and narrower apical part of the peduncle characteristic of *S. duidae.* The base of the leaf blade in this specimen is so narrowly attenuate as to appear petiolate and could be interpreted as sufficiently petiolate as the material seen of *S. grandis.*

An additional character, however, for differentiating the two taxa is that in *S. duidae* the bracteoles surrounding each flower are more conspicuously pungent and more conspicuously imbricate with looser, longer, narrower apices, whereas in *S. grandis* the bracteoles are more appressed, with shorter, less pungent tips from a more broadly shaped contour. This paratype thus breaks down the distinctions between the two taxa, which are otherwise separated by the differences enumerated above.

Saxofridericia compressa vs. *S. spongiosa*

Maguire's dimensions given for the diameter of the heads, peduncles below the summit of the head, and the leaf width do not apply to collections from VEN not seen or not annotated by him. Thus, the width of leaf blades separating *S. compressa* and *S. spongiosa* (4–5 cm against 7–10 cm broad respectively) must be changed to 3–8 cm and 4.5–9 cm, respectively.

Saxofridericia petiolata vs. *S. inermis*

The fibrous marcescent character of the leaf sheaths of *S. petiolata* versus the nonmarcescent, nonfibrous character of *S. inermis* is not apparent on specimens identified by Maguire. Although used as one of the separating key characters (1958), it does not serve to identify most extant herbarium material.

STEGOLEPIS

Stegolepis microcephala Maguire

This is keyed out by Maguire as having the "mature sheaths hardened and nerveless." However, the type specimen has the sheath clearly nerved.

Stegolepis membranacea Maguire

The bracteoles are described as somewhat obtuse, but in *Steyermark et al. 129658* from Marahuaca, the bracteoles are subacute, and the sheath and the summit of the auricle have thin brown margins. The specimen is referred to *S. membranacea* because of the nerved sheath (in the upper part) and lack of broad white scarious auricle.

Stegolepis neblinensis Maguire

This species was placed in the section having spikelets 5–50, but in *S. neblinensis* the spikelets are only 1–3 (peduncles 2–4). In the Spanish key (*Fl. Ven.*) there is confusion in the couplet "10" which gives "sepals" not reflexed.

If the indurated sepals are absent, and only the bracteoles remain, then the length measurement is only 2 cm instead of the "2.5–3.5 cm" given for this species.

Stegolepis parvipetala Steyerm.

On the basis of the number of spikelets, supposed to be "70–100," the isotype (VEN) cannot be properly disposed, since the spikelets are less than 70 (actually there are 50 or fewer), thus relegating it to another part of the key. The key on p. 109 (1982, *Fl. Ven.*) gives the length of the spikelets as "10–16" mm. However the text (p. 120) gives "14–16" mm. In the key to the subspecies, the spikelets are "14–15" in subsp. *parvipetala* and "10–12" in subsp. *chimantensis*.

Stegolepis parvipetala is characterized by the rounded or broadly obtuse apices of the lower and middle bracteoles, blunt apex of the spikelet, thick diameter of the peduncle, conspicuously swollen summit of the trigonous summit of the peduncle, and small petals.

Stegolepis pauciflora Gleason

Although this species is placed by Maguire in that part of the key (1982, *Fl. Ven.*, p. 111) having "auricles of the sheath not ligulate," actually they may attain a length of 25 mm, whereas in *S. hitchcockii* they are ca. 10 mm long.

Stegolepis ptaritepuiensis Steyerm.

The key (1958) gives leaf blades "2–2.5 cm" wide, but the text states "2–4.5 cm" wide.

Stegolepis pungens Gleason

The key in *Fl. Ven.* (1982: 110) gives spikelet measurement "3–8.8" cm. It should be "3–3.8" cm as given in the text. Actually some spikelets are less than 3 cm (2.5–2.8 cm).

Stegolepis steyermarkii Maguire

This species is poorly segregated in the key on the basis of the nervation of the leaf sheaths and their relative thickness or induration. Although nerves may be present along the margin, they are not always present on the rest of the sheath as in some other species. The sheaths may be indurated, as in *Steyermark et al. 92498*, making it difficult to determine into which part of the key to place the specimen.

Stegolepis steyermarkii vs. *S. ferruginea*

Although these two species are very similar, they may be distinguished by the key characters given by Maguire (1965: 71), with *S. steyermarkii* having narrower and longer leaf sheaths, glabrous vs. minutely puberulent petals, narrower leaf blades (not given by Maguire), a more conspicuous, broader, and more elevated midrib below, and a more attenuate narrower leaf apex.

Although the two species are apparently distinct, it should be noted that the length of some leaf sheaths of *S. steyermarkii* is not as long as that originally stated, i.e., 15–20 × 4.5 cm in text (18–20 × 3.5–4.5 cm in key). The type specimen shows the basal part of the plant with the sheath length complete. However, one of the paratypes (*Steyermark & Nilsson 296* NY) has a lone sheath only 12.5 cm long, taken from an inner relatively shorter sheath. Other collections, such as *Croat*

53998, have sheaths 16 cm long. The latter specimen has the sheathing portion cut off above the base so that the length shown is not complete.

Stegolepis vivipara

Examination of the isotype (*Steyermark & Wurdack 332*) at VEN shows only 15–20 spikelets and not 25–35 as stated in the original description. The heads are 3.5 cm in diameter. The bracteoles are ± 20–25 and not "ca.16" as given by Maguire (1965). They are orbicular or orbicular-ovate, as stated, and pale brown with scarious margins. The midnerve is prominent below with many fine nerves, but much less manifest than in *S. parvipetala* and subsp. *chimantensis*. The upper leaf surface has many fine nerves with a sulcate midrib as in *S. parvipetala*. The leaf sheath is soft, papyraceous, or submembranaceous and has many fine, closely crowded nerves. The leaf apex is subacute or narrowed to an obtuse or subobtuse apex. The broadly obovate petals, described as 22–24 mm long by Maguire (1965), are only 15 mm long and 12 mm wide in the dried state. The sepals are many-costate and 3.5–5 mm wide (3–4 mm as given by Maguire).

All the bracts of a spikelet are more or less uniformly broadly suborbicular-ovate, obtuse, or subobtuse, whereas in *S. angustata* the upper ones are more narrowed to a subobtuse or subacutely obtuse apex and are relatively longer than broad. In *S. vivipara* the bracts are more uniform and only slightly longer than broad. Also, the bracts of *S. vivipara* are paler and have more scarious margins and a brown apex when contrasted with *S. angustata*, in which the bracts are darker brown and lack scarious margins and a brown apex.

NOTES ON *SLOANEA* (ELAEOCARPACEAE) IN THE VENEZUELAN GUAYANA

The following notes are based on a treatment of the genus *Sloanea* in preparation for a *Flora of the Venezuelan Guayana*. This has necessitated a study of newly collected material obtained from recently completed expeditions to previously unexplored areas, as well as a restudy of specimens identified by previous workers. I am grateful to the curators of F, GH, NY, US, and VEN for the loan of critical material.

As a result of the present study, nine new species are recognized, and critical comments on other species are given. The revision by C. E. Smith (1954) on the New World species of *Sloanea* elaborated 62 species, of which nine included taxa from the Venezuelan Guayana and eight species from other parts of Venezuela. An additional species, *S. floribunda* Spruce ex Benth., collected at San Carlos de Rio Negro, was erroneously ascribed to Brazil instead of Venezuela. Two additional species from the Venezelan Guayana, *S. crassifolia* and *S. steyermarkii*, were published by Smith in 1962 and 1967, respectively. Steyermark and Marcano-Berti described *S. megacarpa* from the Guayana in 1966, and additional taxa originating from the Venezuelan Guayana were described by Steyermark in 1976 and 1978. Species not originally cited by Smith are now known to occur in the Venezuelan Guayana as a result of recent expeditions into that territory. They include, in addition to those published since Smith's revision and the nine described below, *S. caribaea*, *S. guianensis*, *S. pubescens*, *S. multiflora*, *S. robusta*, *S. synandra*, and *S. terniflora*. *Sloanea pitttieriana* and *S. ptariana*, previously included by Smith as synonyms of other taxa, have been newly studied and found to merit specific recognition.

Sloanea floribunda Spruce ex Benth., J. Linn. Soc., Bot. 5: suppl. 66. 1861.

Sloanea maroana Steyerm., Pittieria 7: 14. 1978.

A reexamination of *S. maroana* Steyerm. shows that it cannot be maintained apart from *S. floribunda*.

Sloanea laurifolia (Benth.) Benth., J. Linn. Soc., Bot. 5: suppl. 70. 1861.

This species was treated by Smith (1954) as highly variable and included *S. oppositifolia* Spruce ex Benth. as well as the collection *Cardona 1951* from the Venezuelan Guayana along the Río Merevari, which was assigned an herbarium name by Pittier but never published. *Schomburgk 936*, upon which *Dasynema laurifolium* Benth. (basionym of *Sloanea laurifolia*) was based, has opposite, acuminate leaf blades identical with that of *Spruce 3689*, the type of *Sloanea oppositifolia* Spruce ex Benth. The leaf blades in both collections are glabrous throughout and ovate- or oblong-lanceolate. *Cardona 1951*, on the other hand, is distinct in having alternate, obovate, rounded leaf blades that are densely tomentose on the upper and lower midnerves. It further differs from the collections of both *S. oppositifolia* and *Dasynema laurifolium* in having acute instead of obtuse awns on the anthers, and styles free to the base instead of shortly parted only at the apex.

Sloanea macrophylla Benth. ex Turcz., Bull. Soc. Imp. Naturalistes Moscow 31(1): 224. 1858.

The dimensions given by C. E. Smith (1954) for the stamens of this species were taken from flowers in a very early stage of anthesis. He described the stamens as "4–6 mm long; filaments 0.5–1 mm long, usually flattened laterally, minutely puberulent; anthers 2–4 mm long, lanceolate, minutely puberulent, connective prolonged into a glabrous awn 0.3–0.5 mm long." However, in other collections referred to this species (*Liesner et al. 20919*) it was noted that as the flowers mature the filaments and appendages of the anthers became more elongated. *Sloanea caudata* Steyerm., placed by Smith (1954) in the synonymy of *S. macrophylla* also has much longer staminal dimensions than those described for that species.

Sloanea pittieriana Steyerm., Fieldiana, Bot. 28: 359. 1952.

This species was reduced to synonymy by Smith (1954) under *Sloanea fendleriana* Benth. *Sloanea fendleriana* was based originally on a specimen collected by Fendler (*2489*) from the Coastal Cordillera of northern Venezuela. *Sloanea pittieriana* was described from a collection originating in the Venezuelan Guayana Highland, some 700 kilometers distant. Reexamination of the type material of these two taxa and study of additional collections shows them to be quite distinct. Although vegetative differences occur, the chief distinctions are found in the termination of the anther and in the spines of the capsule. In *S. pittieriana* the apex of the anther is obtuse and has an obsolete, minute, scarcely discernable knob. By contrast, the anther of *S. fendleriana* terminates in a shortly acuminate summit, originally described by Bentham (1861) as "breviter acuminatae," or as "prolonged into a small puberulent knob or short awn," as described by Smith (1954). Fruiting material of *S. fendleriana* collected near the type locality in Estado Aragua (Pittier National Park, *Pittier & Nakichenovich 15425* VEN), identified by Smith, has merely granulose capsules lacking spines, whereas capsules obtained within the distributional area of *S. pittieriana* and referred to that species have slender, rigid, glabrous spines.

Vegetative differences are likewise evident. In *Sloanea fendleriana* the lateral secondary nerves terminate dichotomously 3–8 mm from the leaf margins, and the veinlets of the lower surface are prominently reticulate. As opposed to this, the lateral nerves of *S. pittieriana*, best observed on the lower leaf surface, usually extend to the margins without branching, although some branching may be present 3–5 mm from the margin. Furthermore, the tertiary venation of the lower surface is less conspicuous, less elevated, and more impressed. Finally, the lateral nerves of *S. pittieriana* are more equidistant than in *S. fendleriana*, the latter with the nerves irregularly spaced.

The following specimens, all from the Venezuelan Guayana, pertain to *Sloanea pittieriana*: BOLÍVAR: Ptari-tepui, *Steyermark 59984* (holotype, F; isotype, VEN); Ptari-tepui, *Steyermark 60261* (F); between Eldorado and Luepa, plateau of Cerro Venamo, *Steyermark & Nilsson 799* (VEN); Amaruay-tepui, *Holst & Liesner 2840* (MO, VEN).

Sloanea ptariana Steyerm., Fieldiana, Bot. 28: 360. 1952.

This taxon, described from Ptari-tepui in the Venezuelan Guayana, was reduced to synonymy by C. E. Smith (1954) under *Sloanea picapica* Standley, a species based on fruiting material from Honduras. The holotype of *S. picapica* (*C. & W. von Hagen 1390* NY), together with additional paratype specimens from Central America, identified as *S. picapica* by Smith, have been restudied by the author. No flowering material of *S. picapica* has been collected up to the present, but Damon Andrew Smith stated in his unpublished thesis (1985) on the Costa Rican species of *Sloanea*, that, although no flowers of *S. picapica* had been seen, stamens were found adhering to very young fruits. He described them as being short-tomentose. His detailed description of the stamens is as follows: "filaments at least 1.7 mm long, 0.04 mm in diameter; anthers 0.6–0.9 mm long, about 0.2 mm wide, basally slightly cordate; anther sacs opening along entire length, but most widely at apex; awn about 0.04–0.08 mm long, obtuse."

Although no flowers of Central American specimens of *Sloanea picapica* were available to C. E. Smith for study, he based his detailed description of the flowers upon the flowering collection of the holotype of *S. ptariana*. However, the stamens of

S. ptariana are quite unlike those found by Damon Smith in *S. picapica.* Although the stamens of *S. ptariana* were originally described as pubescent, reexamination, as verified by C. E. Smith (1954), showed that they were glabrous throughout. In addition to the glabrity of the stamens in *S. ptariana,* the filaments of that taxon are longer (3–3.5 mm) than those of *S. picapica.*

Additional differences between these two taxa may be observed in their leaves. In *Sloanea ptariana* the lateral nerves extend nearly unbranched to the margin and anastomose 1–3 mm from it. In the Central American specimens of *S. picapica* the lateral nerves branch farther from the margin (in *Little 25400,* 4–6 mm from the margin before anastomosing). The apex of the leaf in *S. ptariana,* moreover, is also longer and narrower throughout its length, and 3–6 mm wide at the base; in the Central American specimens of *S. picapica* the apex averages shorter and broader at the base, where it is 7–9 mm wide.

Based upon the staminal and vegetative differences noted between *Sloanea ptariana* and *S. picapica,* I am reinstating the former as a distinct species. This eliminates the previously held erroneous concept of a disjunct geographical range for *S. picapica,* a disjunct range not normally found between Central American and Guayana Highland taxa.

Sloanea bolivarensis Steyerm., sp. nov. TYPE: Venezuela. Bolívar: 7 km NE of Ciudad Píar, 7°28'N, 63°14'W, 350–500 m, 10 Apr. 1981, *Ronald Liesner & Angel Gonzalez 11479* (holotype, VEN; isotypes, MO, NY). Figure 1.

Arbor 25 m, foliorum laminis obovatis apice obtuse acutis basi acutis majoribus 17–20 cm longis 8–11 cm latis, marginibus utroque latere 11–18 repando-dentatis subtus costa media nervis lateralibusque hirsutulis; petiolis 1.7–2.5 cm longis dense hirtellis; inflorescentiis lateralibus umbellatim 2–3-floris, pedunculis 1.5–2 cm longis dense hirtellis; pedicellis 10–15 mm longis dense hirtellis; sepalis quattuor aequalibus 7–9 mm longis; antheris 1.8–2.1 mm longis hispidulis connectivo in acumen hispidulum 1.5 mm longum producto; filamentis 1.2–1.5 mm longis dense hirsutulis; ovario hispidulo, stylo torto glabro.

Tree, 25 m tall, the branches hirtellous. Leaves alternate or subalternate. Petioles 1.7–2.5 cm long, densely hirtellous; leaf blades obovate, obtusely acute at the abruptly prolonged apex, narrowed to an acute base, the larger ones 17–20 cm long, 8–11 cm wide, the margins each side 11–18 repand-dentate or coarsely obtusely dentate; lower midrib and lateral nerves hirsutulous, upper midrib minutely hirtellous, glabrous elsewhere on lower and upper leaf surfaces; lateral nerves 12–16 each side, ascending at 25–30°; tertiary venation finely elevated, minutely reticulate both sides. Inflorescence lateral, near summit of branch, umbellately 2–3-flowered; peduncle 1.5–2 cm long, densely gray-hirtellous; pedicels 10–15 mm long, densely gray-hirtellous. Sepals 4, equal, ovate, acute, 7–9 mm long, 3–5 mm wide, both sides minutely puberulous. Anthers lanceolate, 1.8–2.1 mm long, hispidulous, dehiscing laterally, the connective prolonged into a hispidulous awn 1.5 mm long, somewhat shorter than the body of the anther; filaments 1.2–1.5 mm long, densely hirsutulous. Ovary hispidulous; style 2.5–2.8 mm long, twisted, glabrous. Capsule not seen.

The twisted style and umbellately few-flowered inflorescence relate this new taxon to *Sloanea garckeana* Schum., from which it differs in having anther awns uniformly pubescent; densely pubescent, shorter pedicels and peduncles; and wider repand-dentate to coarsely dentate leaf blades.

Specimens of *Sloanea garckeana* identified by C. E. Smith and D. Alforo Castañeda show a range of variation. The species, originally based on the collection *Riedel 888* from the province of Rio de Janeiro, has entire or subentire, oblong or oblong-lanceolate, acuminate leaf blades 2–5 cm wide, 2–3-flowered inflorescences on elongated peduncles 5–6 cm long, sepals 8–9 × 4–4.5 mm, anthers (including the apical appendage) 5 mm long with the appendage described as glabrous, and tomentose filaments 3–4 mm long. Although Smith (1954) allowed for a range in variation of the anther appendage from sparsely pubescent to glabrous, the material I have examined has glabrous awns principally. Smith (1954) also allowed for a wide range of variation in glabrity and length of peduncles and pedicels.

Sloanea cataniapensis Steyerm., sp. nov. TYPE: Venezuela. T. F. Amazonas: Dept. Atures, N side of Río Cataniapo, 48 km SE of Puerto Ayacucho, 5°35'N, 67°15'W, 200–300 m, 10 May 1980, *Julian A. Steyermark, Gerrit Davidse & Francisco Guanchez 122215* (holotype, VEN; isotype, MO). Figure 2.

Arbor 15 m, foliorum laminis elliptico-ovatis vel oblongo-ellipticis apice abrupte acutis basi acutis vel subobtusis 7–12.5 cm longis 3.5–6.5 cm latis integerrimis praeter costam mediam subtus minute puberulentem glabris; inflorescentiis 3–7-floris, pendunculis primariis semel ramosis 5.5–9 cm longis dense puberulentibus omnibus umbellatim 3-pedicellatis, axibus lateralibus 1-floris; pedicellis 2–4 cm longis dense puberulentibus; sepalis quattuor

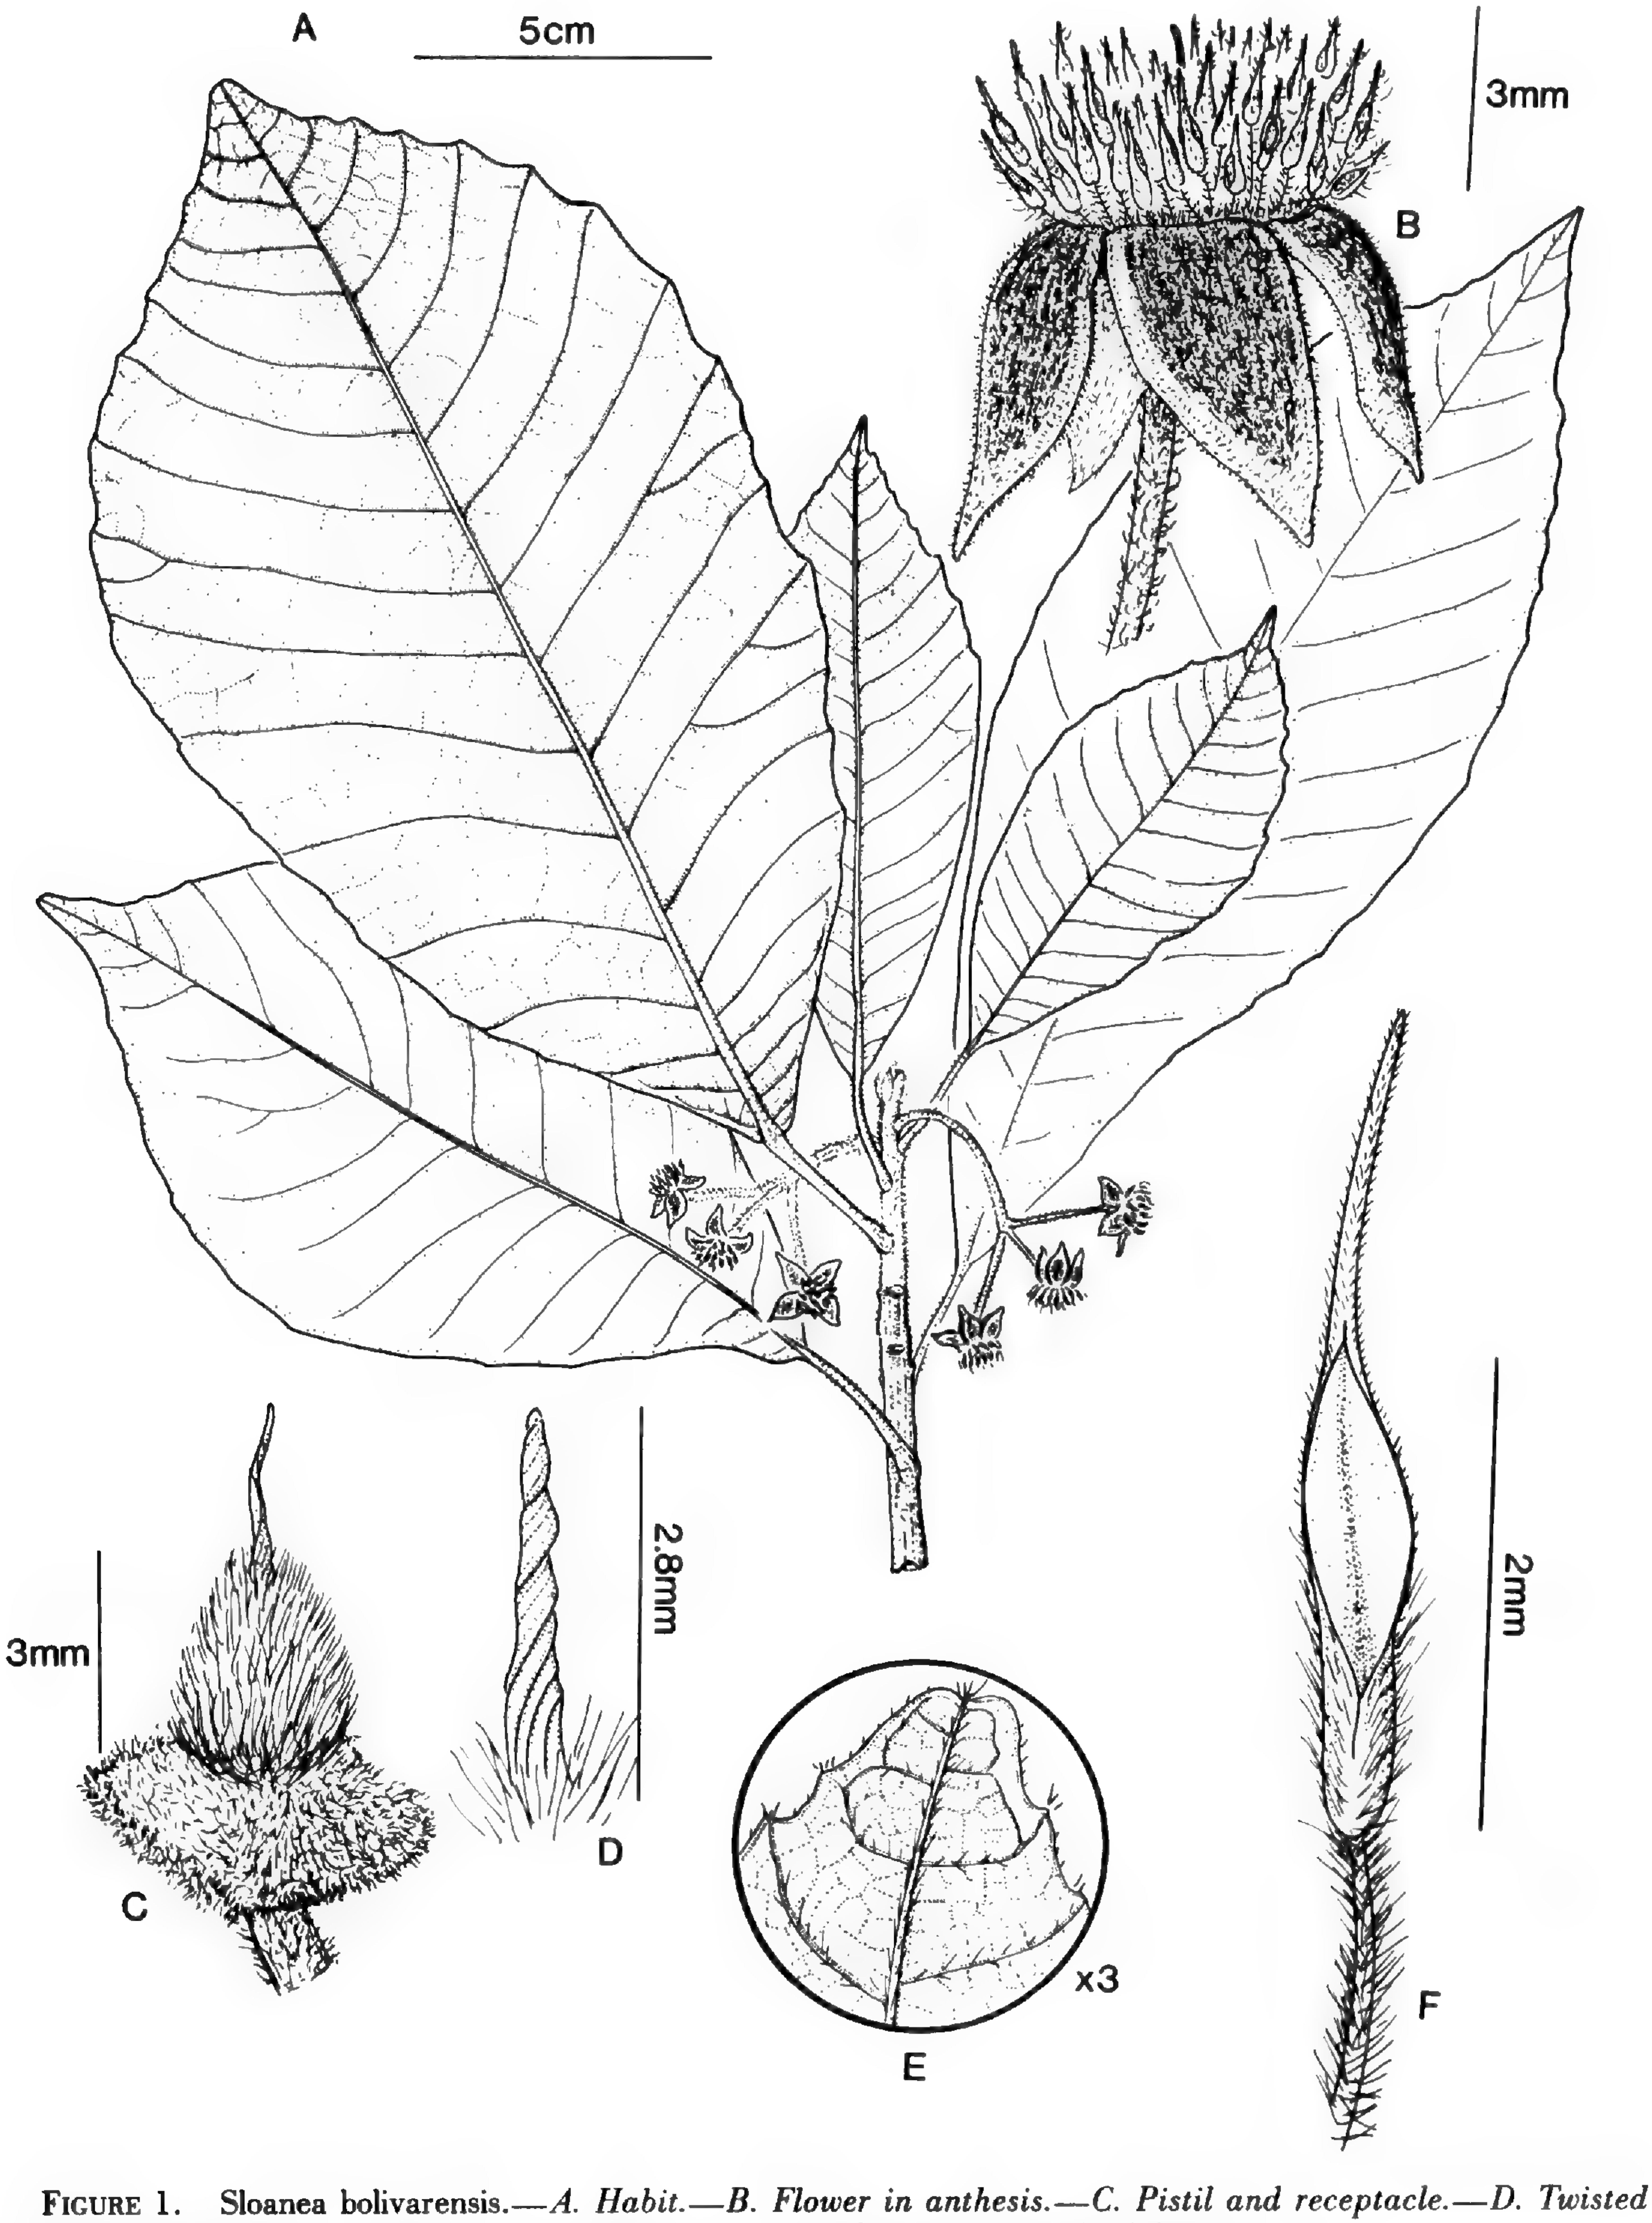

FIGURE 1. Sloanea bolivarensis.—*A. Habit.—B. Flower in anthesis.—C. Pistil and receptacle.—D. Twisted style.—E. Leaf blade, detail of apical abaxial side.—F. Stamen, laterally dehiscent.*

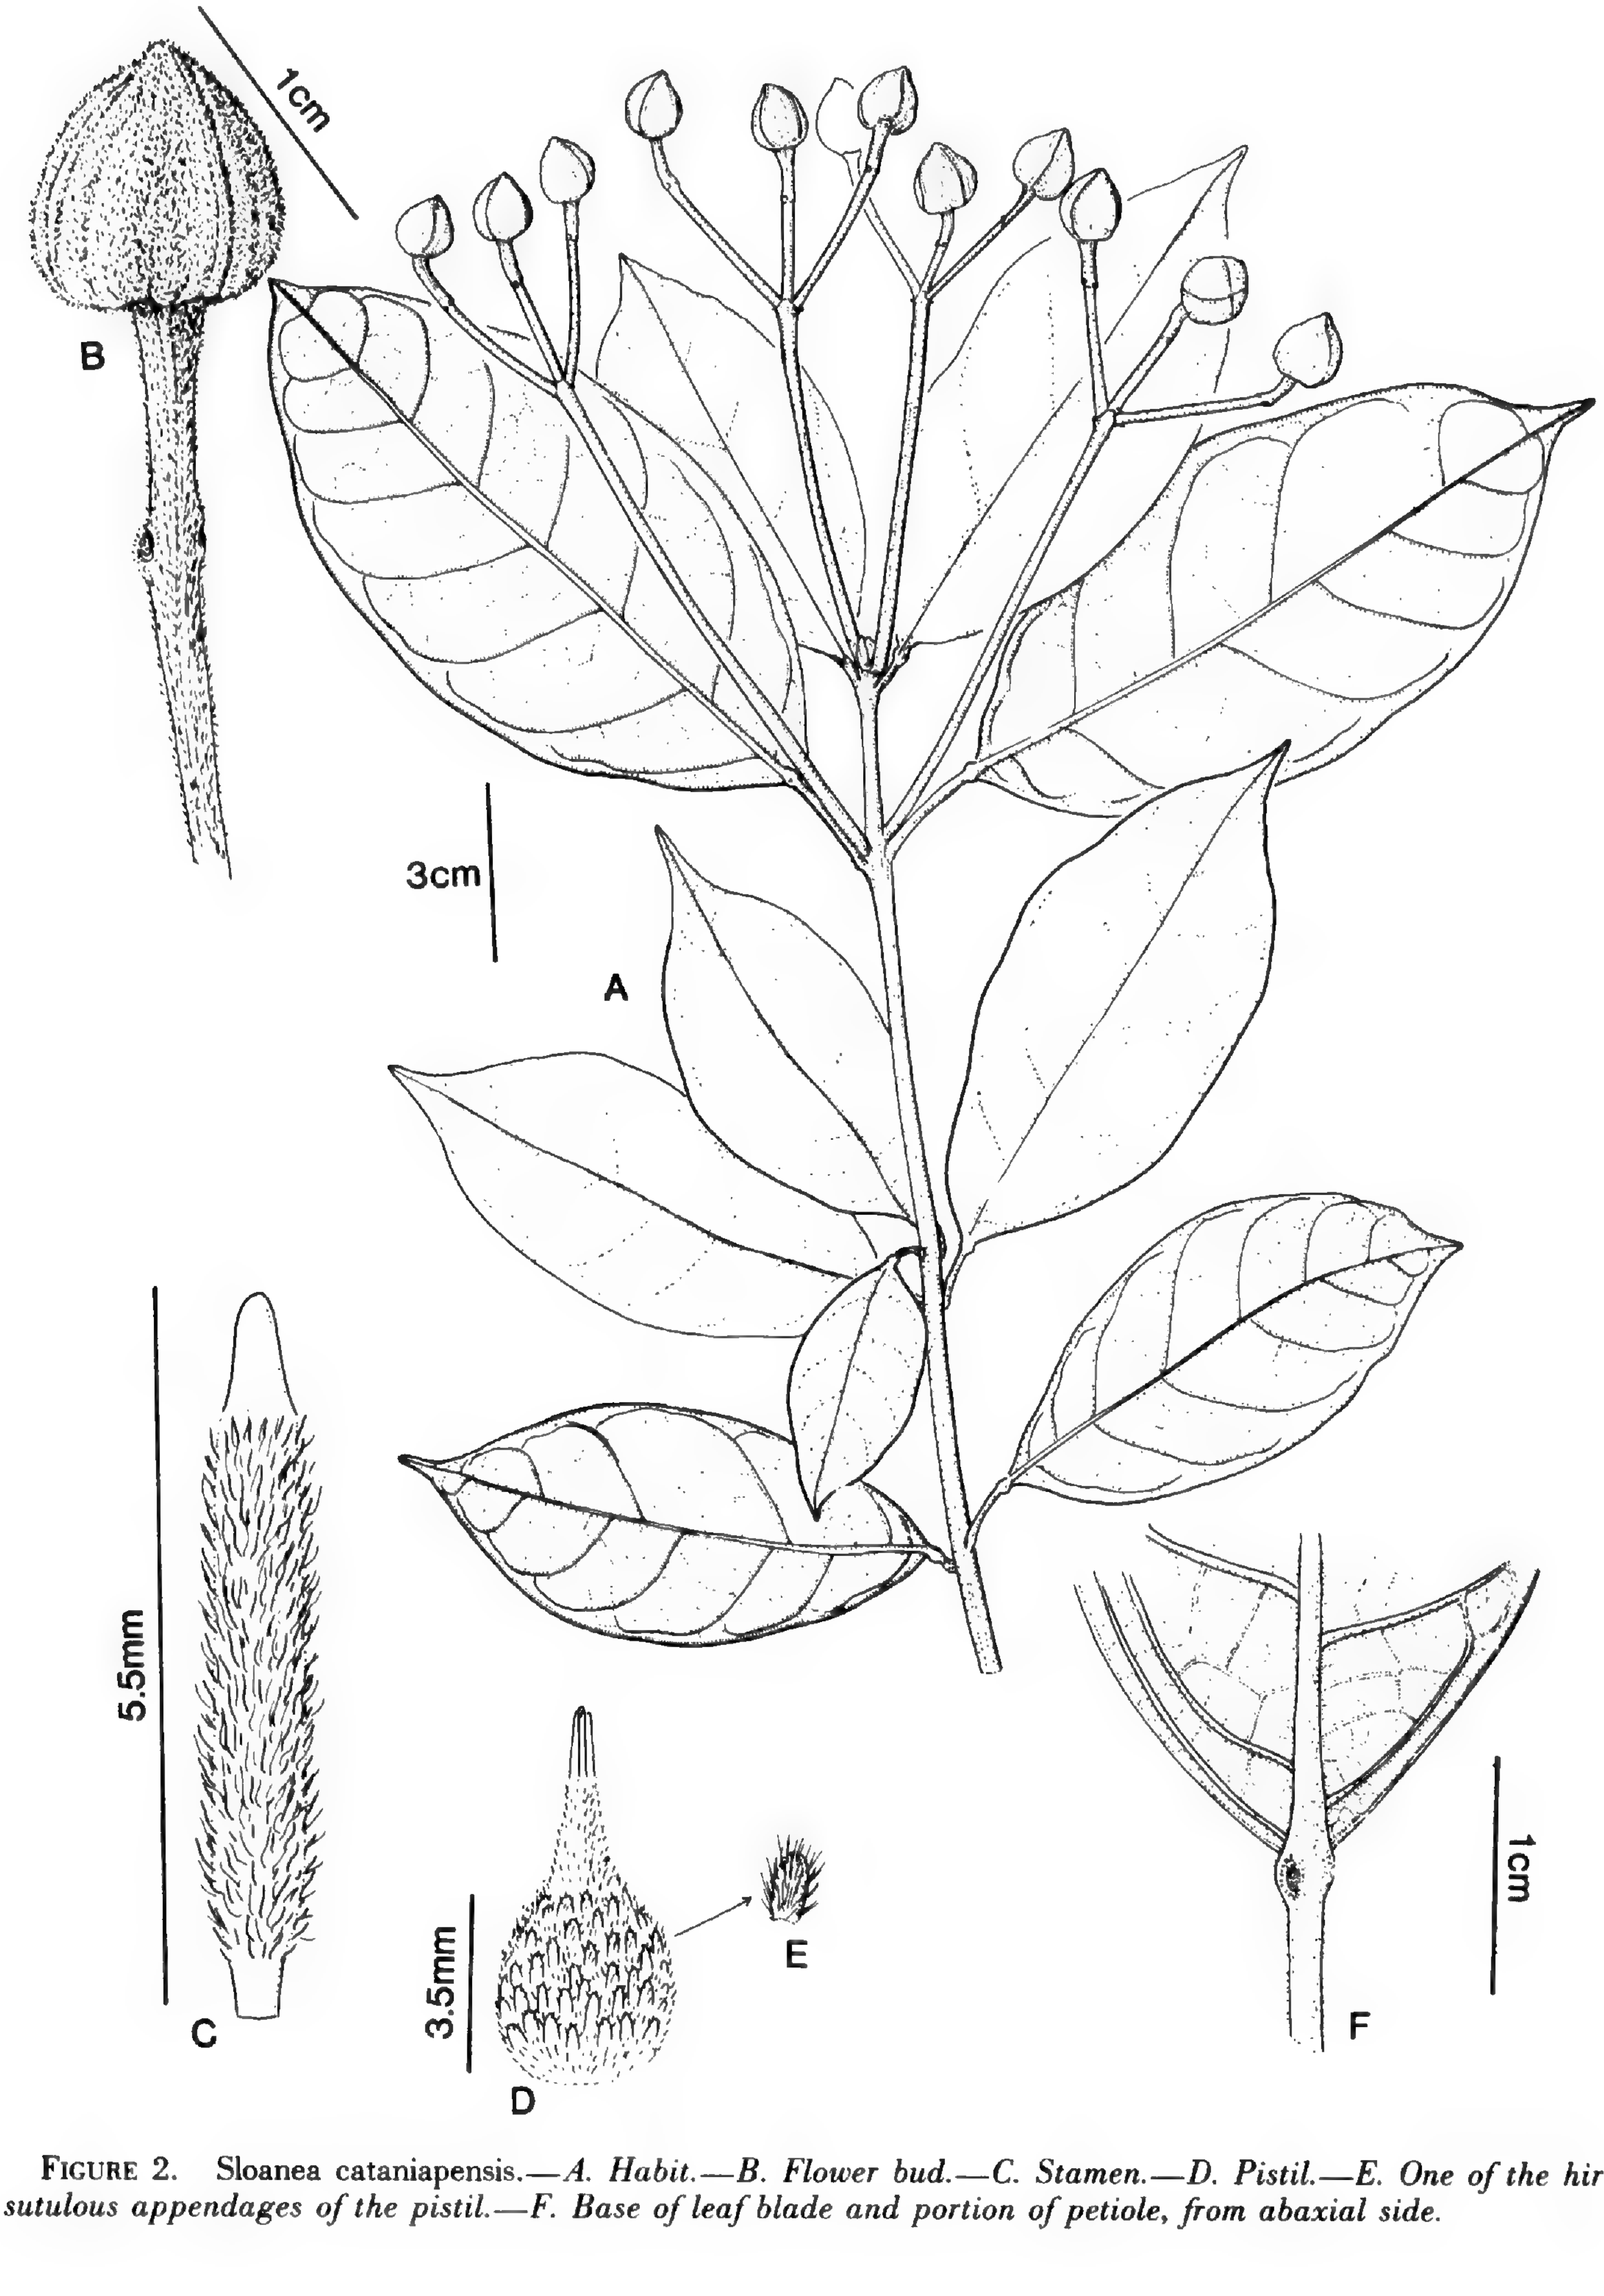

FIGURE 2. Sloanea cataniapensis.—*A. Habit.—B. Flower bud.—C. Stamen.—D. Pistil.—E. One of the hirsutulous appendages of the pistil.—F. Base of leaf blade and portion of petiole, from abaxial side.*

aequalibus 10 mm longis 7.5 mm latis; antheris (alabastro) linearibus 5.5 mm longis dense hirsutulis connectivo in acumen rotundatum glabrum 0.7–1 mm longum productis; filamentis (alabastro) 0.5–0.7 mm longis glabris.

Tree 15 m tall, upper portion of branchlets densely puberulent. Leaves alternate or opposite. Petioles 1–2 cm long, densely fulvous puberulent; leaf blades chartaceous, elliptic-ovate or oblong-elliptic, abruptly acute at apex, acute to subobtuse at base, 7–12.5 cm long, 3.5–6.5 cm wide, entire, glabrous except for the densely minutely puberulent midrib on the lower side; lateral nerves 5–6 each side, elevated below; subsulcate above, ascending at a 45° angle, terminating and anastomosing 1–2 mm from the margin; tertiary venation subelevated reticulate below, subrugulose above. Inflorescence umbellate to paniculate, 3–7-flowered; primary peduncles elongate, 5.5–9 cm long, 2.5–3 mm wide; secondary axes unbranched, 1-flowered, densely fulvous-puberulent; pedicels 2–4 cm long, 1.5–2 mm wide, densely fulvous-puberulent. Flower bud suborbicular, slightly acute at apex, 1 cm long, 1 cm wide basally. Sepals 4, covering the rest of the flowering parts in bud, equal, thickish, with thickened margins, broadly ovate, obtusely acute at apex, 10 mm long, 7.5 mm wide, densely fulvous-puberulent without, sericeous within. Stamens ca. 60; anthers (in bud) linear, 5.5 mm long (including apical appendage), 0.7–0.8 mm wide, densely hirsutulous upward, dehiscent by an apical pore, the connective prolonged into a rounded glabrous awn 0.7–1.1 mm long; filaments (in bud) 0.5–0.7 mm long, glabrous. Ovary broadly ovoid, 3.5 mm long, minutely hispidulous; style conic-linear, 2 mm long, densely hispidulous-appressed in the basal portion, elsewhere glabrous; stamens 4, glabrous.

Related taxa, such as *Sloanea laxiflora* Spruce ex Benth. and *S. synandra* Spruce ex Benth., have branched lateral or secondary axes of the primary peduncles, whereas in *S. cataniapensis* the primary peduncles branch only at their summits into three pedicellate flowers. Other differences are shown by the longer pedicels, shorter filaments, more densely pubescent anthers with longer ascending pubescence, sepals obtusely acute, and more densely puberulous lower midrib of the leaf blade.

Sloanea davidsei Steyermark, sp. nov. TYPE: Venezuela. T. F. Amazonas: Depto. Río Negro, Río Pacimoni, between its mouth and its junction with the Río Baria and Río Yatua, 1°53′–1°27′N, 66°35′–66°32′W, 80 m, 23–25 July 1984, *Gerrit Davidse 27733* (holotype, VEN; isotype, MO). Figure 3.

Arbor 4–15 m, ramulis superne dense patenti-pilosis; foliorum laminis maturis oblongo-obovatis apice rotundatis basi acutis obtusis vel rotundatis 7–14 cm longis (3.5–) 4–9 cm latis integerrimis, costa media nervis lateralibusque pilis patentibus dense munitis, superficie inferiore pilis minutis dense tomentosa; inflorescentiis simplicibus umbellatim 3–4-floris; pedunculis 0.5–3.5 cm longis dense pilosulis; pedicellis (6–)10–20 mm longis dense pilosulis; sepalis quattuor aequalibus late ovatis 5–8 mm longis; antheris 1.5–2 mm longis; connectivo in appendicem hirsutulum 0.7–1 mm longum producto; filamentis 1.2–2.8 mm longis; stylis liberis glabris; capsulis ovoideis 2.2–3 cm longis, spinis setulosis acicularibus inaequalibus majoribus 12–50 mm longis.

Tree 4–15 m tall, upper part of branches minutely and densely pilosulous with spreading hairs. Leaves alternate or opposite. Petioles 1.2–3 cm long, densely tomentose; leaf blades oblong-obovate, rounded at apex, acute, obtuse, or rounded at base, 7–14 cm long, (3.5–)4–9 cm wide, entire; lateral nerves 10–14 each side, elevated below, sulcate above, ascending at a 45° angle, anastomosing at the margins; midrib and lateral nerves below densely pilosulous with spreading hairs; midrib above sulcate, densely tomentellose; lateral nerves above slightly pubescent. Inflorescence lateral or terminal, simply 3–4-umbellately flowered, (2–)4–5.5 cm long; peduncle 0.5–3.5 cm long, densely pilosulous with spreading hairs; bracts at base of pedicels linear-lanceolate, acute, 3.5 mm long, densely tomentose without, sparsely appressed within; pedicels (6–)10–20 mm long, densely pilosulous. Sepals 4, equal, enclosing the flower in preanthesis, ovate, acute, 5–8 mm long, 2.5–5 mm wide, densely cinereous-pubescent without, more sparsely appressed pubescent within, the margins thickened, densely pubescent. Anthers oblong-elliptic or oblong-lanceolate, including the awn 1.5–2 mm long, densely hirsutulous, laterally dehiscent, the connective prolonged into a hirsutulous subobtuse awn 0.7–1 mm long; filaments 1.2–2.8 mm long, equaling or longer than the anther. Ovary ovoid or suborbicular-ovoid, 3.5–4 mm long, 3 mm wide, brown-hispidulous, 4-angled; styles 4, free, divergent, glabrous, 1.5–2 mm long. Capsule ovoid, 2.2–3 cm long, densely covered with usually red, acicular, unequal, straight spines, the longer ones 12–50 mm long with appressed setulose projections along their length, the shorter bristles 3–4 mm long, overlying surface of dense, pale hispidulous hairs; mesocarp reddish. Seed golden, reddish proximally.

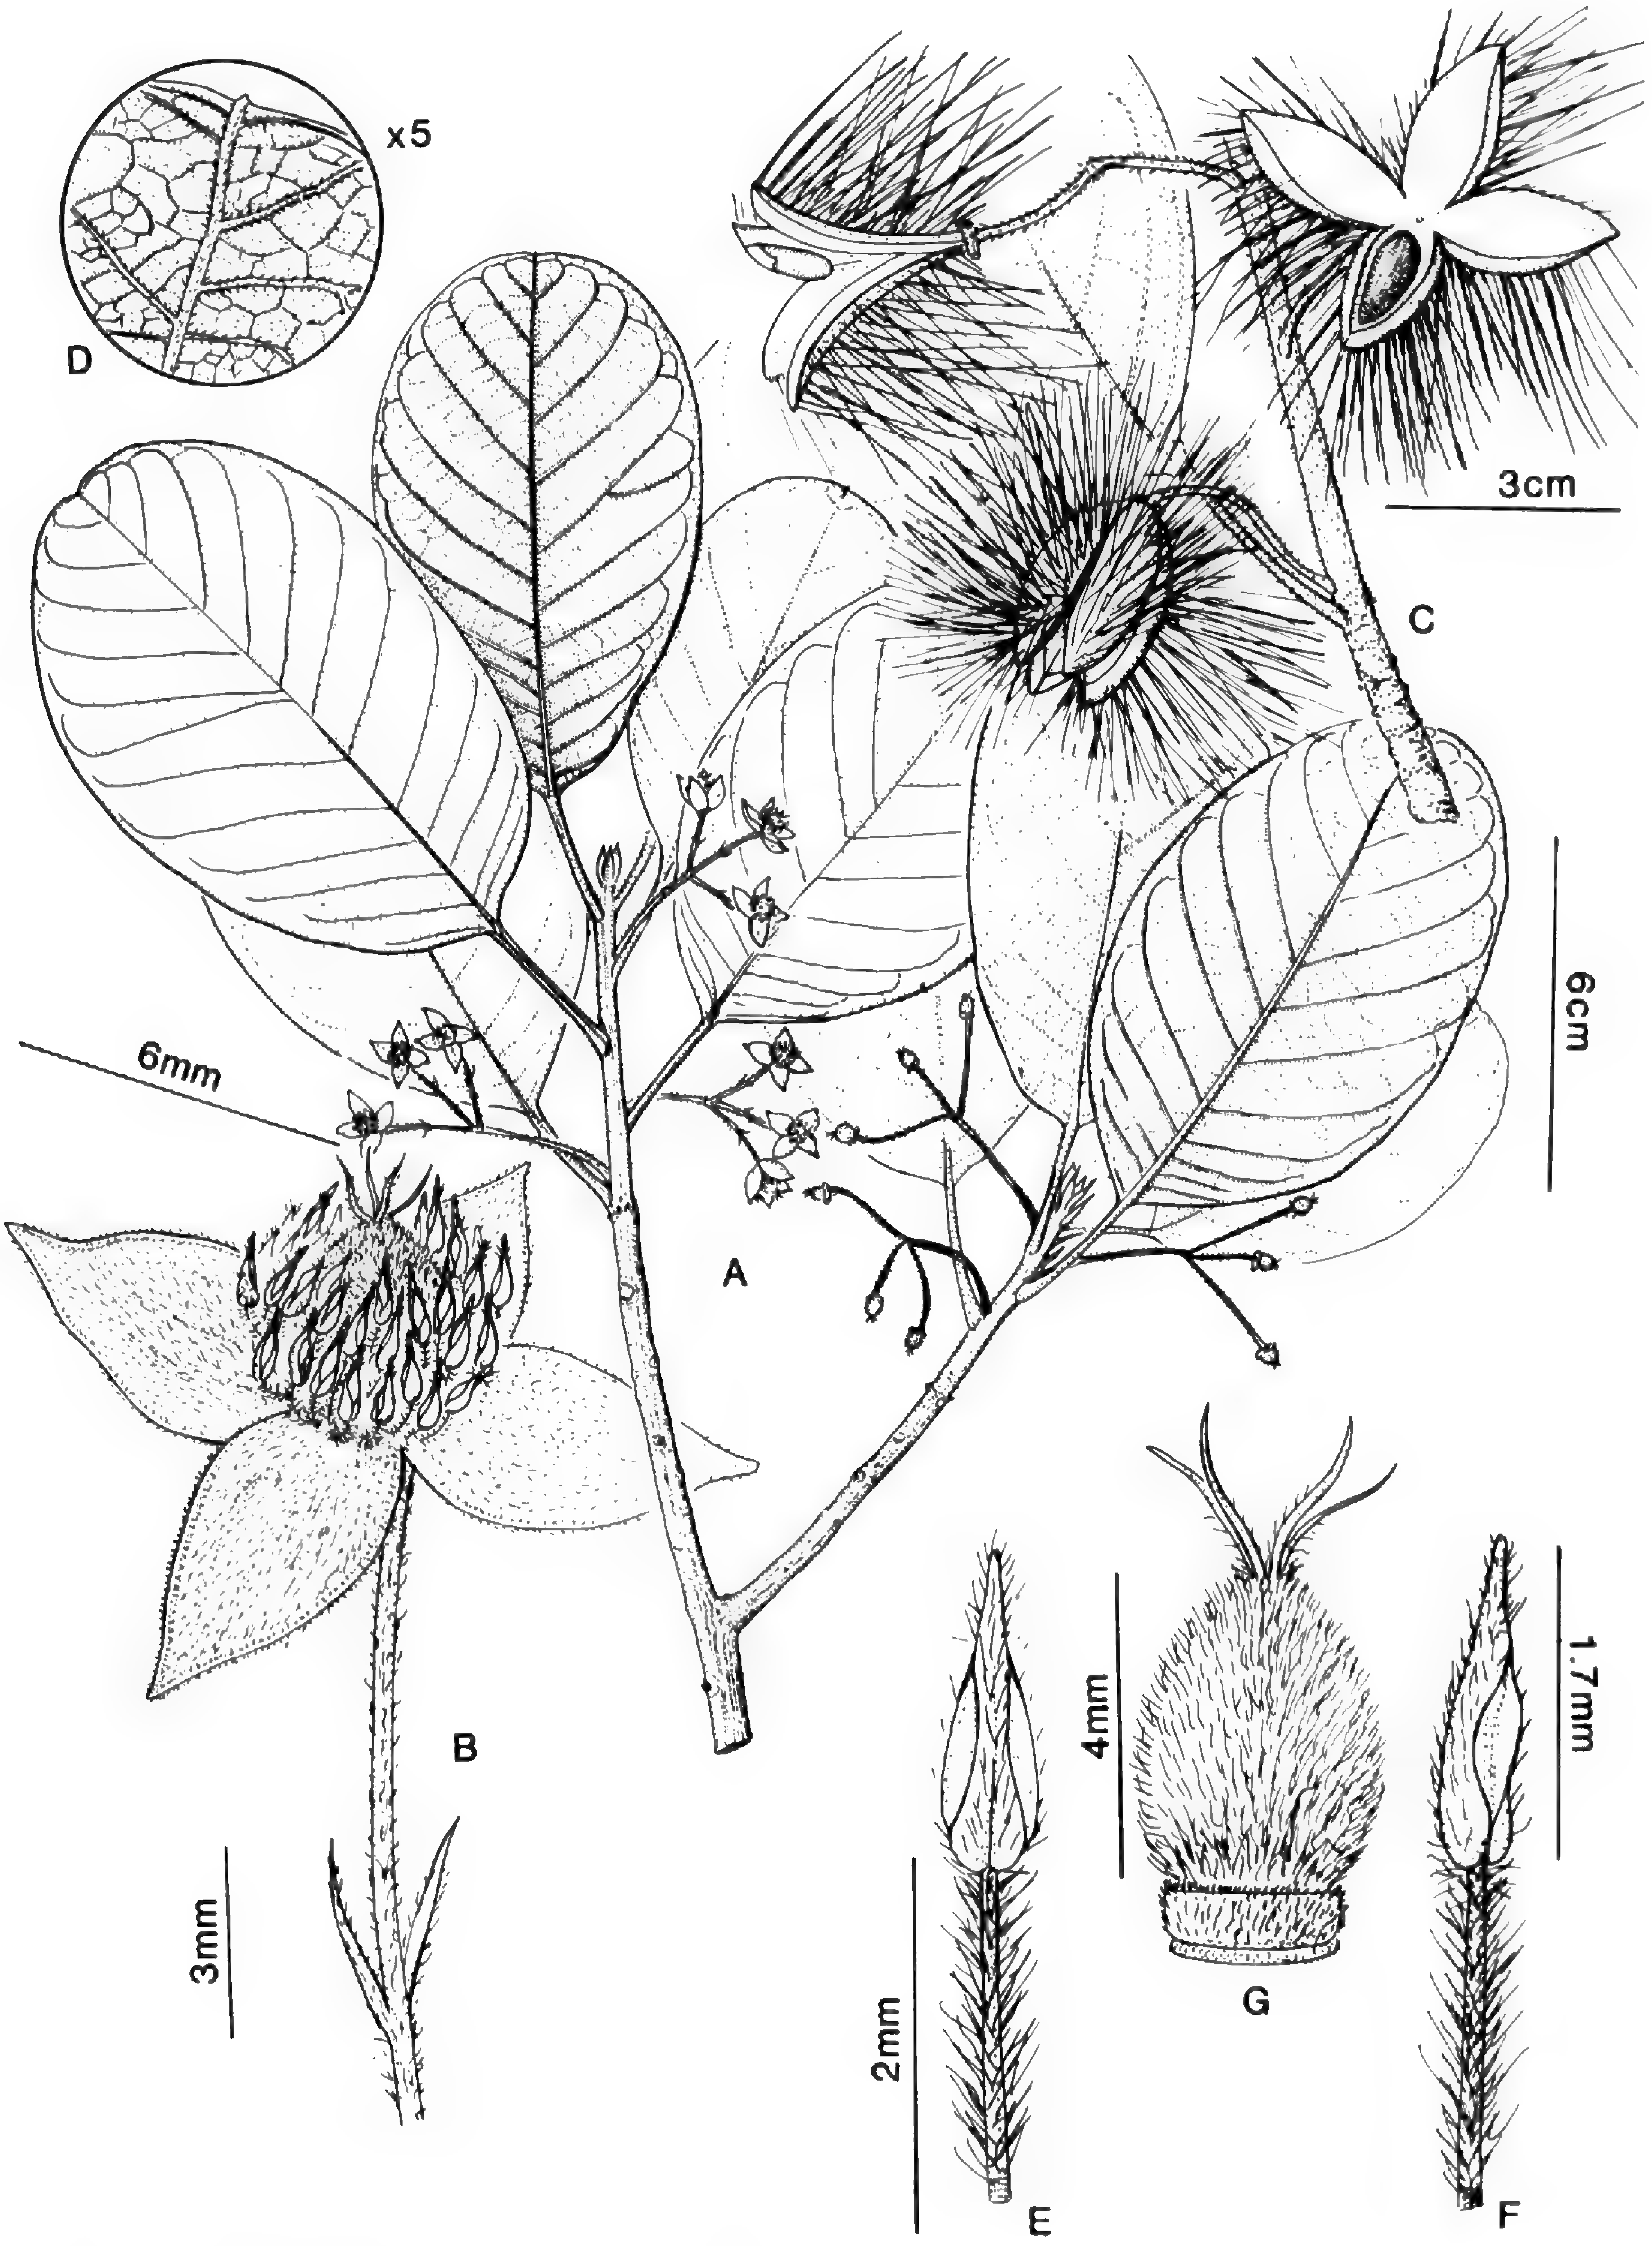

FIGURE 3. Sloanea davidsei.—*A. Habit.—B. Flower and pedicel, in anthesis with bracts.—C. Portion of infructescence.—D. Portion of lower leaf surface.—E. Stamen, with lateral dehiscence, ventral view.—F. Stamen, lateral view.—G. Pistil.*

Paratypes. VENEZUELA. T. F. AMAZONAS: Río Guainía between San Miguel and Maroa, 100–400 m, 30 June 1959, *Wurdack & Adderley 43260* (MO, NY); DEPT. RÍO NEGRO: selva pluvial por las orillas del Medio Pacimoni, 1°40'N, 66°35'W, 3 Dec. 1984, *Stergios & Aymard 7582, 7583* (MO, PORT); 0.5 km N of mouth of Río Casiquiare, 1°57'N, 67°7'W, 5 Feb. 1980, *Liesner & Clark 9140* (MO, VEN); igapó forests along Caño Cuweje, 32 km S of San Carlos, 1°56'N, 67°03'W, 119 m, 4 Apr. 1980, *Clark 7480* (MO); laja on right bank of Caño Cupueni, opposite mouth of Río Atabapo, 120–130 m, 12 Nov. 1953, *Maguire, Wurdack & Bunting 36219* (MO, NY).

Common names. Uruch, onoto rebalsero; onotillo, urucurana.

The common names are derived from the superficial resemblance to the spinose fruits of *Bixa orellana* and *B. urucurana.* The species is related to *Sloanea kuhlmanii* Ducke of Amazonian Brazil but differs in the absence of a corrugated receptacle, in the shorter stamens with densely hirsutulous anthers and their appendages, in the entire leaf margins nonemarginate at the apex, in the densely pubescent peduncles and pedicels, and in the densely pubescent lower leaf surfaces, especially on the nerves. The younger leaves of *Davidse 27733* and *Wurdack & Adderley 43260* have a more abundant tomentum on the lower leaf surface. The pubescence of the older, more mature leaf blades tends to be more sparse and shortly ascending or spreading along the midrib and/or nerves, whereas the lower surface itself, including the tertiary veins, remains glabrous or essentially so.

Sloanea longiaristata Steyerm., sp. nov. TYPE: Venezuela. T. F. Amazonas: Depto. Atabapo, forested slopes, Cerro Marahuaca, 1–2 km N of Sima Camp, 3°43'N, 65°31'W, 1,100 m, 8–9 Mar. 1985, *Ronald Liesner 18455* (holotype, VEN; isotype, MO). Figure 4.

Arbor 5–15 m, ramulis juvenilibus tomentosis; petiolis 0.7–2 cm longis dense tomentosis; foliorum laminis late oblongo-obovatis vel elliptico-oblongis apice rotundatis vel breviter obtusis basi acutis vel subacutis 10–15 cm longis 5–11 cm latis praeter utrinque costam mediam nervos lateralesque tomentosis glabris integris vel subundulatis; inflorescentiis lateralibus racemosis 1.5–4.5 cm longis 3–8-floris dense hirtellis pilis patentibus munitis; pedunculis 5–7 mm longis dense hirsutulis; pedicellis 4–15 mm longis dense hirsutulis pilis patentibus munitis; sepalis quattuor reflexis lanceolatis acutis 2.5–4 mm longis, utrinque hirsutulis; antheris elliptico- vel ovoideo-oblongis 0.7–1 mm longis dense hirsutulis lateraliter dehiscentibus; connectivo in aristam glabram elongatam 1.3–2 mm longam producto; filamentis 1.5–2.1 mm longis dense hirsutulis; stylis quadripartitis vel basi vix connatis 2.8–4 mm longis praeter basim adpresso-hispidulam glabris; capsulis ignotis.

Tree 5–15 m high, the young branches tomentose. Leaves alternate, crowded at the summit of the branches. Petioles 0.7–2 cm long, densely tomentose; leaf blades coriaceous, broadly oblong-obovate or elliptic-oblong, rounded at summit, or with a short broadly obtuse projection, cuneately acute or subacute at base, 10–15 cm long, 5–11 cm wide, the leaf surfaces glabrous, but the upper and lower midribs tomentose and the lower lateral nerves slightly pubescent, the margins entire to subundulate; lateral nerves 6–8 each side, elevated below, slightly impressed above, ascending at 45–60°, terminating mainly at the margins or unbranched before reaching margins; tertiary venation forming obliquely parallel connecting veins with the lateral nerves of the lower side, slightly elevated or impressed below. Inflorescence lateral, racemose, 1.5–4.5 cm long, 2.5 cm wide, 3–8-flowered, rachis moderately hirtellous with spreading hairs. Peduncles 5–7 mm long, densely hirsutulous. Bracts subtending pedicels, alternate, linear, 2 mm long, densely hirtellous. Pedicels 4–15 mm long, densely hirsutulous with spreading hairs. Sepals 4, reflexed, lanceolate, acute, 2.5–4 mm long, densely hirsutulous without, less pubescent within. Anthers elliptic or ovoid-oblong, 0.7–1 mm long, densely hirsutulous, laterally dehiscent, the connective prolonged into a conspicuously elongated glabrous awn 1.3–2 mm long; filaments 1.5–2.1 mm long, densely hirsutulous, much exceeding the anther body. Ovary ovoid-subglobose or ovoid-oblong, 3–3.5 mm long, 2–2.5 mm wide, densely hispidulous; styles 4, deeply divided or connate at the base, 2.8–4 mm long, glabrous except in the appressed-pubescent basal portion. Young capsule 4-celled.

Paratypes. VENEZUELA. T. F. AMAZONAS: 1–2 km SE and E of San Carlos, 20 km S of confluence of Río Negro and Brazo Casiquiare, 1°56'N, 67°3'W, 120 m, 22 Apr. 1979, *Liesner 6875* (MO, VEN). DEPT. ATABAPO: Cerro Marahuaca, Sima Camp, S-central portion of forested slopes along E branch of Caño Negro, 3°43'N, 65°31'W, 1,140 m, 21–22 Feb. 1985, *Steyermark & Holst 130507* (MO, VEN).

This species is most closely related to *Sloanea duckei* C. E. Smith and *S. rufa* Planch. ex Benth. From *S. rufa* it differs in the longer anthers and longer awns, more elongated inflorescences and pedicels, broadly rounded leaf apices, glabrous lower leaf surface, and styles more divided. From *S. duckei* it differs in the longer awns; longer filaments; pubescent petioles, midribs, and secondary nerves of the leaf blades; broadly obovate or oblong-obovate leaf blades acute or subacute at base; shorter peduncles; and 4 instead of 5–7 sepals. From

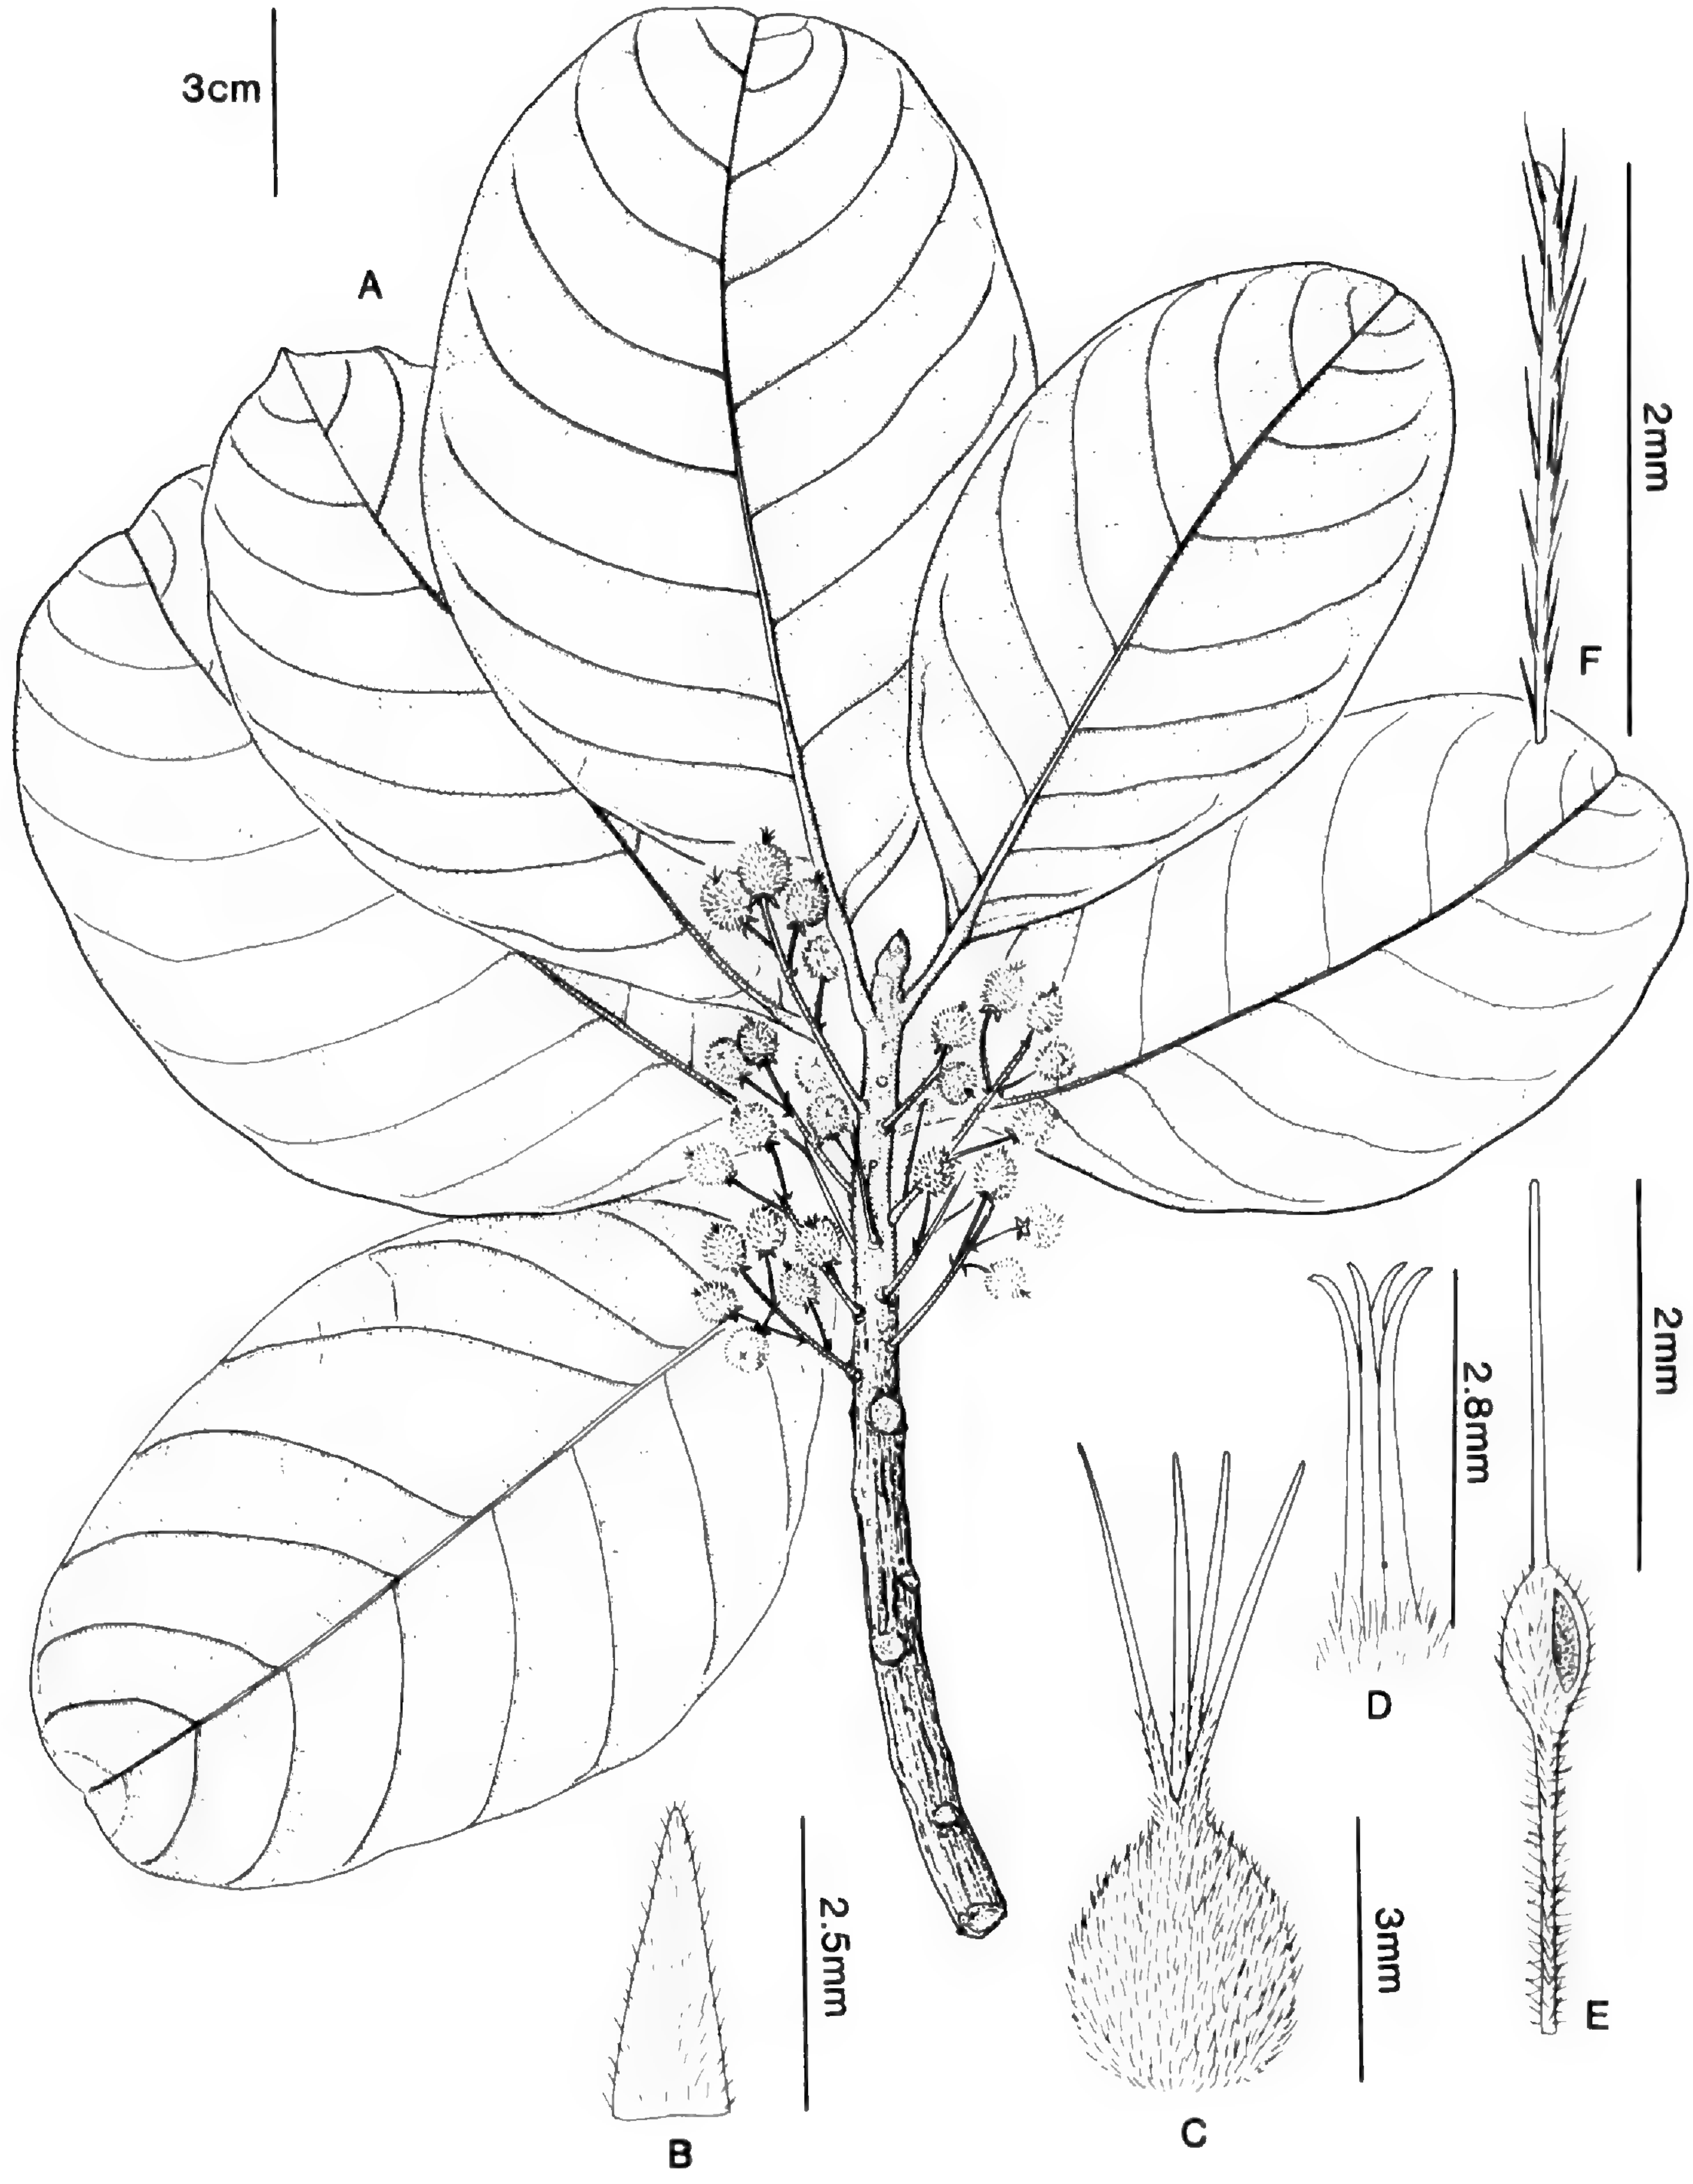

FIGURE 4. Sloanea longiaristata.—*A. Habit.—B. Sepal, exterior view.—C. Pistil, showing free styles.—D. Pistil, showing coherent styles.—E. Stamen.—F. Portion of bristly hairs of young fruit.*

other related species belonging to section *Brevispicae* C. E. Smith, such as *S. stipitata* Spruce ex Benth. and *S. robusta* Uittien, it is distinguished by the elongate awns longer than the anther body, shorter petioles, and differences in the leaf blades.

The collection *Liesner 6875* from the region of San Carlos is doubtfully assigned to this taxon. It differs in having the styles more united and smaller, glabrous leaf blades with the apices more obtusely prolonged rather than rounded and with more-undulate margins.

Sloanea merevariensis Pittier ex Steyerm., sp. nov. TYPE: Venezuela. Bolívar: Alto Río Guaña (Merevari) near Brazil frontier, without date, *Felix Cardona 1051* (also numbered *1053, 1055*) (holotype, F; isotypes, US, VEN). Figure 5.

Arbor; ramulis minute pubescentibus; petiolis 2.5–3.3 cm longis, minute adpresso-puberulentibus; foliorum laminis obovatis apice rotundatis basi acutis 8.5–13 cm longis 4–6.5 cm latis, costa media supra dense tomentosa, subtus pilosula pilis laxis munita; nervis lateralibus subtus puberulis pilis patentibus praeditis; nervis lateralibus utroque latere 9–10; inflorescentiis umbellatis vel corymboso-racemosis 3–5-floris; pedunculis 6–7 mm longis moderate adpresso-puberulentibus; pedicellis 7–8 mm longis moderate adpresso-puberulentibus; sepalis quattuor reflexis ovatis acutis 4–4.5 mm longis; antheris 1.5–1.6 mm longis hispidulis lateraliter dehiscentibus, connectivo in acumen late lanceolatum acutum 0.3–0.4 mm longum producto; filamentis 2 mm longis pilosulis; stylis quadripartitis erectis supra medium glabris infra medium minute puberulis. Capsula ignota.

Tree with minutely pubescent branches. Leaves alternate. Petioles 2.5–3.3 cm long, minutely appressed-puberulent except on the more densely pubescent canaliculate upper side; leaf blades obovate, rounded at apex, acute at base, 8.5–13 cm long, 4–6.5 cm wide, glabrous on the upper and lower surfaces except densely tomentose above on the slightly sulcate midrib, this moderately laxly pilose below and laxly puberulous on lower lateral nerves, the nerves 9–10 each side, ascending at 45–50° and anastomosing 3–5 mm from margins; tertiary venation minutely reticulate, elevated both sides, with subparallel obliquely transverse connections with the lateral nerves. Inflorescence lateral and terminal, umbellate or corymbose-racemose with 3–5 flowers. Peduncles 6–7 mm long, moderately appressed-puberulent; pedicels 7–8 mm long, moderately puberulent. Sepals 4, reflexed, dark in drying, subequal, 4–4.5 mm long, 3–3.5 mm wide at base, moderately pubescent without, sparsely appressed pubescent within, the margins pubescent. Anthers lance-elliptic, 1.5–1.6 mm long, hispidulous, laterally dehiscent, the connective prolonged into a short lanceolate, subacute, minutely puberulent awn 0.3–0.4 mm long; filaments 2 mm long, pilosulous. Ovary subglobose, 0.7 mm long; styles 4-parted, erect, 1.5 mm long, minutely puberulous in lower half, glabrous above. Capsule unknown.

This species was distributed by C. E. Smith as *Sloanea laurifolia* (Benth.) Benth. As indicated in another part of the text, *S. laurifolia* is treated by the present author as having less variability than that allowed by Smith. *Sloanea merevariensis* may be differentiated by the obovate, rounded leaf blades having the upper midrib densely tomentose.

Sloanea parvifructa Steyerm., sp. nov. TYPE: Brazil (near Venezuelan border). Serra da Neblina, Rio Negro, Rio Cauaburi, Rio Maturacá, between Missão Salesiana and Serra Pirapucú, 800–1,000 m, 23 Jan. 1966, *Nilo T. Silva & Umbelino Brazão 60865* (holotype, MO; isotype, NY).

Arbor 10 m, ramulis prope apicem dense minuteque pubescentibus; petiolis 1.5–2.7 cm longis minute puberulentibus; foliorum laminis obovato-spathulatis, apice rotundatis vel late obtusis, basi acutis 13–19 cm longis, 4.5–7 cm latis obscure repandis vel integris praeter costam medium sparsim puberulam utrinque glabris; nervis lateralibus utroque latere 7–8; floribus non visis; infructescentiis lateralibus racemosis 4–5-fructus gerentibus 3–3.5 cm longis; pedunculis 5–9 cm longis; pedicellis fructiferis 8–10 mm longis dense puberulis; capsulis parvis, valvulis 9–10 mm longis 7 mm latis, tenuibus, spinis tenuibus 1.5–3 mm longis antrorse pubescentibus.

Tree 10 m tall, the branches minutely pubescent toward the summit. Leaves alternate. Petioles 1.5–2.7 cm long, densely minutely puberulent; leaf blades obovate-spathulate, rounded or broadly obtuse at apex, narrowed at the acute base, 13–19 cm long, 4.5–7 cm wide, obscurely repand or entire, except for the sparsely pubescent upper and lower midribs, glabrous on both surfaces; lateral nerves 7–8 on each side, ascending at 50–60°. Flowers not seen. Infructescence lateral, racemose, bearing 4–5 fruits, the fruiting axes 3–3.5 cm long, 1.5 mm wide, widely spreading from stem, densely puberulous with spreading-ascending trichomes; peduncle 5–9 mm long; fruiting pedicels slender, 8–10 mm long, densely puberulous with spreading-ascending hairs. Capsules relatively small, the valves 9–10 mm long, 7 mm wide; bristles slender, purple, 1.5–3 mm long, antrorsely pubescent. Seeds oblong, 7 mm long, 4.5 mm wide.

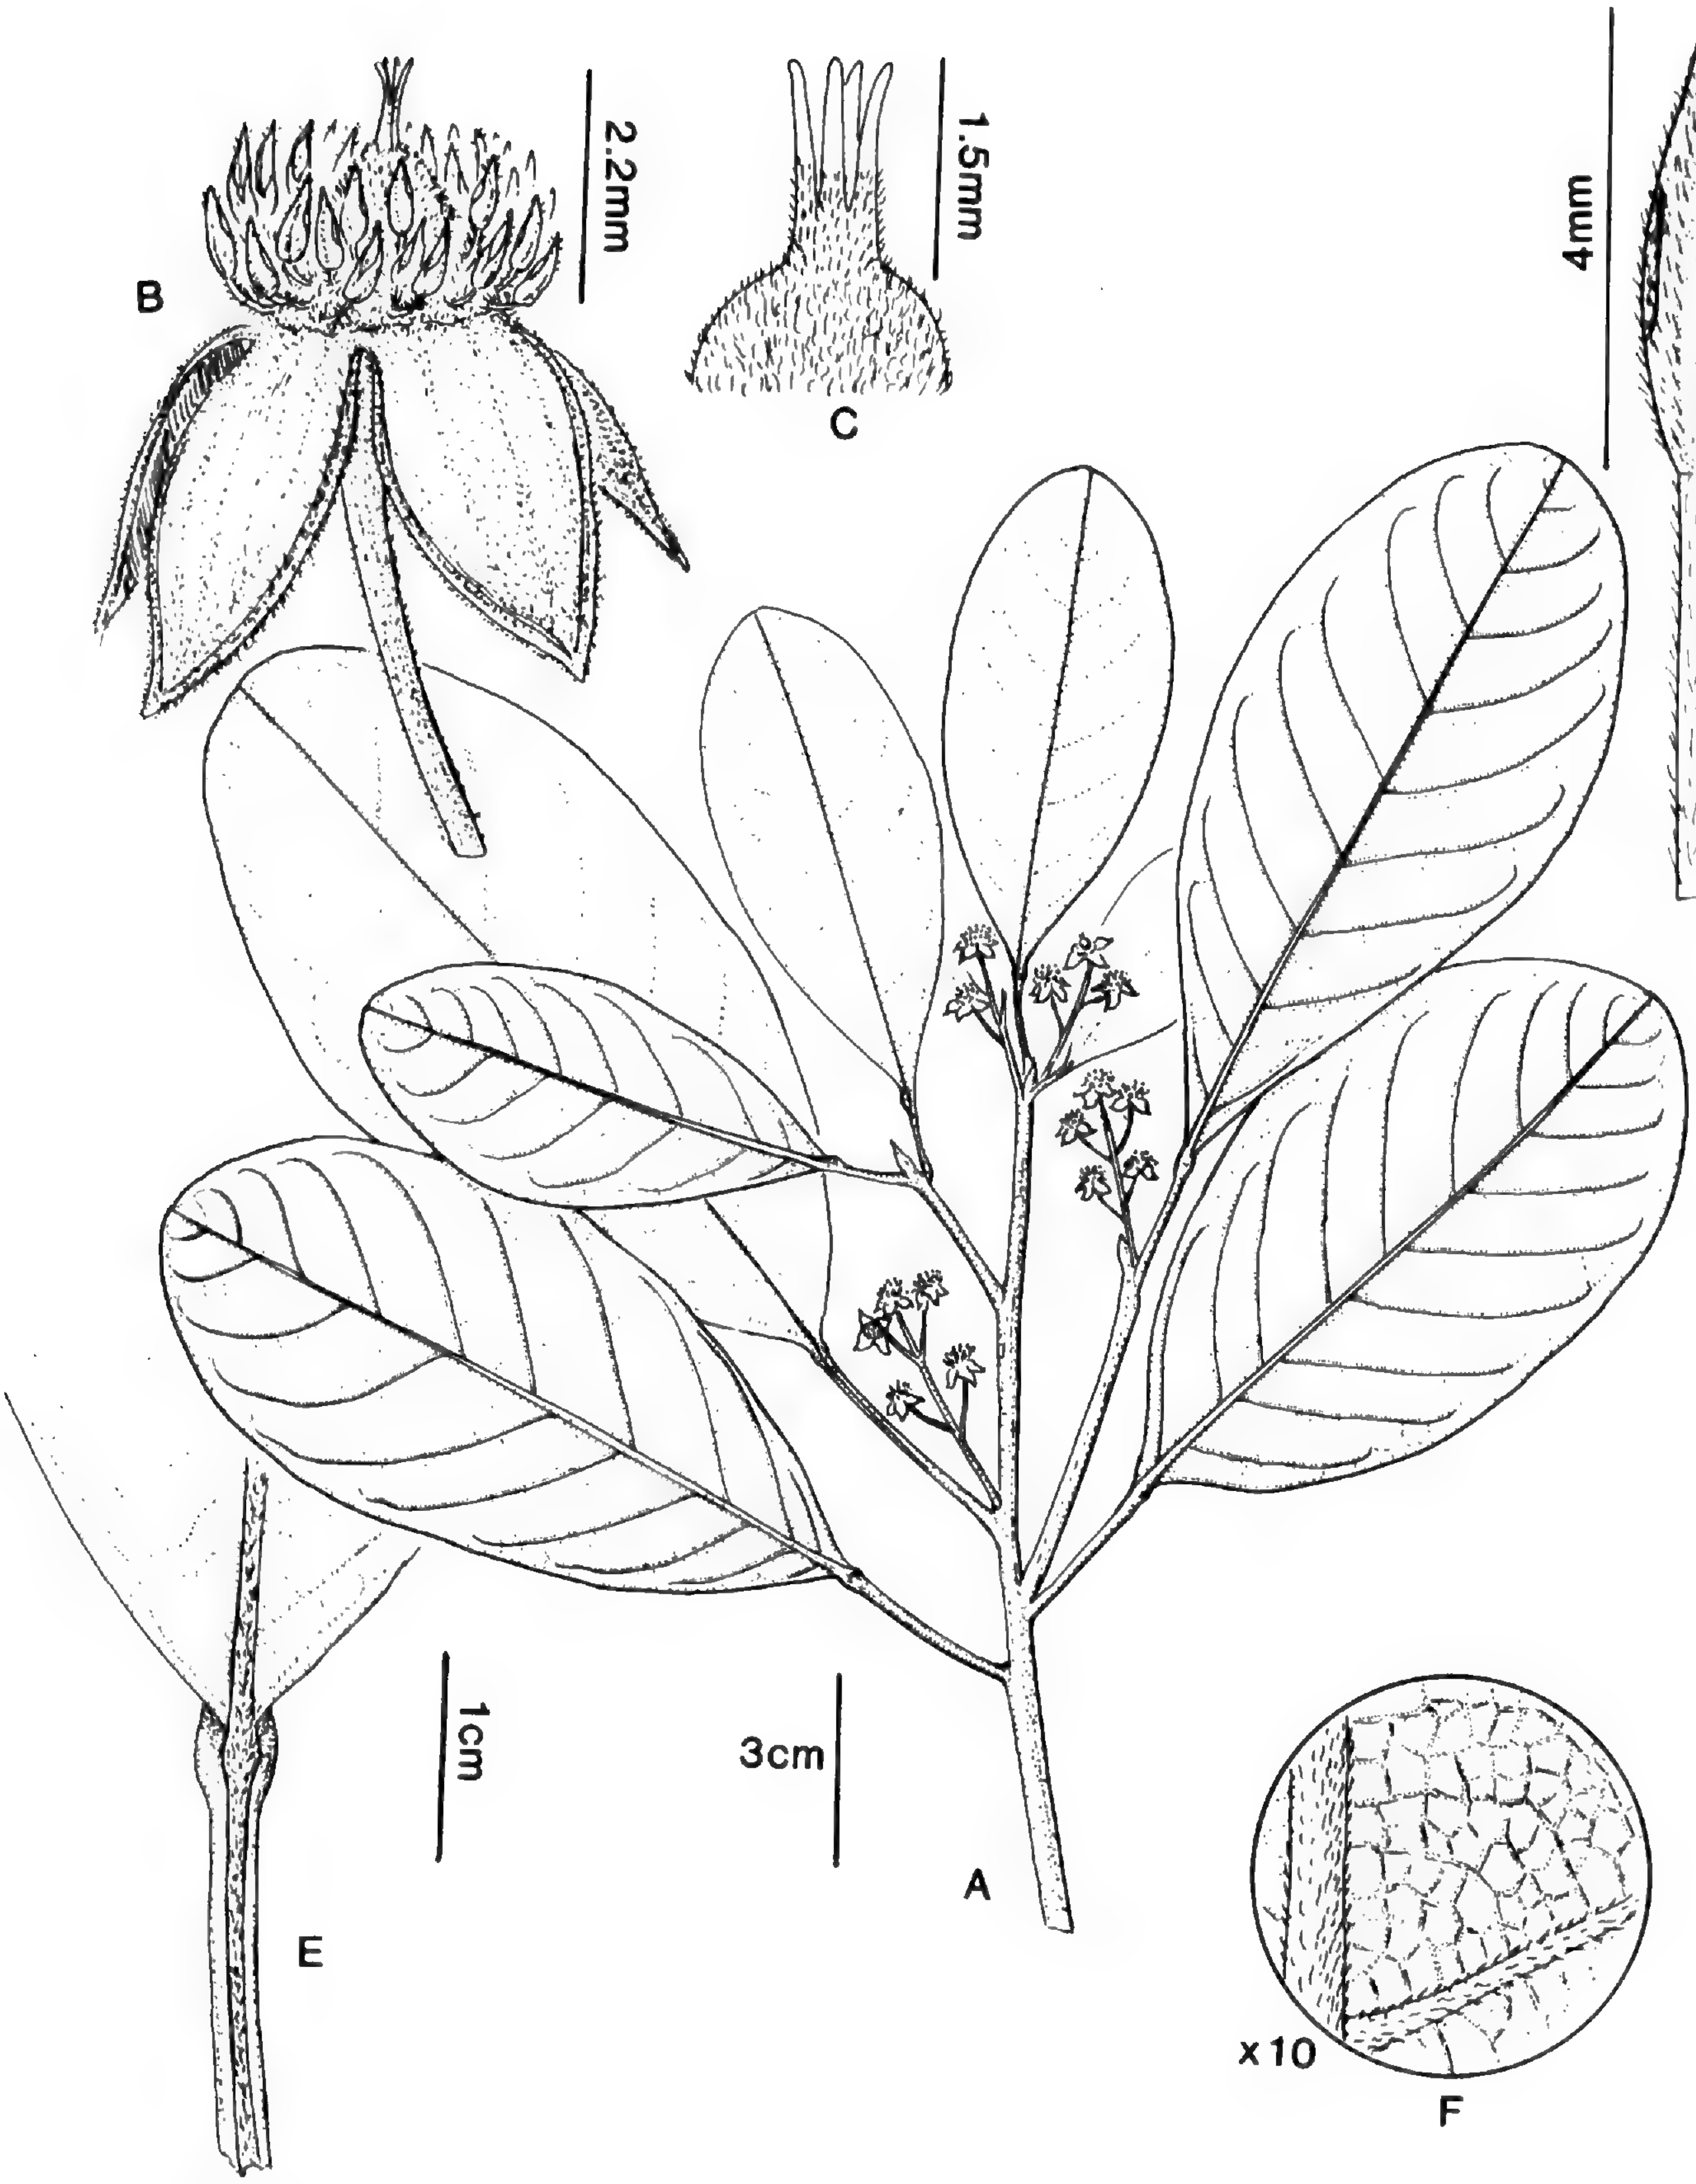

FIGURE 5. Sloanea merevariensis.—*A. Habit.—B. Flower, at anthesis.—C. Pistil.—D. Stamen.—E. Base of leaf blade, adaxial view, with petiole.—F. Lower portion of leaf blade.*

From the related *Sloanea duckei* C. E. Smith of Amazonian Brazil, the new species differs in having densely puberulent petioles, a puberulous lower midrib, and lateral nerves ascending at a greater angle. From *S. spathulata* C. E. Smith of Territorio Acre, Brazil, it differs by having longer infructescences with longer pedicels, much shorter bristles, shorter petioles, more strongly ascending lateral nerves, and obliquely transversely connecting tertiary nerves straighter, less branched, and less prominent.

Sloanea sipapoana Steyerm., sp. nov. TYPE: Venezuela. T. F. Amazonas: Cerro Sipapo (Paráque), Camp Savanna, 1,500 m, 15 Dec. 1948, *Bassett Maguire & Louis Politi 27674* (holotype, MO; isotype, NY). Figure 6.

Arbor ad 15 m alta ubique plerumque glabra, foliis alternis; petiolis 0.9–1.5 cm longis; foliorum laminis coriaceis lanceolatis vel lanceolato-ellipticis apice acutate acuminatis basi obtusis vel subacutis majoribus 8.5–13.5 cm longis 2.5–5 cm latis integerrimis; costa media supra elevata; nervis lateralibus supra vix manifestis subtus paullo elevatis utroque latere 11–13; venatione tertiaria subtus subtiliter reticulata; infructescentia laterali; pedunculo 2.5–3.5 cm longo glabro; pedicellis 1.5–2 cm longis glabris vel sparsim puberulentibus; capsulis inermibus 2–2.5 cm longis minute puberulentibus.

Tree to 15 m tall with glabrous branches. Leaves alternate, glabrous throughout. Petioles 0.9–1.5 cm long; leaf blades coriaceous, lanceolate or lance-elliptic, slenderly acutely acuminate at apex, obtuse to subacute at base, the large ones 8.5–13.5 cm long, 2.5–5 cm wide, entire; midrib elevated above and below; lateral nerves 11–13 each side, ascending at 25–35°, not reaching margin, scarcely evident above, slightly elevated below, anastomosing with tertiary venation 2–7 mm from margin; tertiary venation finely reticulate on lower surface, scarcely evident on upper surface. Infructescence lateral. Peduncle 2.5–3.5 cm long, 1–1.5 mm diam., glabrous. Pedicels 1.5–2 cm long, glabrous to sparsely puberulent. Capsules unarmed, 4-valved, 2–2.5 cm long, the surface densely and minutely puberulent. Seed oblong, 1.1 cm long, 0.8 cm wide.

Paratype. VENEZUELA. T. F. AMAZONAS: Cerro Sipapo (Paráque), upper Caño Negro and right branch (north) of Caño Profundo, 1,455 m, 10 Jan. 1949, *Maguire & Politi 28266-A* (MO, NY).

Apparently a member of section 4, *Corymbo-Racemi* C. E. Smith, most closely related to *Sloanea oppositifolia* Spruce ex Benth. (= *S. laurifolia* (Benth.) Benth.), from which the new species differs in the alternate, coriaceous leaf blades with an elevated midrib, inconspicuous lateral nerves, and finely reticulate tertiary venation of the lower surface.

Sloanea steyermarkii C. E. Smith

Sloanea steyermarkii C. E. Smith, described from a collection taken from the summit of Auyan-tepui, a massive sandstone table mountain of the Venezualan Guayana, appeared to be a distinct, isolated endemic species, characterized by the dense, congested, subsessile inflorescence; coriaceous, rugose leaf blades rounded at the apex; densely buff- or ferruginous-tawny tomentose lower leaf surfaces with the tomentum completely covering the midrib, nerves, and lower surface; and small, densely bristly fruits with bristles 2–4 mm long.

Additional collections obtained from the summits of various other sandstone table mountains throughout the Venezuelan Guayana have similar patterns of leaf size, shape, rounded apex, congested inflorescences, and small fruits with short bristles but differ chiefly in the density of the pubescence on the lower leaf surface. In typical *Sloanea steyermarkii*, known from the mountains situated within the eastern drainage of the Río Caroní and its tributaries (Ptari-tepui, Chimantá-tepui, Auyan-tepui, and Uaipán-tepui of Estado Bolívar), most or all of the leaves retain dense abaxial tomentum. However, a specimen collected from Uaipán-tepui (*Koyama & Agostini 7185*) has only the youngest leaves with a dense buff tomentum completely covering the lower surface, whereas the older ones have lost most of the dense tomentum and retain only mere traces on the lower surface and along the midrib and nerves.

Westward on the summits of the sandstone mountains, beginning with the western drainage of the Río Paragua of Cerro Guaiquinima and the Río Caura of Cerro Guanacoco and the Meseta del Jaua, the indument of the lower surface is less prominent and is manifested only by pale sparse puberulence along the midrib and some of the lateral nerves. This tendency toward glabrity continues westward on the summits of the sandstone mountains of the Territorio Federal Amazonas (Cerro Huachamacari, Yapacana, Aracamuni, Autana, and Sipapo). The taxa that have previously been treated as species, *Sloanea autanae* from Cerro Autana, *S. yapacanae* from Cerro Yapacana, and *S. jauaensis* (including var. *minor*) from the Meseta del Jaua, are best treated by recognizing subspecies with glabrous or glabrate leaf variations of a more widely ranging *S. steyermarkii* geographically isolated in the western portion of the Guayana Highland.

KEY TO THE SUBSPECIES OF *SLOANEA STEYERMARKII*

1a. Lower leaf surface chiefly densely tomentose beneath, at least on the younger leaves, completely covering the surface and nerves with a dense buff- or ferruginous-tawny tomentum; plants of Ptari-tepui westward to Chimantá Massif and Auyan-tepui, Edo. Bolívar .... *S. steyermarkii* subsp. *steyermarkii*

1b. Lower leaf surface glabrous or with a minute scattered pubescence; lower midrib and/or lateral nerves more or less puberulent to glabrous 2

2a. Leaf blades entire, mainly rounded or

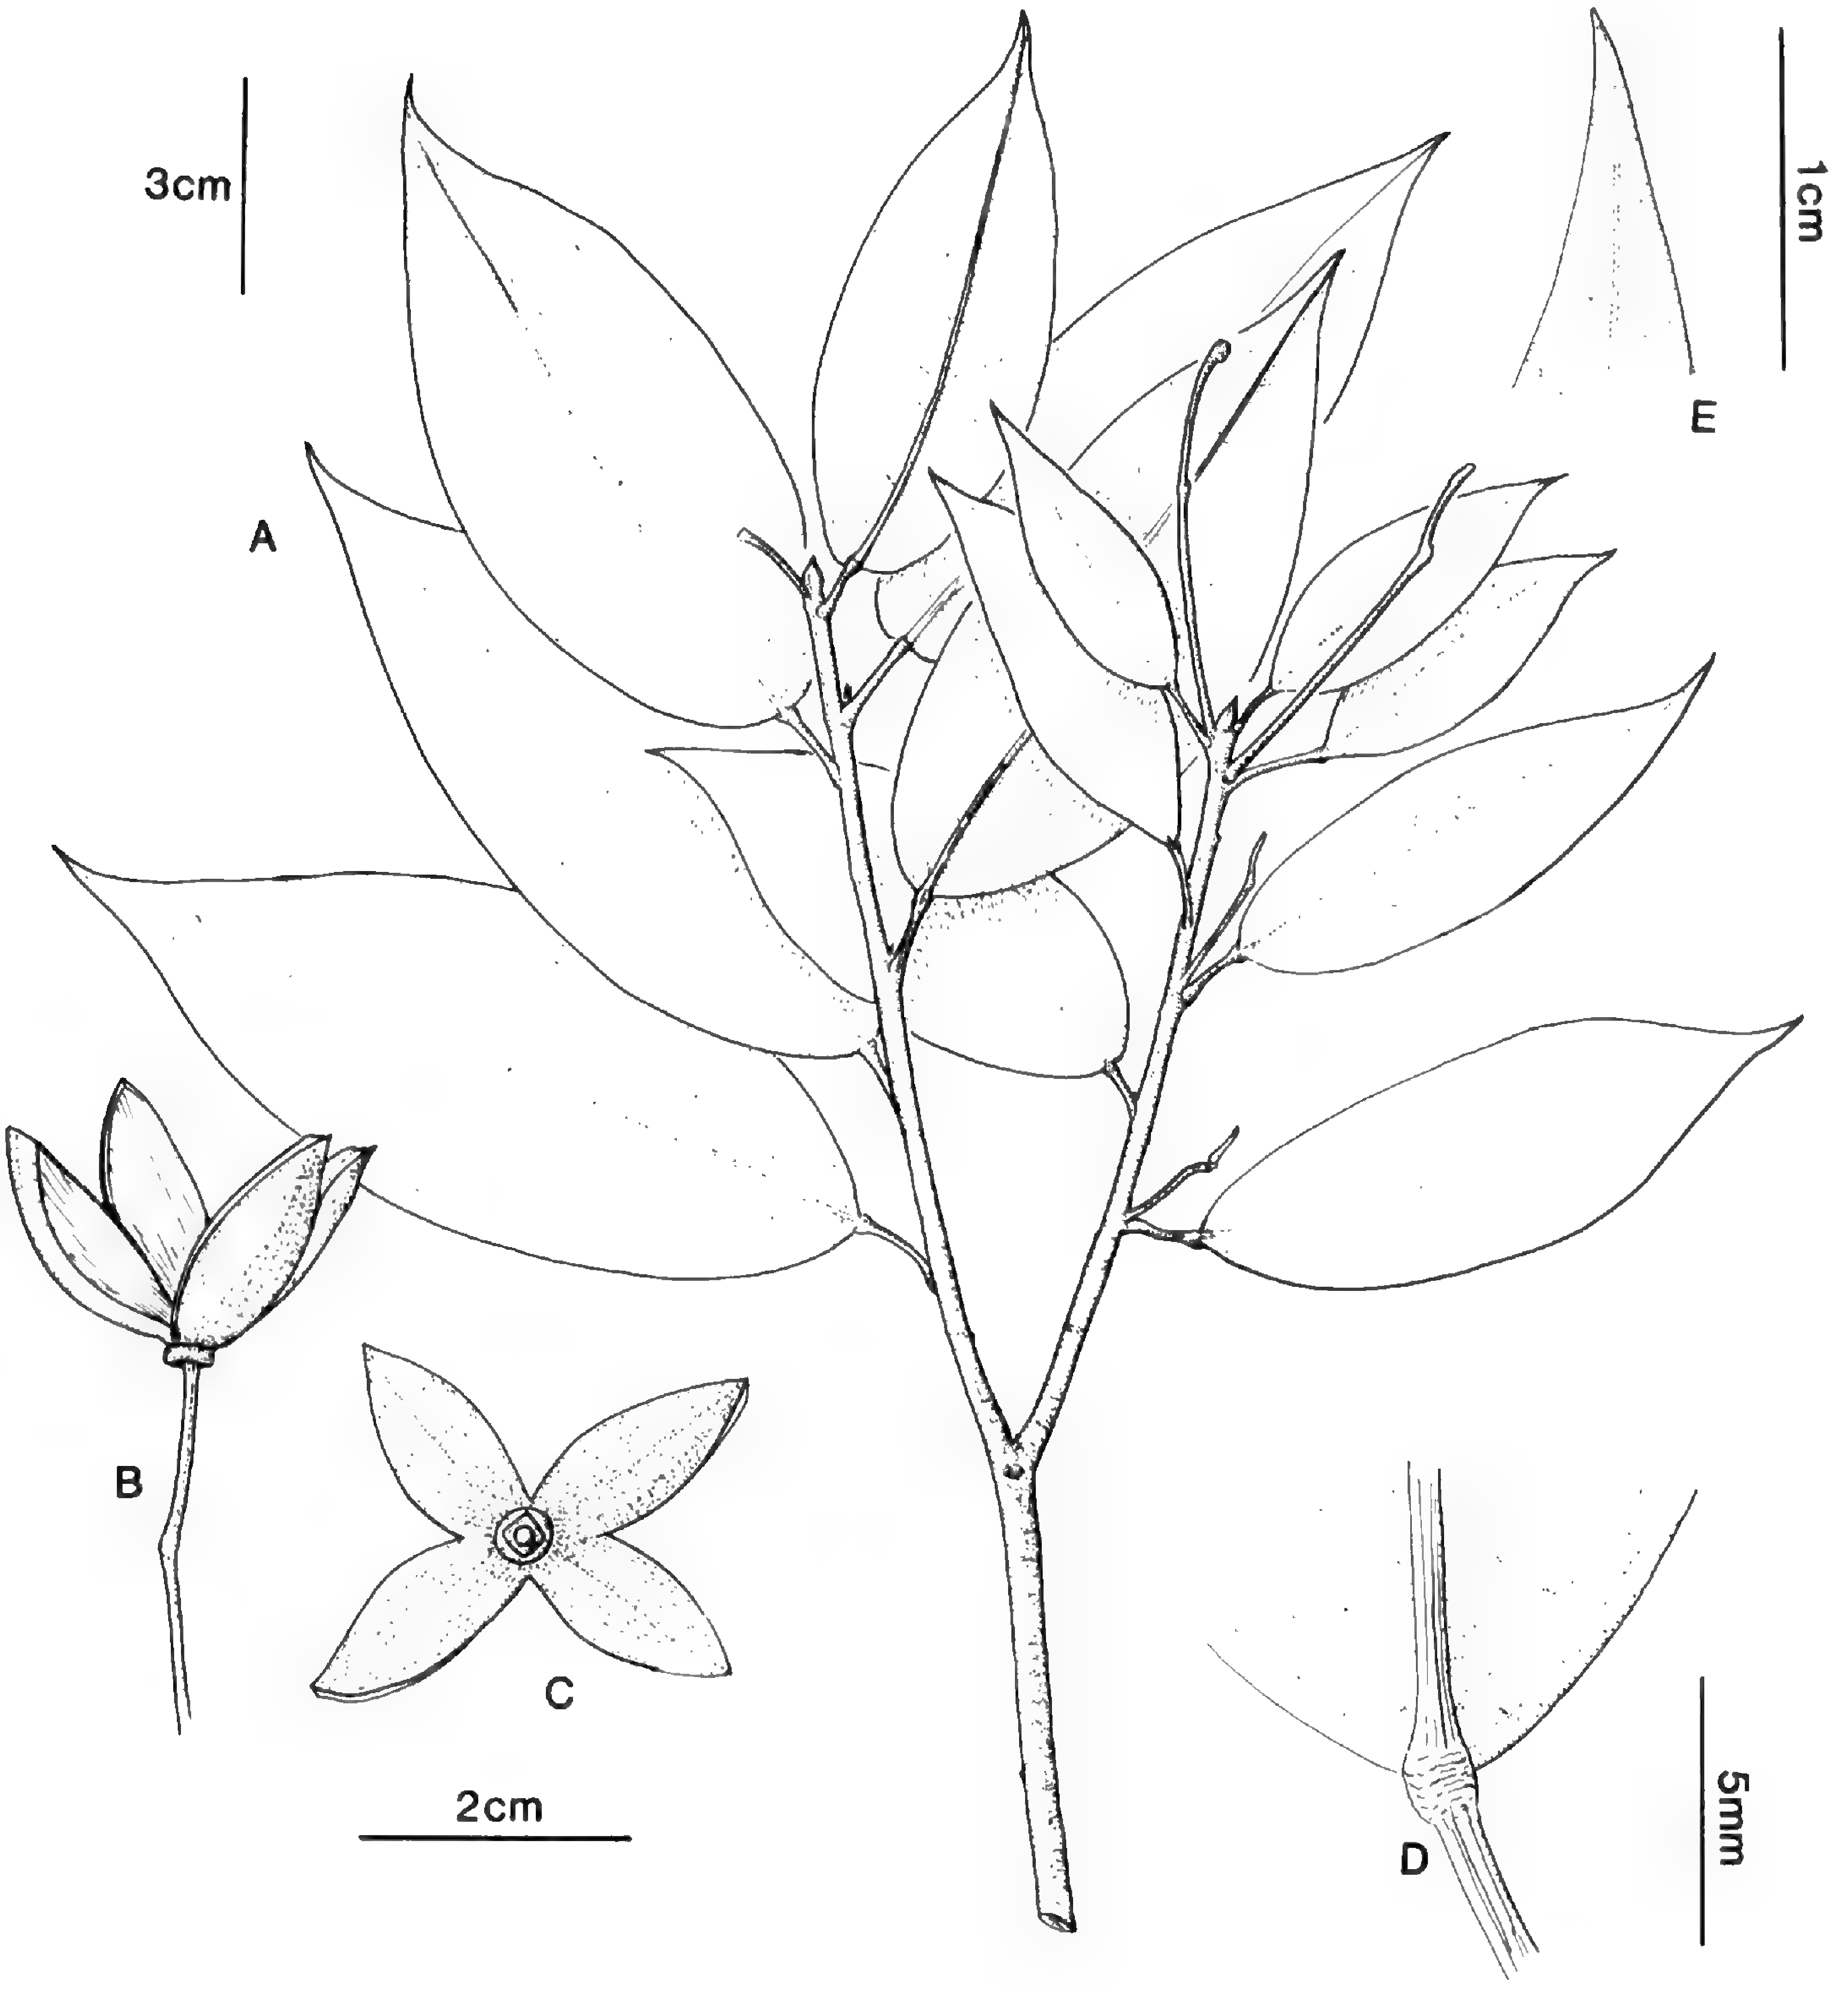

FIGURE 6. Sloanea sipapoana.—*A. Habit.—B. Capsule, lateral view, dehiscing.—C. Capsule, ventral view.—D. Leaf base, with portion of petiole, abaxial view.—E. Leaf blade showing apex, adaxial view.*

broadly obtuse at the apex .... *S. steyermarkii* subsp. *jauaensis*

2b. Leaf blades undulate-repand, often narrowed to a less obtuse apex .... *S. steyermarkii* subsp. *autanae*

Sloanea steyermarkii C. E. Smith subsp. **jauaensis** (Steyerm.) Steyerm., stat. nov. *Sloanea jauaensis* Steyerm., Bol. Soc. Venez. Ci. Nat. 33(132–133): 353. 1976.

Sloanea jauaensis Steyerm. var. *minor*, Bol. Soc. Venez. Ci. Nat. 33(132–133): 354. 1976.
Sloanea yapacanae Steyerm., Pittieria No. 7: 15. 1978.

Specimens examined. VENEZUELA. BOLÍVAR: Meseta del Jaua, Cerro Jaua, 4°48′50″N, 64°34′10″W, porción sur-oeste, 1,810–1,880 m, *Steyermark et al. 109841* (type of *Sloanea jauaensis*, VEN); Meseta del Jaua, Cerro Jaua, 4°48′50″N, 64°34′10″W, porción sur-oeste, 1,810–1,880 m, *Steyermark et al. 109695* (type of *S. jauaensis* var. *minor*, VEN); Cerro Guaiquinima, Río Paragua, below SE escarpment, 1,600–1,700 m, *Maguire 33029* (NY); Cerro Guanacoco, 4°46′30″N, 63°55′5″W, 1,450 m, *Steyermark et al. 109760* (NY, VEN). T. F. AMAZONAS: Cerro Huachamacari, Summit Camp, 1,800 m, *Maguire et al. 30088, 30097* (MO, NY); Cerro Yapacana, 3°45′N, 66°45′W, 1,000–1,200 m, *Steyermark & Bunting 103186* (type of *S. yapacanae*, VEN); Cerro Yapacana, 1,200 m, *Maguire et al. 30737* (NY); Cerro Sipapo, S basin, 1,835 m, *Maguire & Politi 28684* (NY).

A sterile collection from the summit of Cerro Aracamuni (*Liesner & Carnevali 22722*) probably is to be referred to this subspecies.

Sloanea steyermarkii C. E. Smith subsp. **autanae** (Steyerm.) Steyerm., stat. nov. *Sloanea autanae* Steyerm., Pittieria 7: 13. 1978.

Specimens examined. VENEZUELA. T. F. AMAZONAS: Cerro Autana, 4°52'N, 67°27'W, 1,230–1,270 m, *Steyermark 105222* (type of *S. autanae*, VEN).

Sloanea subpsilocarpa Steyerm., sp. nov. TYPE: Venezuela. T. F. Delta Amacuro: bosque pluvial, E de Río Grande, ENE El Palmar, near limits of Edo. Bolívar, 29 Nov.–18 Dec. 1964, *Luis Marcano-Berti 447* (holotype, VEN; isotypes, MO, NY). Figure 7.

Arbor 28–30 m; petiolis 0.6–3 cm longis; foliorum laminis oblongis vel oblongo-ellipticis apice obtuse acutis obtusis vel raro rotundatis basi obtusis vel rotundatis 8–16 cm longis 4–7 cm latis integerrimis ubique glabris; nervis lateralibus utroque latere 4–6(–8); venatione tertiaria supra prominente reticulata; inflorescentia (post anthesim) subpaniculata 2–5-flora; pedunculis 1.5–2 cm longis tomentellis; pedicellis post anthesin 1–2 cm longis fructiferis 2–2.5 cm longis tomentellis; sepalis quattuor coriaceis late ovatis acutis dense fulvo-tomentellis 10–13 cm longis 9 mm latis; antheris 2 mm longis adpresso-pubescentibus prope poros sub apicales lateraliter dehiscentibus, connectivo in acumen lanceolatum obtusum glabrum 1.5 mm longum producto; filamentis 0.5–1 mm longis sparsim adpresso-pubescentibus vel glabris; ovario 5 mm longo dense fulvo-tomentoso; stylis 2 mm longis fulvo-strigillosis; capsulis inermibus vel sparsim breviter tuberculatis subglobosis 4.5 × 4.5 cm.

Trees 28–30 m tall. Leaves alternate. Petioles 0.6–3 cm long; leaf blades oblong or oblong-elliptic, acute or obtuse, rarely rounded at apex, obtuse or rounded at base, 8–16 cm long, 4–7 cm wide, entire, glabrous both sides; midrib sulcate above, elevated below; lateral nerves 4–6(–8) each side, impressed above, elevated below, branching and anastomosing 4–9 mm from the margins, ascending at 50–60°; tertiary venation prominently reticulate and subelevated above, reticulate and subelevated below. Inflorescence (past flowering) subpaniculate, terminal or lateral, 2–5-flowered; peduncles (past flowering) 1.5–2 cm long, 1.5 mm wide, 2–2.5 cm long (fruiting), brown-tomentose; bracts ovate, acute, 4–5 mm long, tomentellous on both sides; pedicels (past flowering) 1–2 cm long, 2–2.5 cm long, 3–3.5 mm wide (fruiting); sepals 4, coriaceous, persistent, broadly ovate, acute, 10–13 mm long, 9 mm wide at base, inner surface blackish, sparsely pubescent basally, densely brown-tomentellous without. Anthers 2 mm long, 0.7–0.8 mm wide, appressed-pubescent, dehiscing laterally by subapical pores, the connective prolonged into a glabrous, lanceolate, obtuse awn 1.5 mm long; filaments shorter than and about width of anther, blackish, 0.5–1 mm long, 0.5 mm wide, sparsely appressed to glabrous. Ovary subglobose-ovoid, 5 mm long, 5 mm wide, obtusely angled, densely brown-tomentose; styles 2 mm long, densely brown strigillose. Fruit unarmed or with a few scattered short, obtuse, glabrous tubercles 0.5–1 mm long on a surface covered with dense brown tomentum intermixed with minute white hairs 0.1–0.2 mm long, subglobose, 4.5 × 4.5 cm; mesocarp ligneous, 6–8 mm thick.

Paratypes. VENEZUELA. T. F. DELTA AMACURO: E de Río Grande, ENE of El Palmar, near limits of Edo. Bolívar, 29 June 1964, *Marcano-Berti 275* (MO, NY, VEN); same locality, *Marcano-Berti 437* (MO, NY, VEN). BOLÍVAR: campamento "El Paraiso" y "La Yagua," a 48 km NE del caserío Los Rosos, este último a 17 km de Upata (sobre la carretera nueva Upata–San Felix), 9 Sep. 1966, *Blanco 578* (VEN).

Common name. Almidon.

This species has been confused with *Sloanea laurifolia* (Benth.) Benth., from which it differs in the larger, thicker sepals, pubescent anthers with a longer, lanceolate awn, subpaniculate inflorescence, larger bracts, and stouter peduncle and pedicels. From *S. latifolia* (Rich.) Schum. (*S. inermis* Ducke) *S. psilocarpa* is distinguished by the shorter stamens with pubescent anthers; larger fruits with shorter, obtuse, glabrous tubercles; broadly ovate sepals broader at the base; and usually obtuse to rounded leaf bases.

Sloanea wurdackii Steyerm., sp. nov. TYPE: Venezuela. Bolívar: Río Parguaza, just below Raudal Maraca (ca. 110 km above river mouth), 115 m, 30 Dec. 1955, *John Wurdack & Joseph Monachino 41017* (holotype, MO; isotype, NY). Figure 8.

Arbor 6–20 m; petiolis 3.5–10 cm longis sparsim puberulentibus admodum glabris; foliorum laminis late oblongo-ovatis apice rotundatis basi subacutis vel rotundatis majoribus 18–25 cm longis 9.5–15 cm latis integerrimis admodum glabris; nervis lateralibus utroque latere 10–12; inflorescentiis elongatis duobus vel tribus simul laxe racemosis vel subpaniculatis 4–8.5 cm longis 2–5-floris, rhachidi glabra vel sparsim puberulenti; pedicellis elongatis apice recurvatis 1–4 cm longis minute puberulentibus; sepalis post anthesim valde reflexis lanceolatis 2.5 mm longis; antheris 0.9–1 mm longis dense adpresso-pubescentibus prope apicem dehiscentibus, connectivo in acumen acutate obtusum pubescentem 0.1–0.2 mm longum producto; filamentis 2 mm longis dense adpresso-pubescentibus; fructu immaturo oblongo 1.5–1.7 cm longo praeter partem basalem 3–4 mm longam inaequaliter spinosis, spinis rigidis 2–3 mm longis.

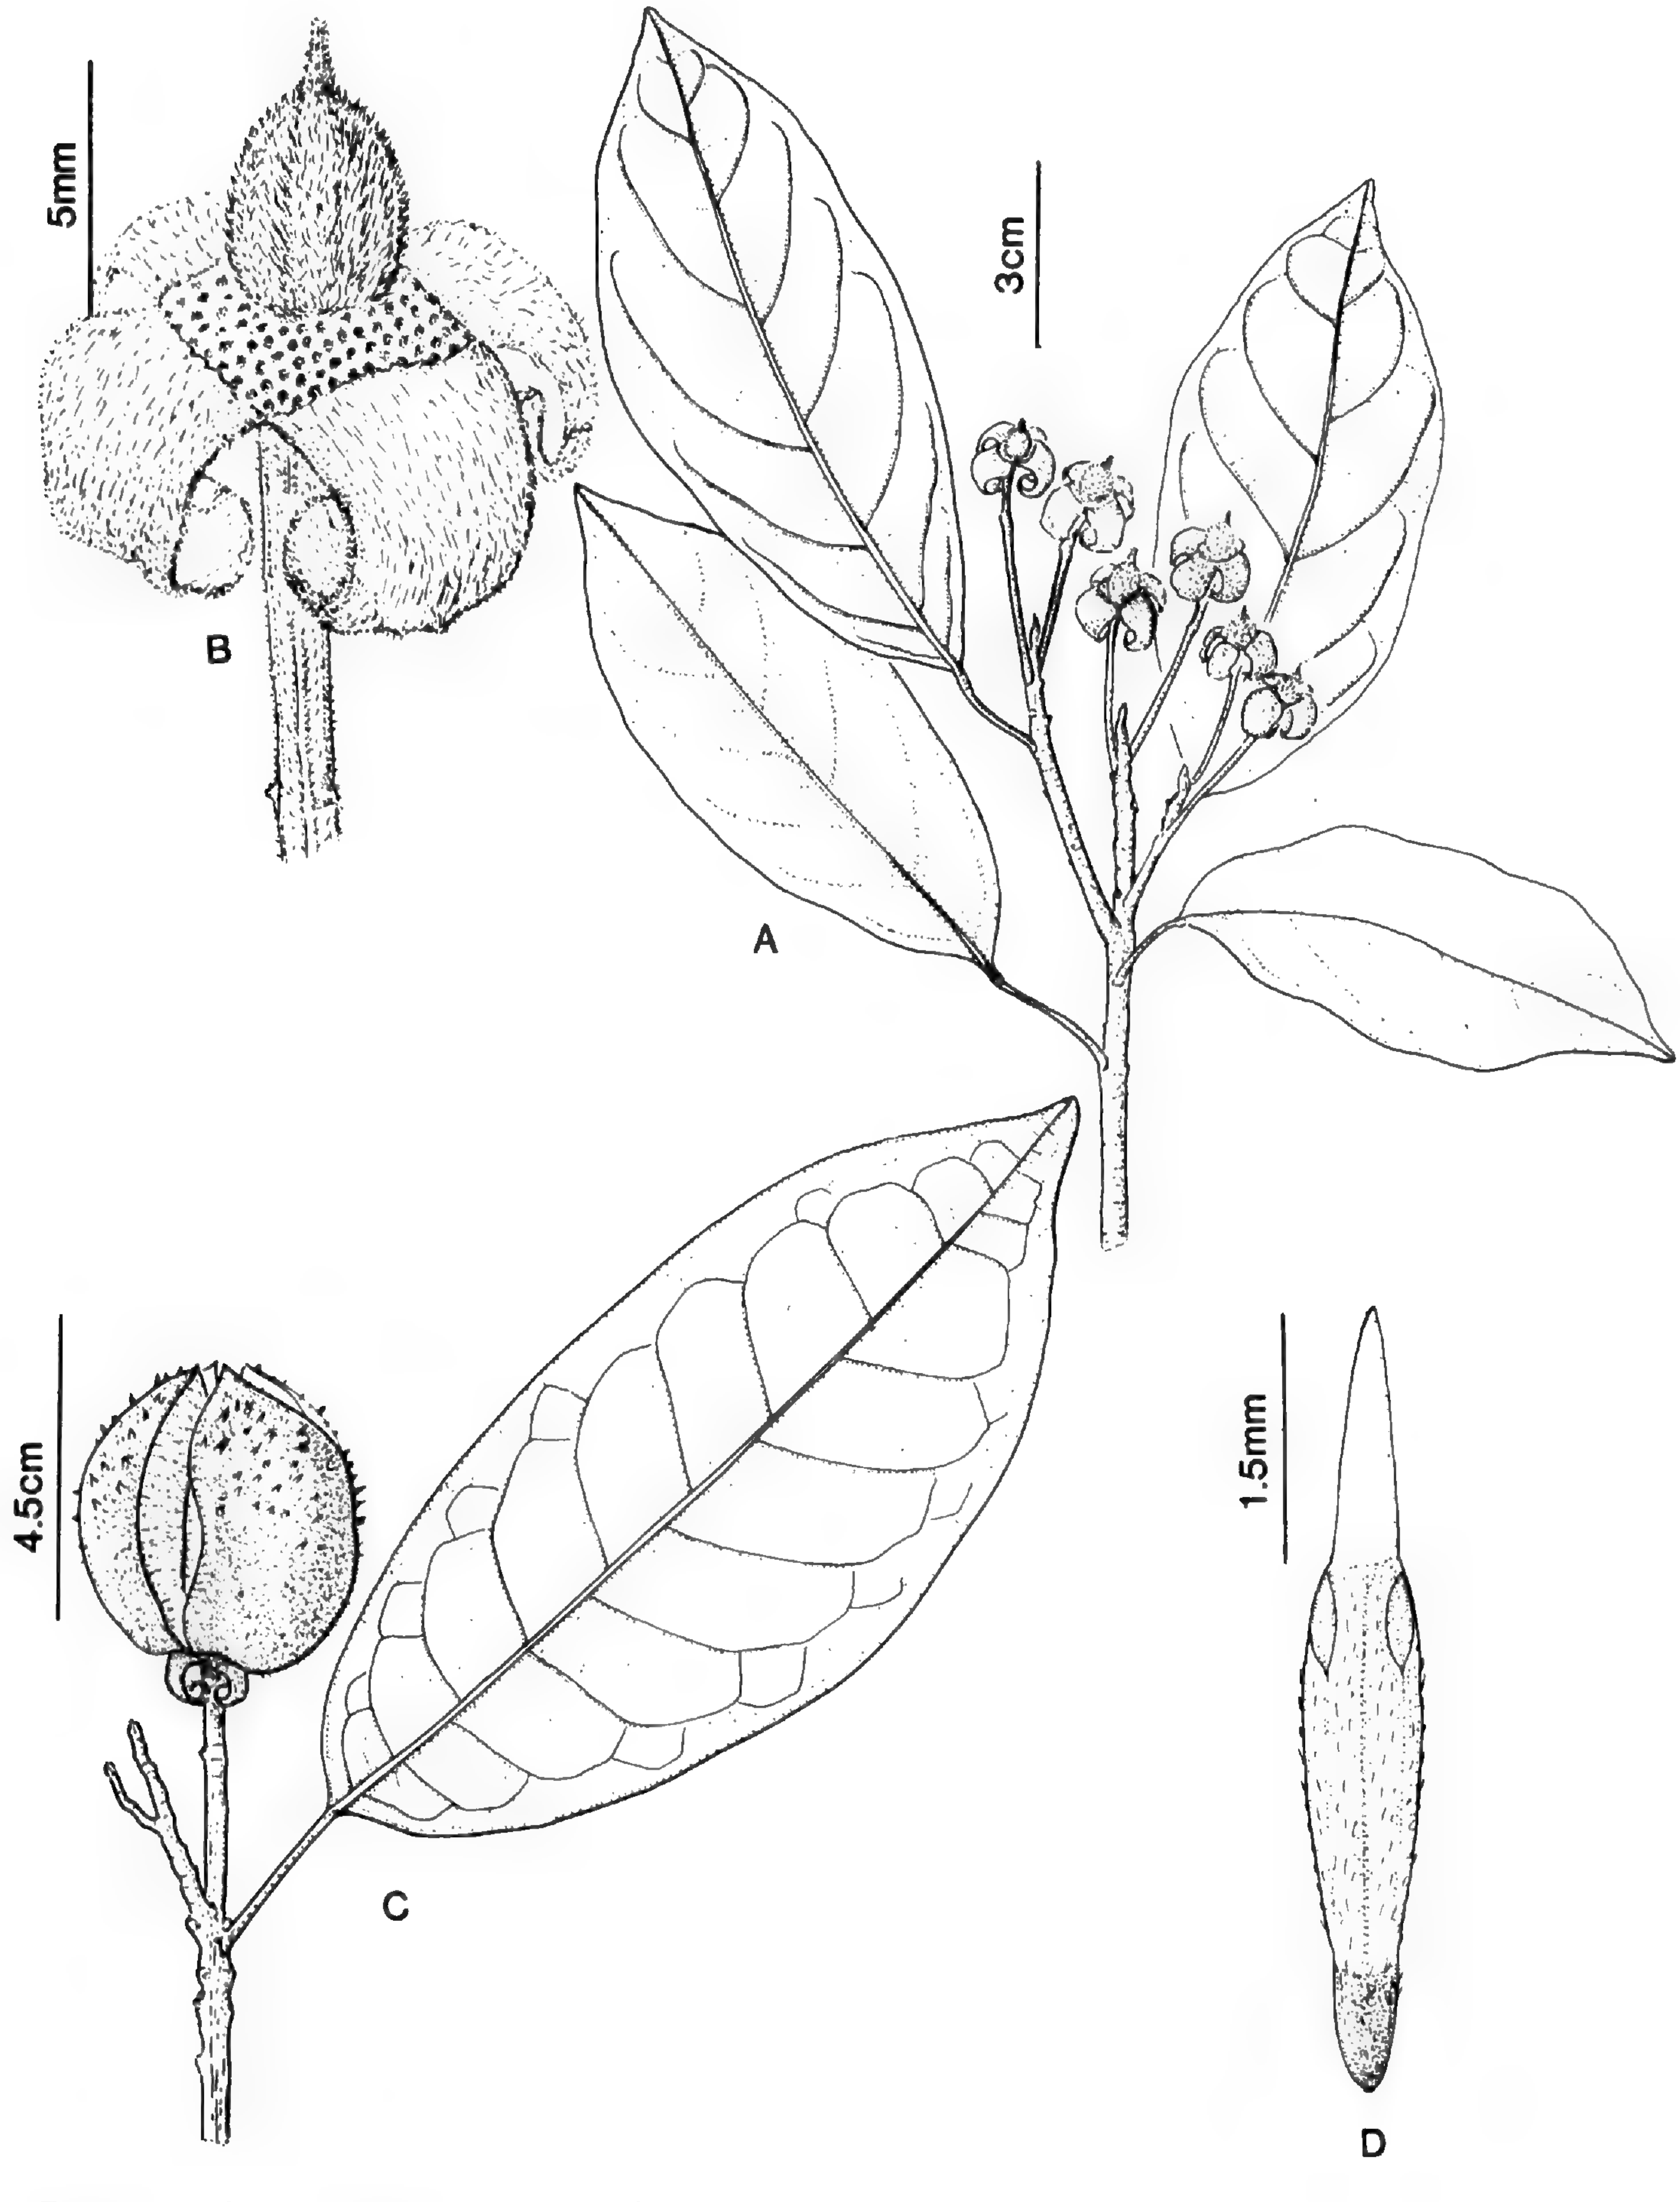

FIGURE 7. Sloanea subpsilocarpa.—*A. Habit.—B. Flower, post anthesis with reflexed sepals.—C. Portion of fruiting branch.—D. Stamen.*

Tree 6–20 m tall. Branches glabrous. Leaves alternate. Petioles 3.5–10 cm long, essentially glabrous but sparsely microscopically puberulent; leaf blades broadly oblong-ovate, rounded at the sometimes mucronate summit, subacute to rounded at base, the larger ones 18–25 cm long, 9.5–15 cm wide, entire or subentire, glabrous both sides; midrib essentially glabrous below but with traces of minute puberulence, prominently elevated; lateral nerves 10–12 each side, ascending at 60–70°,

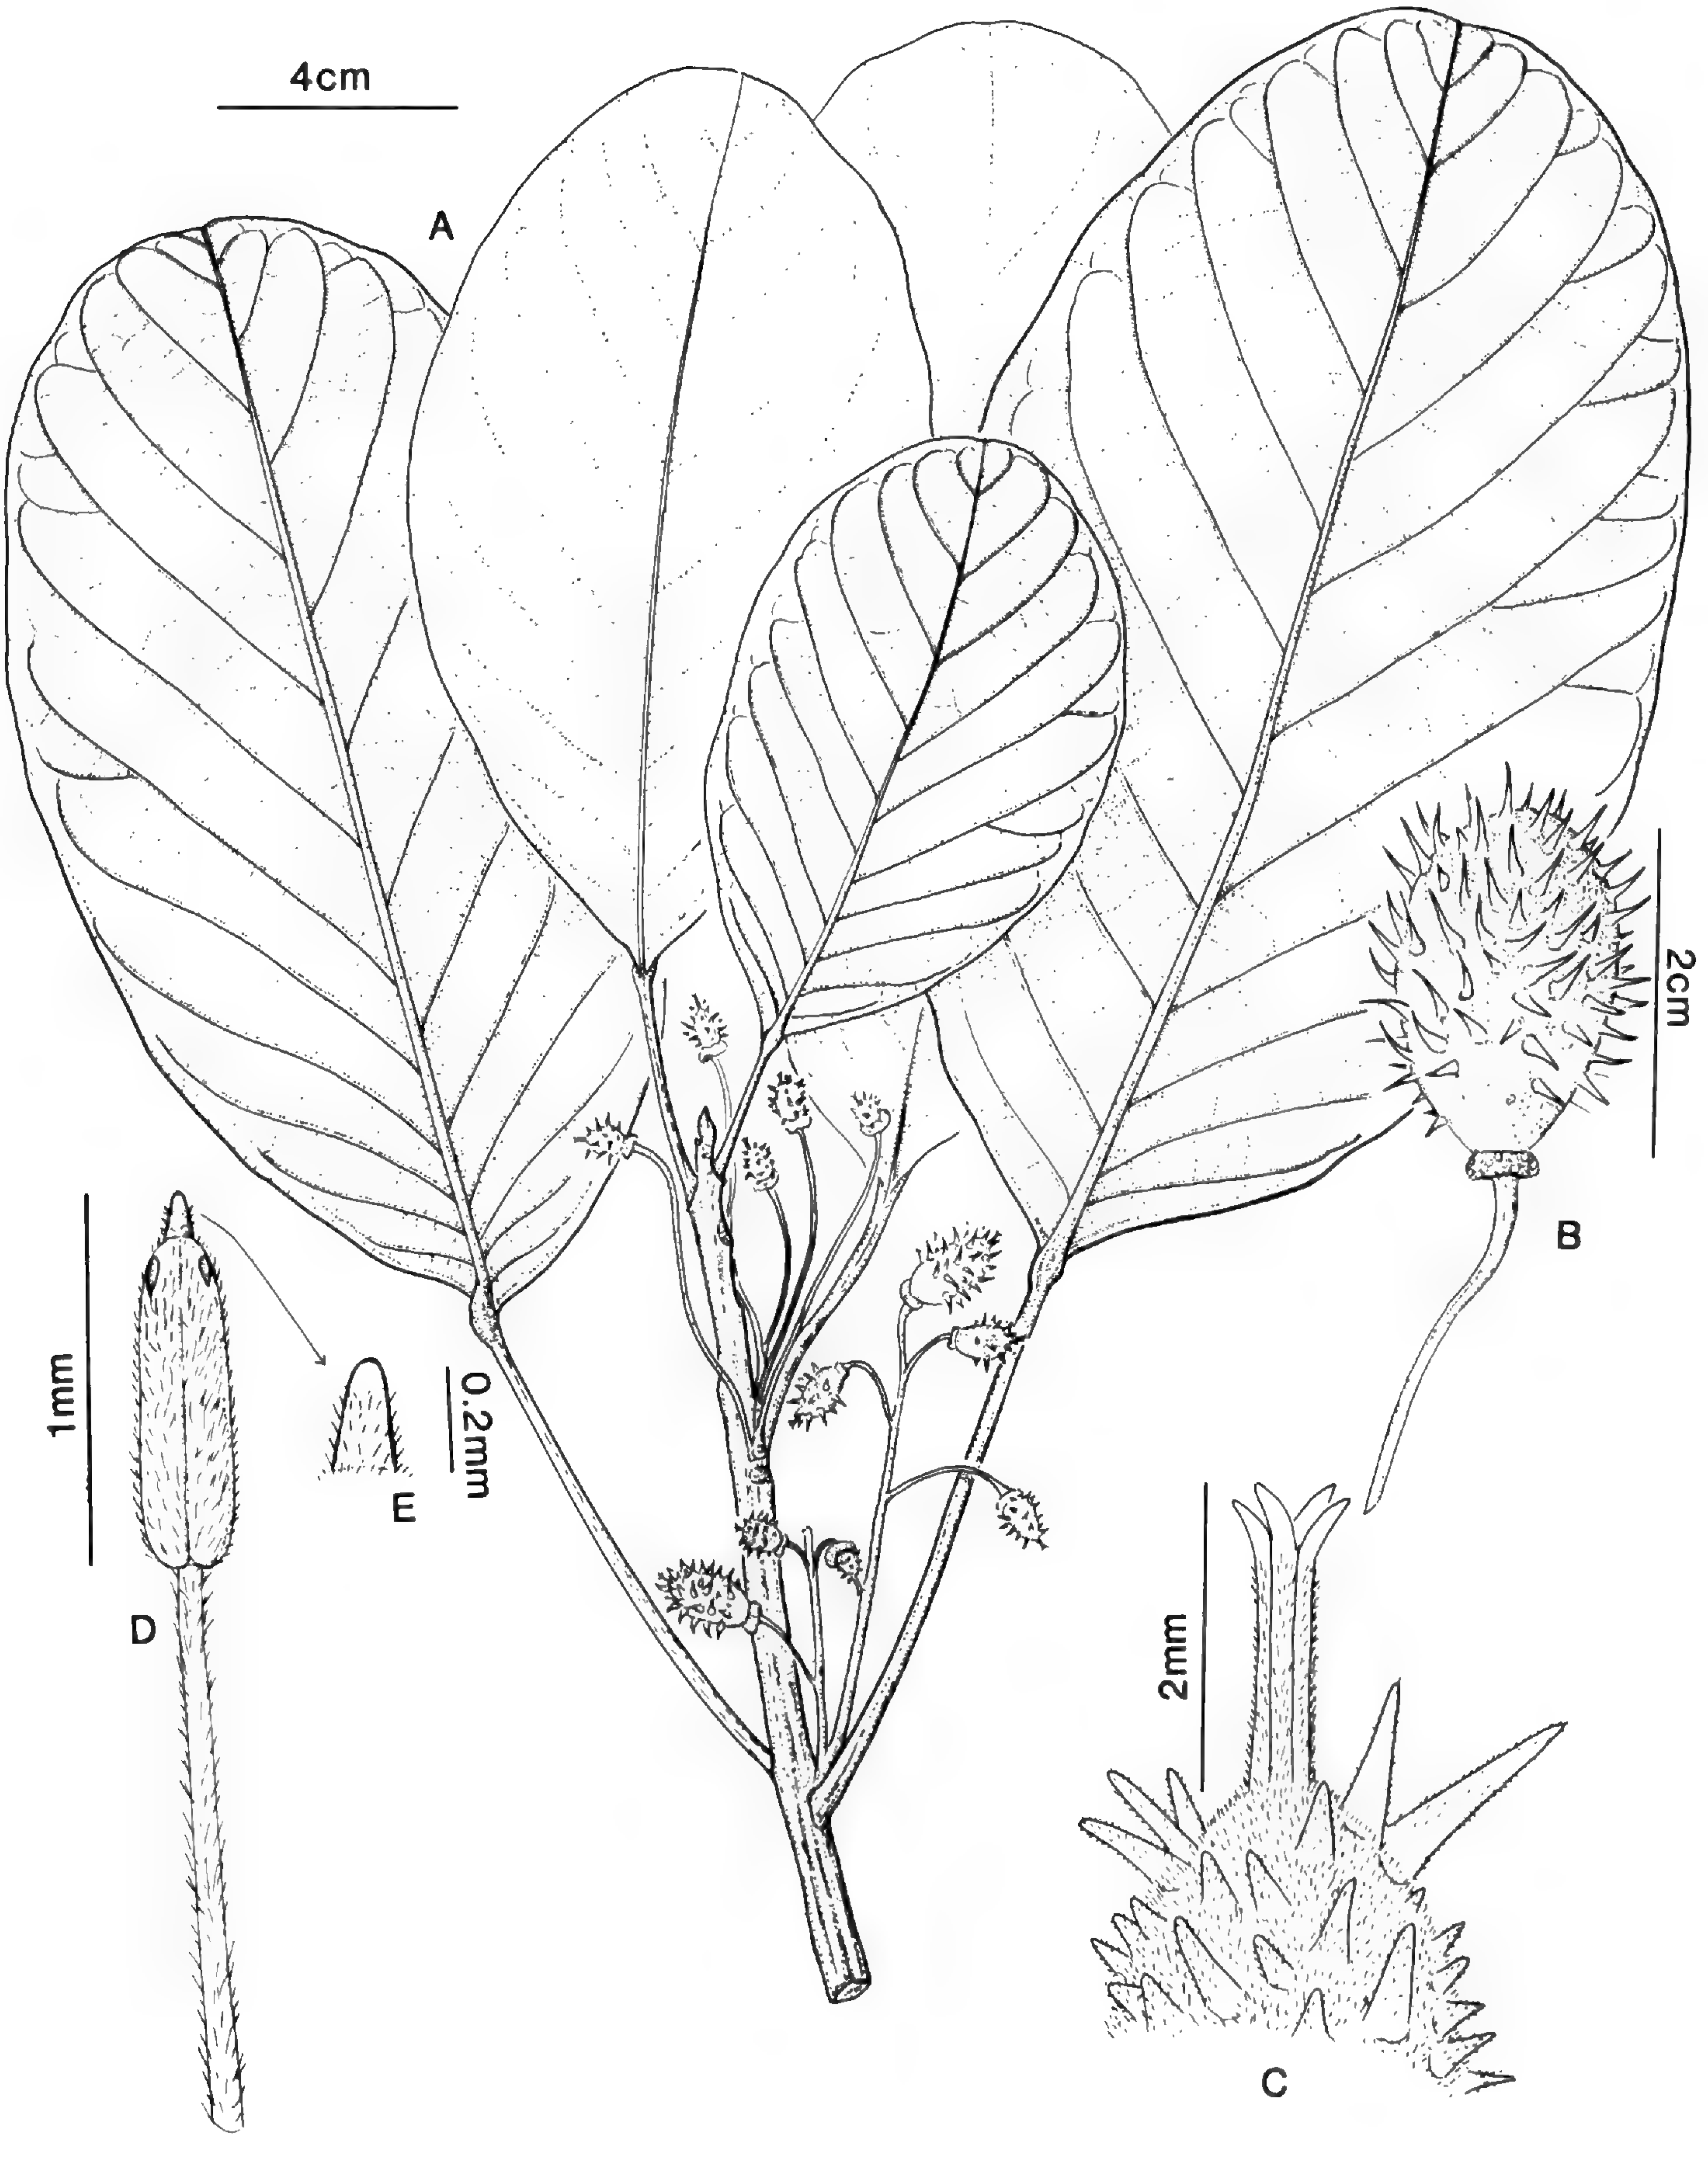

FIGURE 8. Sloanea wurdackii.—*A. Habit.—B. Capsule with pedicel.—C. Pistil.—D. Stamen.—E. Apical connective of anther.*

anastomosing 2–7 mm from the margin, elevated below, impressed above; tertiary venation minutely reticulate, slightly elevated above. Inflorescences elongated, subpaniculate or laxly racemose, 2–3 together, 4–8.5 cm long, 2–5-flowered, the rachis glabrous or minutely sparsely puberulent; pedicels elongated, recurved at apex, 1–4 cm long, the lowest 3.5–4 cm long, minutely puberulent. Sepals strongly reflexed after flowering, lanceolate, 2.5 mm long, 0.7–1 mm wide at base, minutely appressed-pubescent both sides. Anthers linear-lanceolate, 0.9–1 mm long, densely appressed-pubescent, dehiscent near the apex, connective prolonged into a short acutely obtuse pubescent knob 0.1–0.2 mm long; filaments 2 mm long, densely appressed-pubescent. Ovary 3 × 3 mm, densely short pubescent with tubercular processes 0.5–2 mm long; style stout, 2 mm long, appressed pubescent from base to apex. Young fruit oblong, rounded at apex, 1.5–1.7 cm long, 1 cm wide, unequally spinose-tuberculate with rigid stout spines broad at base, 2–3 mm long except absent in the basal 3–4 mm, the tubercles minutely appressed-pubescent; more mature fruit wine purple, 2 cm long, 1.5 cm wide, the spines slender-tipped.

Paratype. VENEZUELA. T. F. AMAZONAS: Dept. Atabapo, Caño Negro, río arriba desde la confluencia con el Río Cunucunuma, 3°40′N, 65°45′W, 200–210 m, 8 Feb. 1982, *Steyermark et al. 126231* (NY, VEN).

This species is characterized by elongated glabrescent pedicels recurved at the apex; elongated, irregularly laxly subpaniculate-racemose inflorescence; short-awned, densely appressed pubescent anthers much shorter than the densely pubescent filaments; stout appressed pubescent style; short, rigid, tubercular spines on a surface lacking tubercules in the basal portion; and general glabrity of stems and leaves. The fruiting structures show similarity to some members of sect. *Paniculi* C. E. Smith, such as *Sloanea caribaea* King & Urban ex Duss. However, the absence of material in full anthesis makes the placing of *S. wurdackii* uncertain. The large leaf blades and elongate petioles somewhat resemble those of *S. schomburgkii* Benth., but that species has longer anthers, which are longer than the filaments.

Although no stamens are present on the paratype, it is referred to the new species because the paratype has the characteristics shortly spinose fruit with rigid slender spines, which are absent in the basal area; the same type of elongated slender, recurved pedicels in an elongated inflorescence; similarly elongated petioles; similar leaf size, shape, and nervation; and general glabrity of the stems, petioles, pedicels, and foliage. The main differences noted in the paratype are the fewer lateral nerves which are farther apart, the lowest ones more spreading at a lesser angle; the leaf bases more rounded or broadly obtuse; and the peculiarly pitted upper surface of the leaf blade.

TAXONOMIC REVISION OF THE CENTRAL AMERICAN *LISIANTHIUS SKINNERI* SPECIES COMPLEX (GENTIANACEAE)[1]

Kenneth J. Sytsma[2]

ABSTRACT

The Lisianthius skinneri *(Gentianaceae) species complex consists of six closely related species in Panama.* Lisianthius skinneri *is widespread in Central America at low elevations and is morphologically variable. Five mostly cloud-forest species are endemic to central Panama:* L. jefensis, L. peduncularis, L. aurantiacus, L. habuensis, *and* L. weaveri. *The last three species are described as new. Divergence in floral and vegetative morphology among species is compared and contrasted with genetic divergence (DNA and isozymes) previously presented. Morphological divergence within the species complex is not correlated with molecular divergence.*

The *Lisianthius skinneri* (Gentianaceae) species complex is a small, geographically restricted, and interrelated assemblage of taxa. *Lisianthius skinneri* ranges widely throughout Central America but is patchily distributed and shows much ecological and morphological variability. Five endemic species in isolated central Panamanian forests and humid coastal sites exhibit divergence from *L. skinneri* in habit, morphology, breeding system, and ecological tolerance. A taxonomic revision of the *Lisianthius skinneri* species complex based on floral and vegetative morphology is presented here. A biosystematic and evolutionary analysis of the *Lisianthius skinneri* species complex using breeding systems, crossing and cladistic relationships (Sytsma, in prep.), and results of isozyme (Sytsma & Schaal, 1985a) and DNA (Sytsma & Schaal, 1985b) studies is presented elsewhere.

Lisianthius P. Browne is an exclusively neotropical genus in the Gentianaceae. *Lisianthius* and a number of related neotropical shrubby genera form a distinctive but rather diverse group collectively known as the "lisianthioid gentians." *Lisianthius* has been broadly interpreted in the past to include all these lisianthioid genera, usually as *Lisianthus* Linnaeus (1767) or *Lisyanthus* Aublet (1775), orthographic variants of the accepted name *Lisianthius* P. Br. (1756) (Taxon 3: 242. 1954). The most comprehensive and recent taxonomic treatment of the Gentianaceae (Gilg, 1895) places *Lisianthius* and *Macrocarpaea* in the tribe Gentianeae, subtribe Tachiinae. The other lisianthioid genera were relegated to the Helieae. The taxonomy of these lisianthioid gentians is in a state of chaos, with only *Lisianthius* (Weaver, 1972) and *Macrocarpaea* (Ewan, 1948; Nilsson, 1968) adequately monographed. A multidisciplinary study is now beginning on these lisianthioid genera (Nilsson, 1970; Maas et al., 1984; Maas, 1985). Many of these genera are confined to poorly accessible high-elevation peaks, thus explaining the small number of available specimens and the poor or incomplete nature of the few existing ones (Sytsma, 1987).

The genus *Lisianthius* consists of 30 species of woody or semiwoody Gentianaceae almost totally confined to Central America and the Greater Antilles. One species, *L. seemannii* (Griseb.) O. Kuntze, ranges into northwestern Colombia. The center of diversity for the genus is in Guatemala and Mexico, which together have 12 species. The genus exhibits a high degree of endemism. Jamaica has eight species, all endemic. Panama has seven species, five of which are endemic. *Lisianthius* species found

ANN. MISSOURI BOT. GARD. 75: 1587–1602. 1988

in Cuba (two species), Hispaniola (one species), and Puerto Rico (one species) are all endemic to each island. Weaver (1972) monographed *Lisianthius* in detail and gave a much needed intrageneric classification scheme. Chromosome numbers for all *Lisianthius* species previously examined (20 out of 30) are identical. Two sections were recognized: *Omphalostigma* and *Lisianthius*. Section *Omphalostigma* (Griseb.) Weaver is composed of only two species, *L. saponarioides* Cham. & Schlecht. and *L. meianthus* Donn. Sm., both exhibiting distinctive salverform corollas and equal filaments inserted near the apex of the corolla tube.

Section *Lisianthius* possesses basically tubular or funnelform corollas and unequal filaments inserted in the lower half of the corolla tube. This section is composed of subsect. *Herbacei* Weaver, annual or perennial suffrutescent herbs with determinate main axes, and subsect. *Fruticosi* Weaver, perennial subshrubs or shrubs with indeterminate main axes. Subsection *Fruticosi* is further divided into three series (*Longifolii* Weaver, *Exserti* Weaver, *Umbellati* Weaver) based on inflorescence architecture, exsertion of stamens and styles, and pollen grain reticulation. With its 18 species, series *Longifolii* is the largest species group in the genus and contains the *Lisianthius skinneri* species complex of Panama.

THE *LISIANTHIUS SKINNERI* SPECIES COMPLEX

BIOGEOGRAPHY AND ECOLOGY

Seven species of *Lisianthius* occur in Panama. Four of these already had been known (Elias & Robyns, 1975) and three are described as new in this paper. Of the seven Panamanian species of *Lisianthius*, six (excluding *L. seemannii* (Griseb.) Kuntze) form an unusual and distinctive interrelated species assemblage, hereafter referred to as the *Lisianthius skinneri* species complex. *Lisianthius seemannii*, ranging from Costa Rica to northwestern Colombia, is not especially closely related to the *L. skinneri* species complex, although it is likewise placed in series *Longifolii* of subsect. *Fruticosi*. *Lisianthius seemannii* has much smaller, usually ovate leaves and vegetatively most closely resembles the Jamaican *L. longifolius* rather than members of the *L. skinneri* species complex. The congested inflorescence in *L. seemannii*, a multicompound dichasium, is unique in series *Longifolii*. The long narrow corolla tube and lobes, paler inside than out, also clearly separate *L. seemannii* from the *L. skinneri* species complex.

Lisianthius skinneri (Hemsley) O. Kuntze is the widest-ranging species in the genus, but with a marked patchy distribution from southeastern Guatemala to the Darién province of Panama. It occurs from sea level to elevations of near 1,500 m in moist to wet tropical forests. The Atlantic Coastal Plain populations in Guatemala, Honduras, and Panama are frequently situated at sea level, while the populations in Costa Rica and the interior of Panama are found at mid elevations or occasionally higher elevations. *Lisianthius skinneri* has not been collected on the Atlantic Coastal region of Nicaragua or Costa Rica. It is not known whether this absence is due to poor collecting in these areas or whether it reflects an unusual geographic disjunction.

The distribution of *Lisianthius skinneri* is clearly correlated with moisture availability. The mid-elevation forests situated on both the Atlantic and Pacific flanks of the Cordillera de Talamanca extending southeastward from Costa Rica into western Panama and the Cordillera de San Blas and Serranía del Darién in eastern Panama receive abundant rainfall. Only on the more humid and wetter Atlantic side has *L. skinneri* been able to occupy lower elevation sites near or at sea level.

The distribution of *Lisianthius skinneri* throughout its range is markedly patchy, with populations usually separated by many kilometers. This is especially evident in central Panama where large portions of the lower to mid elevations have been extensively explored and collected. *Lisianthius skinneri* is very local in occurrence, as seen in the distribution map of all known populations in Panama (Fig. 1). Some gaps in this distribution will be eliminated with more collecting, especially towards high elevations and on the Atlantic watershed, but undoubtedly the patchy distribution of this species will remain.

Most populations occur in disturbed or partially open habitats. Forest edge sites along roads and paths are now more common because of increasing utilization of the lower elevation forest by people. Often populations are seen in more closed habitats such as tree fall gaps. Scattered groups of individuals are also occasionally encountered in undisturbed forests but do not form the larger clumped populations typically seen in the more disturbed habitats. Population size varies from few to about a hundred individuals. Most populations, however, cover less than 50 square meters and are composed of about 50 flowering shrubs.

In contrast to the wide-ranging distribution of *Lisianthius skinneri*, the other members of the *L. skinneri* species complex are all endemic to central Panama. The physiography of the central Panama mountain system is unusual because it is relatively

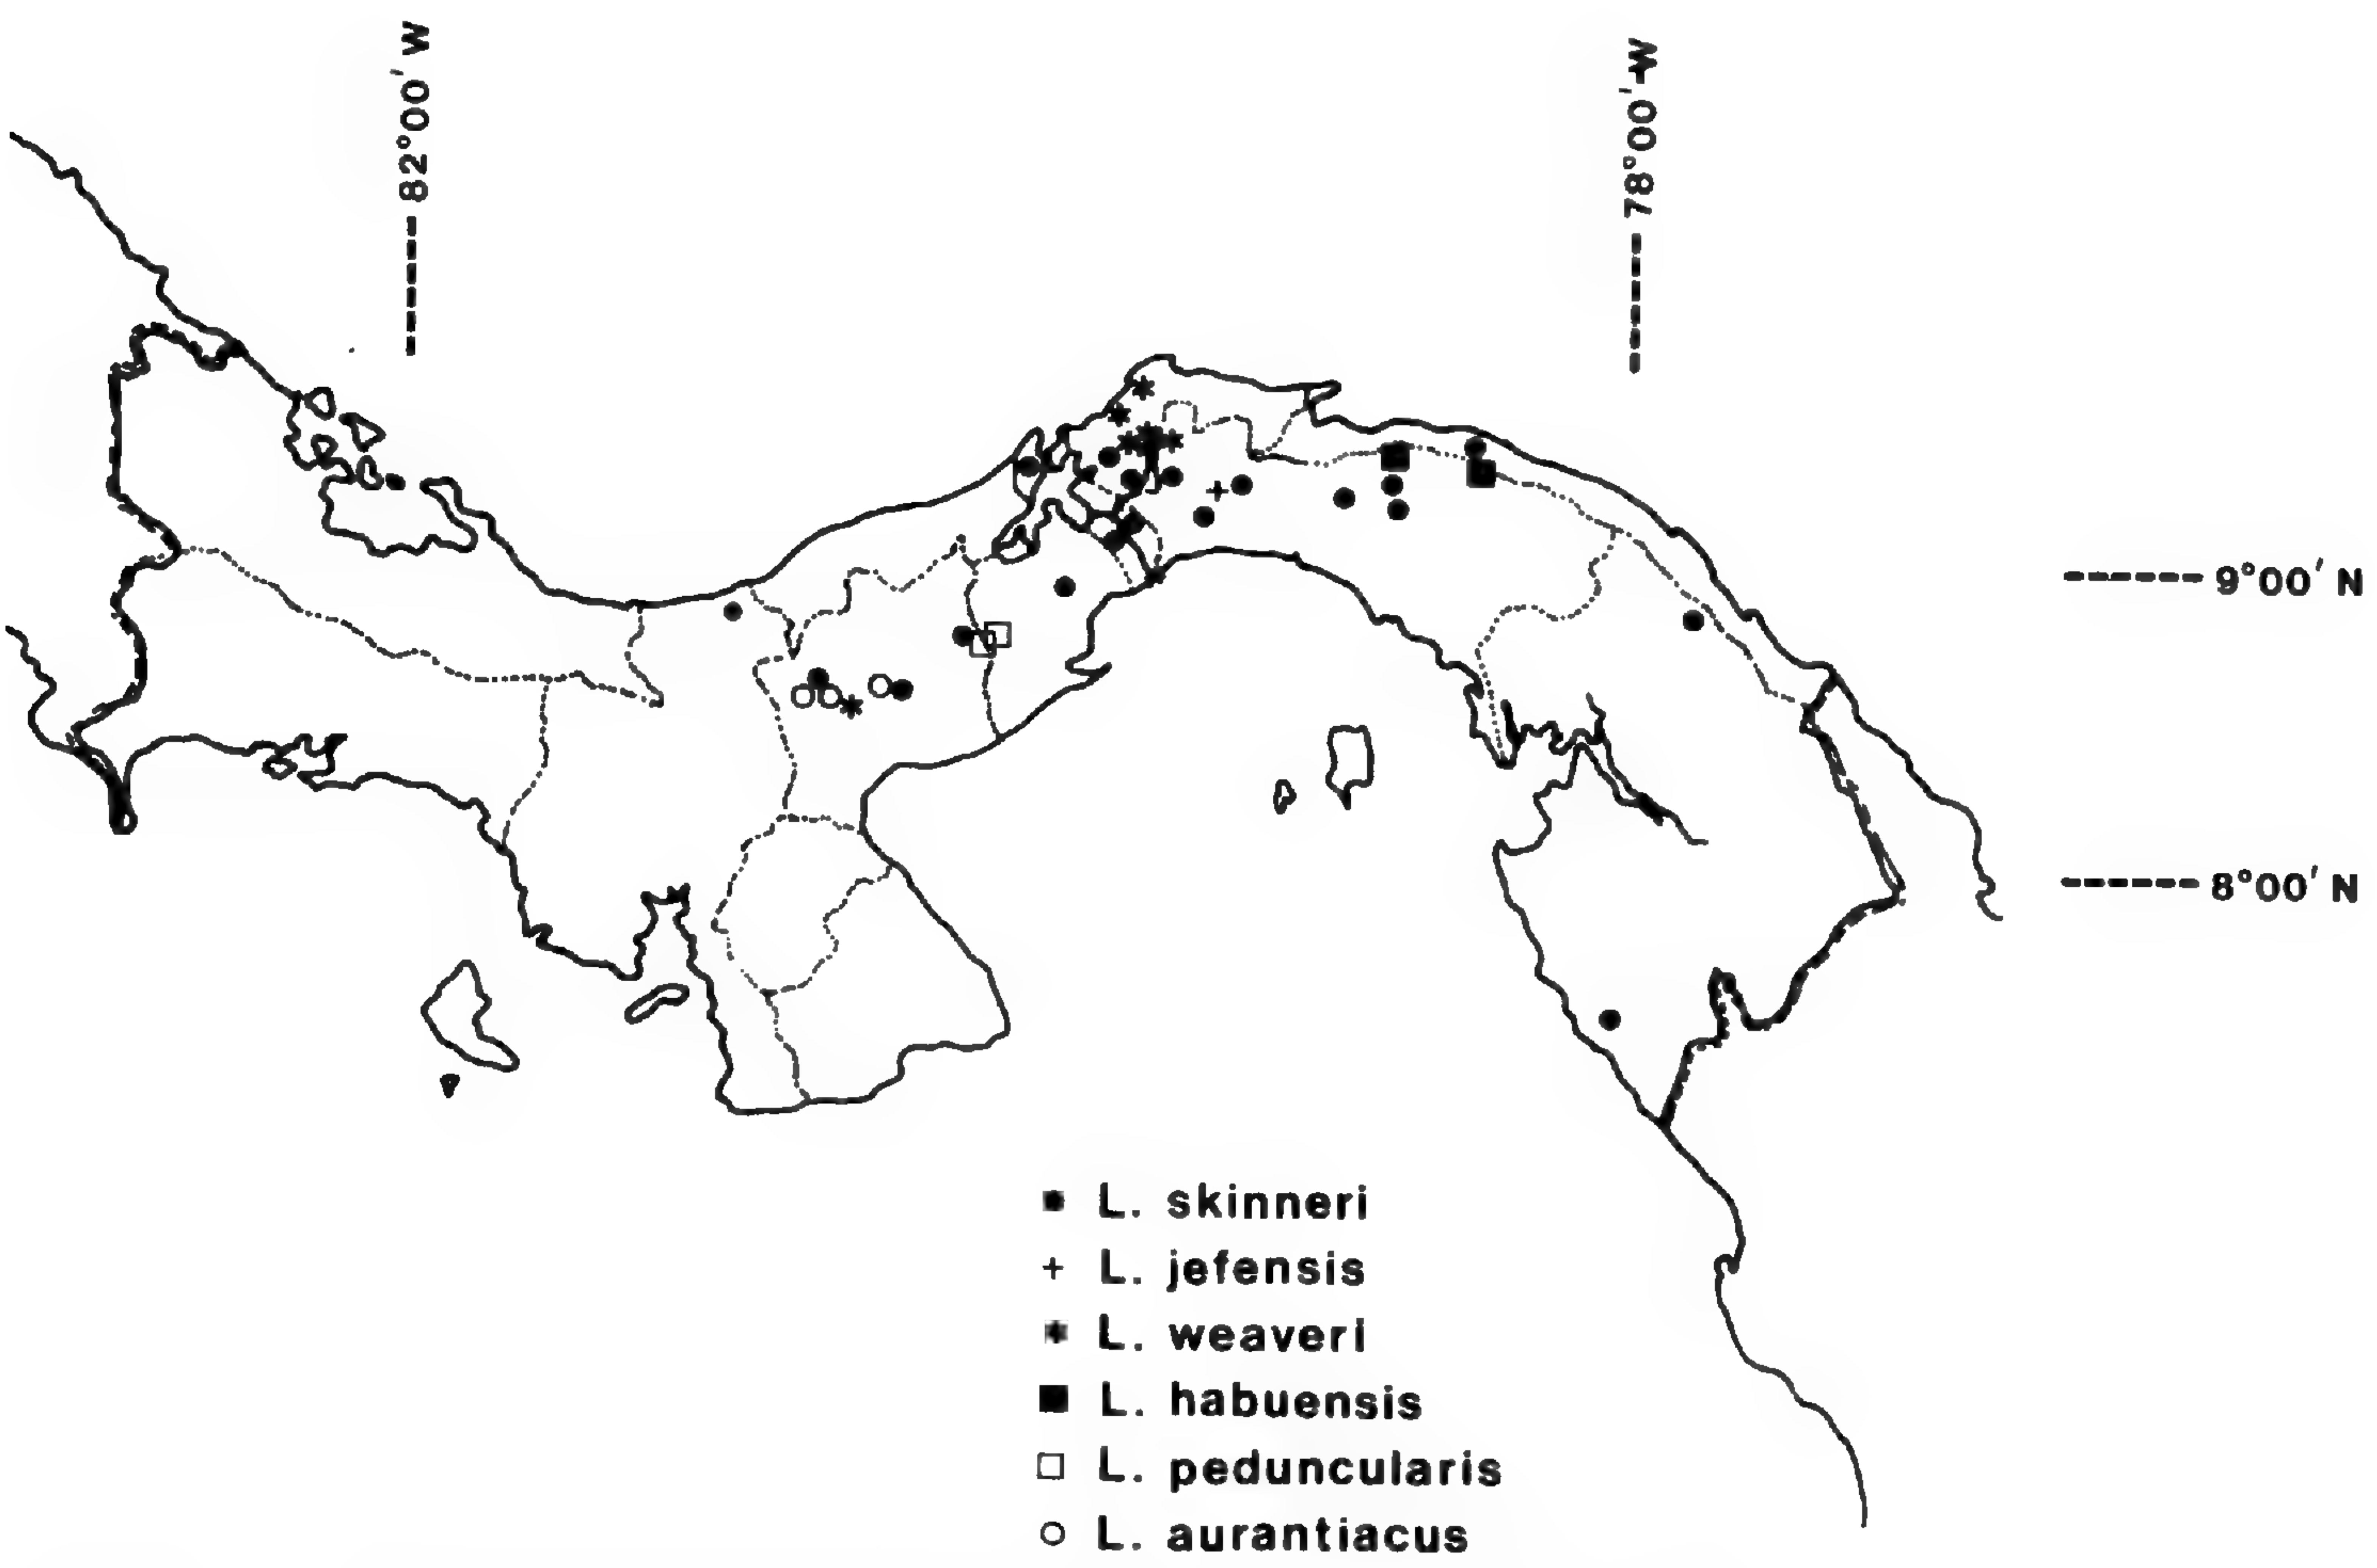

FIGURE 1. *Distribution of the* Lisianthius skinneri *species complex in Panama.*

low in relief, sinuous in nature, and discontinuous in extent. The central Panama region is thus marked by isolated, cloud forest peaks (600–1,500 m) interrupted by more extensive low- to mid-elevation forests. Four of the additional five species in the *L. skinneri* species complex are restricted to separate cloud forest peaks in this region (Fig. 1). These species include *L. jefensis* Robyns & Elias, *L. peduncularis* L. O. Williams, *L. aurantiacus* sp. nov., and *L. habuensis* sp. nov. *Lisianthius weaveri* sp. nov. is unique in the species complex in that several populations occupy forest-edge sites near beaches on the Atlantic side. Like the cloud-forest populations, these populations still occupy a high-rainfall environment. All species except *L. aurantiacus* and *L. weaveri* are comprised of few populations restricted to a small area. *Lisianthius aurantiacus* and *L. weaveri* are more widespread in distribution but are markedly patchy in occurrence.

MORPHOLOGY

Morphological characters used to delimit species in the *Lisianthius skinneri* species complex are almost exclusively confined to features of the inflorescence and flower. Additional vegetative characters are occasionally divergent in the group and will also be presented. Only characters that are variable among members of the species complex, and hence of possible phylogenetic interest, will be presented here. A more formal description of all characters will be given in the next section. Measurements were made primarily on dried specimens. Floral characters of the Panamanian populations were measured directly on FAA-preserved material. Only herbarium specimens were examined for populations of *L. skinneri* occurring outside Panama.

Habit. All species except *Lisianthius aurantiacus* are true shrubs. *Lisianthius aurantiacus* in open sites is typically arboreal and can reach heights over 6 m. These trees are slender-stemmed and evenly branched to the top. In more closed forest environments, *L. aurantiacus* is a 2–3 m branched shrub, as are the remaining taxa. Occasionally, taller individuals of *L. peduncularis* are seen in the elfin forest atop Cerro Carocoral. Like most species of sect. *Lisianthius* subsect. *Fruticosi,* these species are not distinctly woody except at the base, even though they persist for years. They usually have a single main stem that is branched above, but totally unbranched flowering plants are seen in *L. skinneri, L. weaveri,* and *L. jefensis.* The main shoot has an indeterminate growth pattern, and the lateral shoots ("flowering branches") have a determinate growth pattern.

Leaves. Two types of leaves are evident in the *Lisianthius skinneri* species complex, true foliage leaves and lateral shoot leaves, which can be a problem if leaf characteristics are used in a systematic analysis. This is especially so because many herbarium collections contain only lateral shoots without true foliage leaves (Weaver, 1972). The foliage leaves of all species except *L. jefensis* are obovate, membranaceous, glossy green above, and paler beneath. Leaves of *L. habuensis* have somewhat undulating margins. *Lisianthius jefensis* leaves are subcoriaceous and usually smaller than those of the other five species. It is interesting that a number of other endemic species on Cerro Jefe also have subcoriaceous to fully coriaceous leaves (pers. obs.). Leaves on the determinate lateral "flowering branches" are smaller, with the transition from foliage leaves to lateral shoot leaves abrupt. Two collections of higher elevation *L. skinneri* from Volcán Arenal, Costa Rica (*Wilbur & Stone 10257*, *Lent et al. 3321*) appear to have thickened leaves as well, although Weaver (1972) did not mention it in his monograph. Lateral shoot leaves are ovate to lanceolate and merge into the foliaceous inflorescence bracts. Lateral shoot leaves are absent from *L. aurantiacus* because flowering branches are reduced to single or paired axillary flowers. Small floral bracts are present, however.

Inflorescences. The inflorescence of *Lisianthius* is very difficult to interpret but is an important characteristic in determining phylogenetic relationships within the genus. Architecture of the inflorescence varies considerably in *Lisianthius*, and Weaver (1972) set forth a probable evolutionary scheme for the development of the various types. The arrangement of inflorescences in sect. *Lisianthius* subsect. *Fruticosi* is characterized almost entirely by opposite branching with each division terminated by dichasia. The dichasia are axillary or, more often, both terminal and axillary on determinate lateral shoots. Foliaceous leaves are located below the lowest trichotomy and the upper divisions are subtended by bractlike appendages. The various arrangements of inflorescences in the *L. skinneri* species complex are depicted schematically in Figure 2.

Lisianthius skinneri, *L. weaveri*, and *L. jefensis* are characterized by a ternate compound dichasium in each axillary inflorescence (Fig. 2a). This inflorescence type comes closest in the *L. skinneri* complex to the primitive multi-compound dichasium that Weaver (1972) postulated for the genus. Simple reduction to a twice-compound dichasium gives the inflorescence type seen in *L. peduncularis* (Fig. 2b). A further reduction of two lateral dichasia (Fig. 2c), or, alternatively, reduction in the terminal dichasium (Fig. 2d) generates the two reduced inflorescences commonly exhibited by *L. habuensis*. Reductions of the *L. peduncularis* type to a single flower, but retaining the three sets of bracts, gives the three-bracted nodes subtending a one-flowered axillary inflorescence sometimes evident in *L. aurantiacus* (Fig. 2e). *Lisianthius aurantiacus*, however, usually has two levels of bracts and either one or two flowers in each axillary inflorescence (Fig. 2f, g).

Calyx. The calyx is variable not only among the species but also within *Lisianthius skinneri*. Populations of *L. skinneri* near sea level in Guatemala and Honduras exhibit the largest calyces in the species. They range from 6 to 8 mm, with the calyx lobes ranging from 3 to 6 mm long. The smallest calyx is seen in populations in the interior of Costa Rica and Panama. Here the calyx ranges from 5 to 6 mm, with the calyx lobes 2 to 4 mm, and is generally appressed and carinate. The calyces in *L. weaveri* are similar to those in *L. skinneri* but are stouter, spreading, and only somewhat ridged. The calyces in *L. peduncularis* and *L. aurantiacus* are very long, 10–13 mm and 13–15 mm, respectively. The calyx lobes of these two species are exceptionally long, averaging about ¾–⅞ of the total length. *Lisianthius jefensis* also has a longer, more attentuate calyx than *L. skinneri*. The calyx in *L. habuensis* is similar in size to *L. skinneri* (6–8 mm long) but with longer dark green lobes (4–5 mm long) that are strongly carinate and scarious on the margins

Corolla. The structure of the corolla in all species is basically uniform (Fig. 3). The basal portion of the corolla enclosing the ovary is constricted into a narrow tube. The stamens are inserted on the inside of the corolla tube at the distal end of the constriction. Immediately above the insertion of the stamens the corolla flares out, often abruptly. Just below the lobes the corolla tube is again constricted, but usually not to the degree as in the basal region. *Lisianthius skinneri* shows extreme variation in the proportions of the corolla. The Guatemalan plants (including the type specimen) have long (5–5.4 cm), narrow, and membranaceous-textured yellow corollas. The corolla lobes are greenish, broad, and short acuminate. Plants from Honduras, Costa Rica, and the interior of Panama closely resemble the Guatemalan plants but have a broader, more inflated corolla tube,

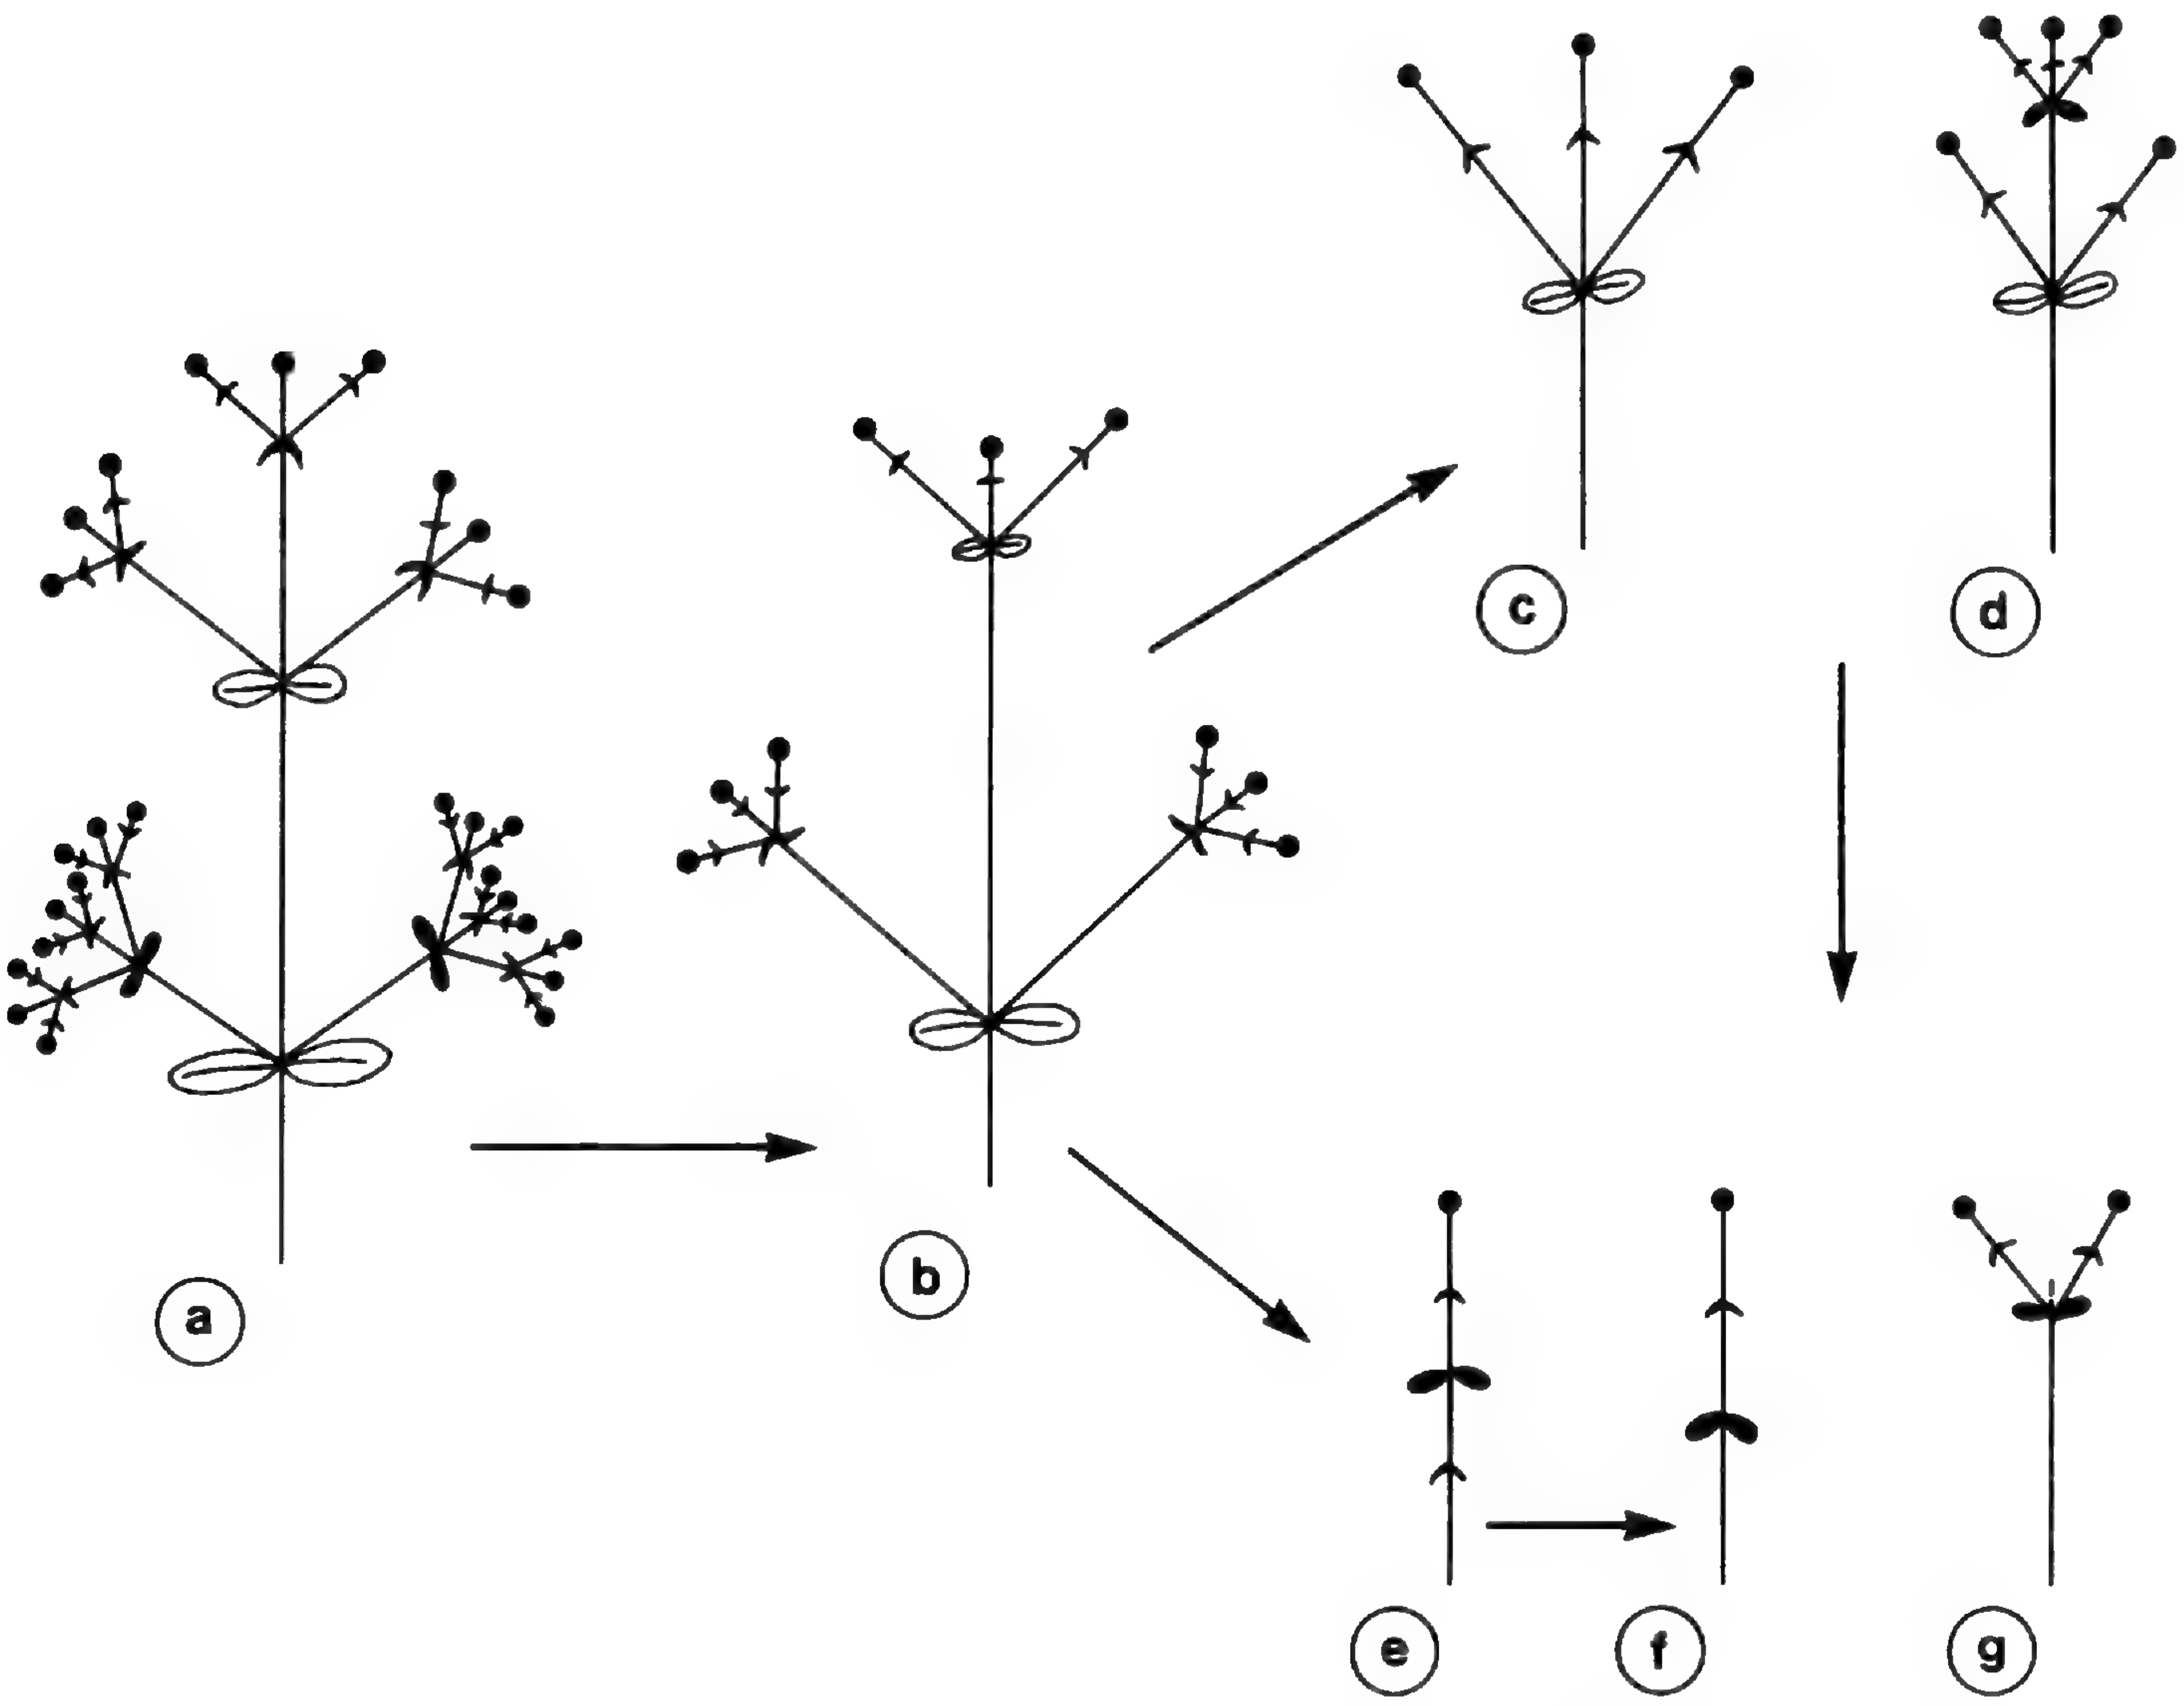

FIGURE 2. *Schematic arrangement of the inflorescences in the* Lisianthius skinneri *species complex. Arrows represent probable evolutionary pathways for inflorescence types and do not imply phylogenetic pathways of the representative species.—a.* L. skinneri, L. jefensis, *and* L. weaveri.—*b.* L. peduncularis.—*c, d.* L. habuensis.—*e–g.* L. aurantiacus.

markedly so in the El Llano–Cartí road populations in Panama. The two previously cited Costa Rican collections from Volcán Arenal (*Wilbur & Stone 10257*, *Lent et al. 3321*) are aberrant in having waxy, thick-textured corollas. The five endemic species in Panama are all characterized by thick-textured, waxy corollas. The correlation of this unique corolla form to wetter higher elevations or to the humid Atlantic Coastal Plain (*Lisianthius weaveri* in part) suggests that this floral character might provide protection against extremely damp conditions and subsequent floral destruction. The high incidence of damaged and rotting, thin-textured flowers on higher-elevation *L. skinneri* plants on Cerro Jefe and the continental divide near Cascajal supports this idea. *Lisianthius jefensis* and *L. weaveri* exhibit the smallest corollas. The corolla of *L. jefensis* is 2.5–4 cm long, with spreading and recurved lobes 4–6.5 mm long, while the corolla of *L. weaveri* is 2.6–4.5 cm long, waxy yellow and green tipped, and surrounds long-exserted styles. The corolla of *L. habuensis* is broad and 4.9–6.1 cm long with the corolla lobes triangular, smallish (3.5–5 mm long and wide at the base), dark green with cream margins, and slightly recurved. The flowers of *L. peduncularis* and *L. aurantiacus* are very similar, both having very long corollas (4.8–6 cm and 5.5–7.8 cm, respectively) and long attentuate lobes (8–10 mm and 9–11 mm, respectively). The pumpkin orange to red corolla color and dark green corolla lobes of *L. aurantiacus* are strikingly different from any Panamanian *Lisianthius*.

Androecium. Weaver (1972) used the placement of stamens as a diagnostic character in separating *Lisianthius skinneri* from *L. jefensis* and *L. peduncularis*. In *L. skinneri* the stamens are inserted well above the apex of the calyx lobes, whereas in the other two species the stamens are inserted at or just above the apex of the lobes. This latter condition also applies to the new cloud-forest species, *L. habuensis* and *L. aurantiacus*. The use of this character as diagnostic is misleading because

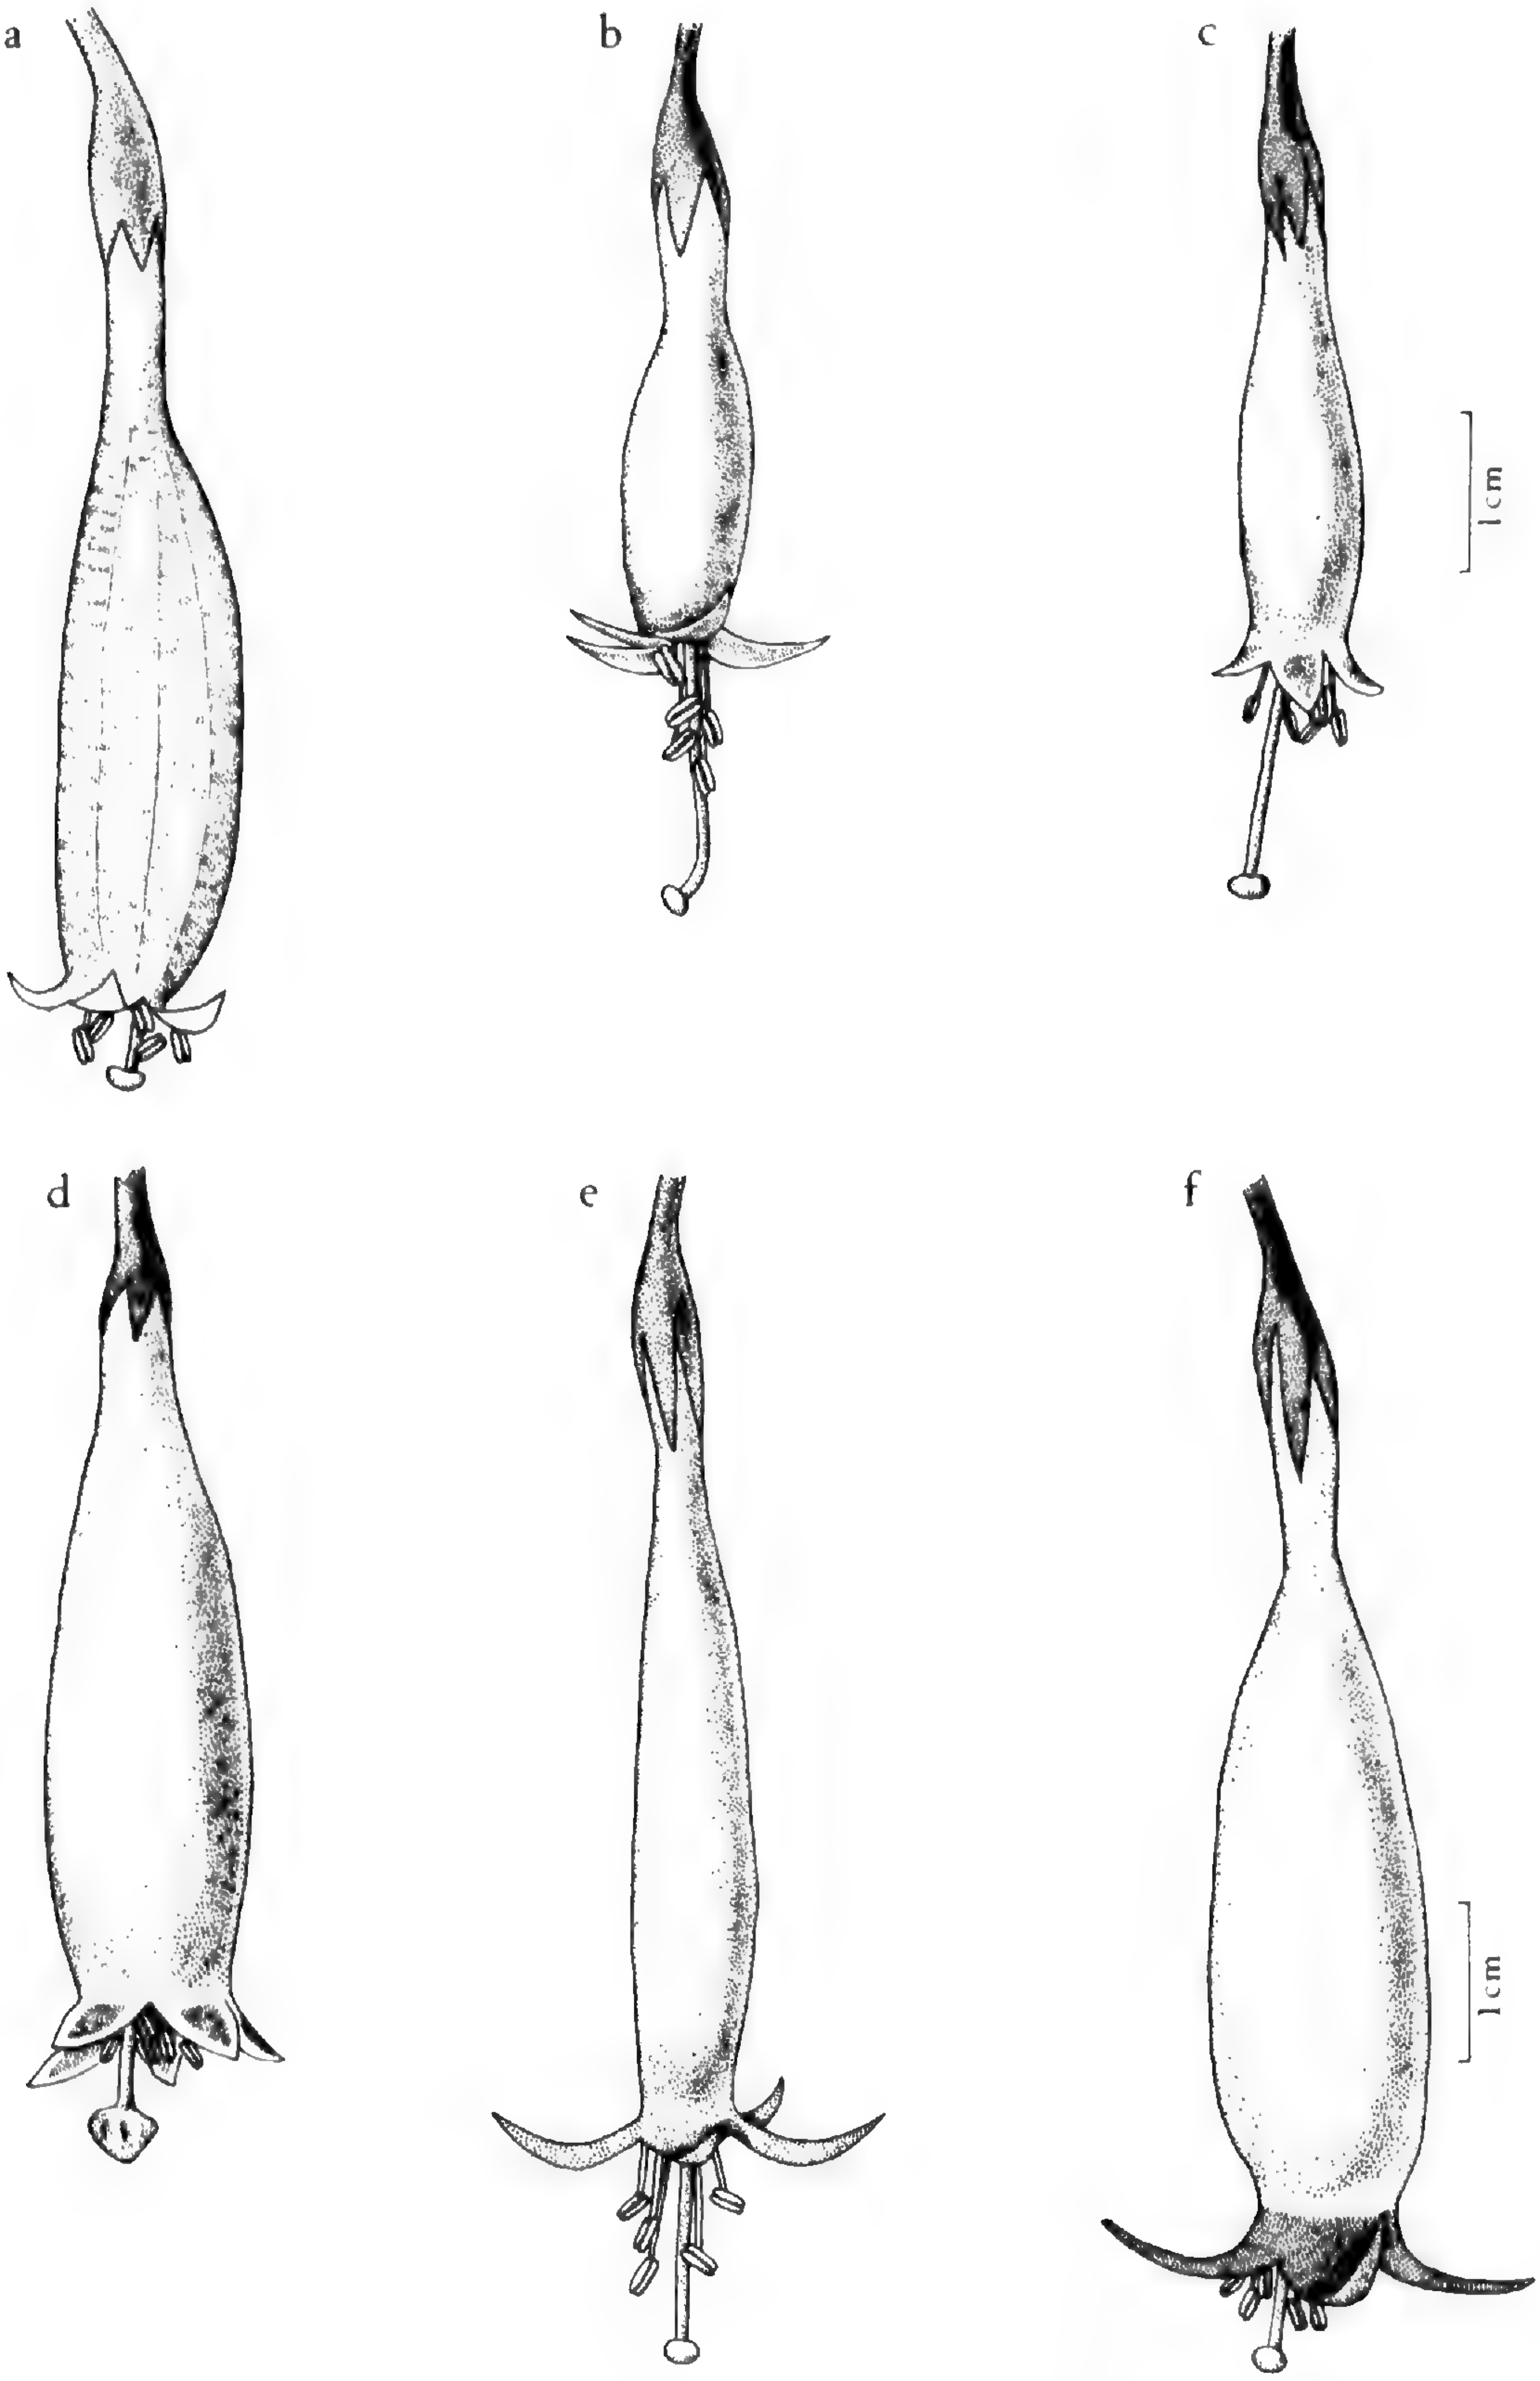

FIGURE 3. *Flowers in the* Lisianthius skinneri *species complex.*—*a.* L. skinneri.—b. L. jefensis—*c.* L. weaveri—*d.* L. habuensis.—*e.* L. peduncularis.—*f.* L. aurantiacus.

it does not reflect a difference in the placement of the stamen, but rather in the length of the calyx. All species in the *L. skinneri* species complex have the stamens attached to the inner corolla tube about the level of the apex of the ovary. Stamen length varies depending on corolla tube length, with most species having stamens protruding slightly from the corolla lobes. The stamens in *L. jefensis* are proportionally longer than in the other species and are conspicuously exserted. Anthers and pollen are whitish yellow in most *L. skinneri* individuals, greenish yellow in some individuals of *L. skinneri* and in the other species, except for *L. aurantiacus*, in which they are bluish green.

Gynoecium. Style, ovary, capsule, and seed size, like the stamens, are correlated with flower size in general. Exceptions include *Lisianthius jefensis* and *L. weaveri*, which both have longer exserted styles. Stigma shape and size are diagnostic characters separating out *L. habuensis*. All other species in the complex exhibit smooth, small stigmas (1–1.5 mm broad). The stigma in *L. habuensis* is unique and divergent in being large (2.5–3 mm broad), conical, and rough textured.

SYSTEMATIC TREATMENT

The grouping of populations into formal taxonomic categories has two underlying purposes. The first and traditionally the primary purpose of such an endeavor is the construction of an information retrieval system that permits effective communication about the populations (Raven, 1979). The taxonomic system constructed should preserve information that enters the system and should minimize its loss once taxonomic decisions have been made. The second purpose is the construction of a taxonomic system that best reflects the phylogenetic or historical relationships of the populations. Often, both goals of taxonomic decision-making cannot be simultaneously satisfied.

In delimiting species in the *Lisianthius skinneri* species complex, problems were encountered in grouping populations into formal categories of "species." As previously indicated, DNA techniques indicated the paraphyletic nature of *L. skinneri* (Sytsma & Schaal, 1985b). Populations of *L. skinneri* examined at the DNA level could be placed in two separate lineages that have been involved in separate speciation events. Cladistic analysis strictly following Hennig's (1966) principles would raise a western Panamanian *L. skinneri* population to the species level to preserve monophyly and to reflect better the apparent phylogeny of the species complex. This separation is unsatisfactory because it violates the first purpose of an effective information retrieval system. Although clearly this western population is *phylogenetically* divergent by DNA analysis, it also clearly falls within the range of morphological variation of the widespread *L. skinneri* as predefined. Because of the broad distribution and ancestral nature of *L. skinneri*, it is very likely that many clusters of populations in *L. skinneri* will be shown by DNA analysis to represent divergent and independent lineages and by similar reasoning would also have to be accorded species status.

In assigning formal names to clusters of populations in the *Lisianthius skinneri* species complex, therefore, additional sources of data were used in addition to genealogical or phylogenetic interpretation. For example, *L. jefensis* is identical to an eastern population of *L. skinneri* by cladistic DNA analysis (Sytsma & Schaal, 1985b) but is maintained as a distinct species derived from *L. skinneri* based on its peculiar morphology, lack of hybridization, and endemic nature. The western Panamanian population of *Lisianthius skinneri*, apparently a member of a lineage that has given rise to other species, is maintained as *L. skinneri* because no changes in morphology, reproductive barriers, or habitat preference are outside the range of variation found in typical members of *L. skinneri*.

KEY TO THE *LISIANTHIUS SKINNERI* SPECIES COMPLEX

1a. Leaves subcoriaceous; anthers and styles conspicuously exserted, and long surpassing the corolla lobes; endemic to Cerro Jefe, Panama .... 3. *Lisianthius jefensis*
1b. Leaves membranaceous; anthers and styles included, or slightly exserted and not conspicuously surpassing the corolla lobes, or only the styles conspicuously exserted.
  2a. Corolla lobes ≥ 7 mm long; calyx lobes ≥ 6 mm long.
    3a. Inflorescence of 1–2 axillary flowers; corolla pumpkin orange to red; plant often treelike .... 6. *Lisianthius aurantiacus*
    3b. Inflorescence of twice compound dichasia; corolla yellow; plants shrubby .... 5. *Lisianthius peduncularis*
  2b. Corolla lobes ≤ 5 mm long; calyx lobes ≤ 6 mm long.
    4a. Calyx lobes 4–5 mm long; inflorescence of simple dichasia, never ternately compound; stigma 2.5–3 mm in diameter, conical, convoluted .... 4. *Lisianthius habuensis*
    4b. Calyx lobes 2–4 (rarely 5) mm long; inflorescence of twice or ternately compound dichasia; stigma 1–1.5 mm in diameter, rounded, smooth.
      5a. Corollas 5–5.4 cm long, thin-textured; styles slightly exserted past anthers .... 1. *Lisianthius skinneri*
      5b. Corollas 2.6–4.5 cm long, thick-textured; styles long exserted past anthers .... 2. *Lisianthius weaveri*

1. Lisianthius skinneri (Hemsley) O. Kuntze, Rev. Gen. Pl. 2: 429. 1891. *Leianthus skinneri* Hemsley, Biol. Centr. Amer. 2: 345. 1882. *L. skinneri* (Hemsley) Perkins, Bot. Jahrb. (Syst.) 31: 492. 1902. TYPE: Guatemala. Locality not given: *Skinner s.n.* (lectotype, K, photographs, F, MO).

Lisianthus arcuatus Perkins, Bot. Jahrb. Syst. 31: 492. 1902. TYPE: none designated.
Lisianthus scopulinus Robyns & Elias, Ann. Missouri

Bot. Gard. 55: 62, fig. 2. 1968. TYPE: Panama. Veraguas: mouth of Río Concepción, *Lewis, Croat & Hawker 2799* (MO).

Shrub or subshrub, 0.5–3 m tall; stem terete, erect, green. Leaves membranaceous, deep to light green, paler below; blades 4–24 cm long and to 7.7 cm wide, obovate to obovate-elliptic, sharply acuminate; the costa prominent, lateral veins 2–3, ascending; petiole amplexicaul, winged. Inflorescences terminal or axillary, composed of ternately compound, laxly flowered dichasia; foliaceous leaved below first division, bracted above; bracts opposite, lanceolate to linear, 2 mm long or longer. Flowers horizontal to nodding; calyx 5–7 mm long, the lobes 3–5 mm long, carinate dorsally, ± scariously margined, stout or attenuate, appressed or spreading; corolla tubular-funnelform, constricted apically and distally, the tube 5–5.4 cm long and to 1 cm broad, bright yellow, occasionally greenish-tipped, membranaceous, the lobes ovate, 2.5–5.5 mm long, 2.5–4 mm wide, yellowish green to dark green, often with cream margins, often recurved at tip, short to long acuminate. Stamens inserted within corolla at apex of ovary; filaments 4.2–4.7 cm long, unequal in length, longest one at least equaling or surpassing corolla lobes; anthers 2–3 mm long and ca. 1 mm wide, bilobate at the base; pollen whitish yellow. Style 4.7–5.1 cm long, usually slightly exserted past anthers; stigma peltate, 1–1.5 mm broad. Capsules fusiform, 1.8–2.2 cm long, beaked by persistent style to 9 mm long; seeds asymmetrical, surface corrugated, to 0.75 mm long. Chromosome number, $n = 18$.

Distribution. From sea level to 1,300 m in moist to wet tropical forests or roadsides, at middle elevations in Costa Rica and the interior of Panama, and along the Atlantic Coastal Plain of Guatemala, Honduras, and Panama.

Lisianthius skinneri as delimited here encompasses all populations of the *L. skinneri* species complex outside Panama and most populations at low to mid elevations in Panama. Based on distribution and DNA analysis, *L. skinneri* is the ancestral species in the complex (Sytsma & Schaal, 1985b). The four endemic cloud-forest species that were examined by DNA analysis arose from at least two lineages within *L. skinneri*. The corolla is longer and thinner in texture (membranaceous) than corollas in the now segregated *L. weaveri*. The latter species has smaller flowers with thickened and waxy corollas like other species in this complex. *Lisianthius skinneri* as defined here is composed of populations showing moderate variability (Weaver, 1972). This is not surprising, considering both the widespread distribution and ancestral nature of the species. This variation, however, presents considerable problems when species circumscription is attempted. *Lisianthus scopulinus* Robyns & Elias from Veraguas Province, Panama, has somewhat large calyx lobes (4–5 mm long) for *L. skinneri*. It resembles *L. skinneri* in all other traits and is here merged with *L. skinneri* as another geographically variable population. One population of *L. skinneri* from Costa Rica is unique in having thickened flowers and in occurring at higher elevations on Volcán Arenal (*Wilbur & Stone 10257*, *Lent et al. 3321*). This population was not visited during the study, so its status as a distinct element in the *L. skinneri* species complex is only tentative.

Representative specimens examined. GUATEMALA. IZABAL: south shore of Lake Izabal, *Proctor et al. 3049* (F). ALTA VERA PAZ: eastern portions of Vera Paz & Chiquimula, *Watson 380a* (G). HONDURAS. ATLANTIDA: 42 km SE of Tela to La Ceiba, *Davidse & Pohl 2194* (MO); San Alejo, *Standley 7829* (F); Cuyamel, *Carleton 584* (F). COSTA RICA. ALAJUELA: 17–22 km beyond San Ramón to Cataratas, *Almeda et al. 4301* (F, MO); middle slopes N side of Volcán Arenal, *Lent 3868* (F, MO); *Lent et al. 3321* (F); Villa Quesada near San Carlos, *Smith 1884* (F, MO); 13.5 mi. E of Arenal, 6.5 mi. W of Fortuna, *Wilbur & Stone 10257* (DUKE, F, MO, NY, US). GUANACASTE: Volcán Miravalles, *Burger & Gentry 9126* (F); Hacienda Santamaria, *Dodge et al. 6320* (F, MO); lower slopes Cerro La Giganta [Cerro Miravalles], 2 km W of Río Naranjo, *Utley & Utley 1899* (DUKE); Tilarán, *Valerio 115* (F); SE lower slopes Volcán Miravalles, *Wilbur & Almeda 16623* (DUKE, F, MO, US). HEREDIA: Finca Hnos. Vargas, Puerto Viejo de Sarapiquí, *Jiménez 3577* (MO); Río La Paz & Cariblanco de Sarapiquí, *Pittier 14159* (US). PANAMA. COCLÉ: La Mesa, N of El Valle de Antón, *Allen 2369* (MO); continental divide past Llano Grande, *Dressler 5627* (MO); Río San Juan below junction with Río Tífe, *Hammel 3436* (MO); 5 mi. past Llano Grande near continental divide, *Sytsma 3872* (MO); 4 mi. past Llano Grande at continental divide, *Sytsma 3939* (MO); 9 km N of Llano Grande, *Hammel 1713* (MO). COMARCA DE SAN BLAS: El Llano–Cartí Rd., 10 km N of Panamerican Hwy., *Folsom 2622* (MO); Nusagandi, along El Llano–Cartí Rd., below (N of) Punta Mamá, 350 m, *de Nevers & Nuñez 3565* (MO); Río Nergala, 100–300 m, *de Nevers & Herrera 4548* (MO); Río Irgandí and Río Cartí Senni, *de Nevers & Herrera 6610* (MO, WIS); Río Cangandí & Río Titamibe, 50–150 m, *de Nevers 4677* (MO); Río Sidro, base of Cerro Habu, *Sytsma et al. 2622* (MO); Cerro Habu, 400–800 ft., *Sytsma et al. 2799* (MO). 2. **Lisianthius weaveri** K. J. Sytsma, sp. nov. TYPE: Panama. Colón: Santa Rita ridge trail along Río Piedras, 8,000 ft., 9 Mar. 1979, *Hammel 6357* (holotype, MO; isotype, WIS). Figure 4.

Frutex ad 2.5 m altus. Folia obovata-elliptica, ad 23 cm longa et 8.5 cm lata. Inflorescentiae axillares et terminales, dichasio biternato vel triternato. Calyx 5–6 mm longis; tubus ad 2 mm longus; lobi 3–4.5 mm longi, scariosescens ad margineum. Corolla aurea, cerea, 2–3.5 cm longa; lobi triangulares, virides, cerescens ad margineum, 2–3 mm longi et lati. Stamina filamentis ± exsertis. Stilus antherae superans 5–10 mm; stigma peltatum, 1–1.5 mm latum. Capsulae fusiformes ad fusiformes late, 1.5–2 cm longa.

Shrub or subshrub, to 2.5 m tall; stem terete, erect, green. Leaves membranaceous, deep green above, paler below; blades to 23 cm long and to 8.5 cm wide; obovate to obovate-elliptic, ± strongly acuminate tipped; the costa prominent, with 2–3 sets of lateral veins, these ascending and becoming parallel with margin; petiole amplexicaul. Inflorescences terminal or axillary in upper nodes; ternately compound dichasia (or only twice compound); foliaceous leaved below, bracted above. Flowers horizontal or nodding; calyx 5–6 mm long, tube to 2 mm long, the lobes 3–4.5 mm long, carinate dorsally, scariously margined, triangular-attenuate, ± appressed; corolla tubular-funnelform, constricted distally and ± apically, the tube 2.2–3.3 cm long and to 8 mm wide, waxy and fleshy, bright yellow; lobes 2–3 mm long and wide, broadly triangular, green but with cream or yellow margins. Stamens inserted within corolla at apex of ovary; filaments to 2.5 cm long, equaling or barely exceeding corolla lobes; anthers 2–2.5 mm long and 0.75–1 mm wide, bilobate at base, pollen yellowish. Style to 3.5 cm long, far exserted (5–10 mm) past anthers; stigma peltate, 1–1.5 mm broad. Capsules fusiform to broadly fusiform, 1.5–2 cm long, beaked by persistent style to 10 mm long.

Distribution. *Lisianthius weaveri* is known from mid- to high-elevation cloud forests in Coclé and Colón provinces and at sea level on the Atlantic Coastal Plain in Colón Province, Panama.

Lisianthius weaveri is the only cloud forest species of *Lisianthius* found on both sides of the the Panama Canal. This species has been collected from a number of sites in the higher ridges leading to Cerro Bruja, so far an inaccessible peak dominating the ridge of mountains paralleling the Atlantic Ocean in eastern Colón Province. Populations of *L. skinneri* collected in the lower reaches of this region are quite distinct from those of *L. weaveri*. *Lisianthius weaveri* is also found near the continental divide above El Cope, Coclé Province, the southeastern edge of the Cordillera de Talamanca extending northwestard towards Costa Rica. Three additional populations occupy high-rainfall, forest-edge sites near the beach on the humid Atlantic side of Panama. *Lisianthius weaveri* resembles *L. jefensis*, also with short and waxy corollas, but lacks the exserted stamens and coriaceous leaves of the latter. The short, fleshy, and waxy corolla and the exserted style readily distinguish *L. weaveri* from lower-elevation *L. skinneri* populations. Weaver (1972) cited the *Weaver & Wilbur 2249* collection as distinctive with its short, fleshy corolla and long exserted style. Although *L. skinneri* is certainly variable in floral features, the collections of *L. weaveri* surpass this level of variability and can be readily distinguishable from all other collections of *L. skinneri*. A possible but as yet untested origin of *L. weaveri* might involve hybridization between *L. skinneri* and *L. jefensis*. In many of its floral characters, *L. weaveri* is strikingly intermediate between these geographically adjacent species. *Lisianthius weaveri* is named in honor for Richard E. Weaver, Jr., monographer of the genus.

Representative specimens examined. PANAMA. COCLÉ: Alto de Calvario, *Folsom & Jaslon 2680* (MO); El Cope, W of sawmill, *Hammel 3545* (MO). COLÓN: Cerro Pilón, *Loften s.n.* (MO); Cerro Santa Rita, *Allen & Allen 5104* (MO); Santa Rita trail to Río Piedras, *Antonio 3737, 3869* (MO, WIS); Río Miguel de La Borda near Guasimo, *Croat 9919* (MO); W of Portobello, *D'Arcy & D'Arcy 6698* (F, MO); Maria Chiquita, *Dwyer & Kirkbride 7771* (DUKE, MO); S approach to Cerro Bruja from Río Escandaloso, *Hammel 3210* (MO); Río Boquerón and Río Escandaloso, *Hammel 3988* (MO, WIS); Santa Rita hills, *Smith & Smith 3434* (F); 3 km SW of Río Guanche, road between Puerto Pilón and Portobelo, *Sytsma & Andersson 4792* (MO); 5–7 mi. SE of Portobelo, *Weaver & Wilbur 2249* (DUKE, F, MO, NY); Santa Rita ridge, *Wilbur et al. 15020* (DUKE).

3. **Lisianthius jefensis** Robyns & Elias, Ann. Missouri Bot. Gard. 55: 60, fig. 1. 1968 (as "*Lisianthus*"). TYPE: Panama. Panamá: Cerro Jefe, *Elias & Hayden 1798* (MO).

Slender shrub or subshrub, 1–2.5 m tall; stem terete, green. Leaves glossy dark green above, paler below; blades to 12 cm long and to 4.5 cm wide, subcoriaceous, oblanceolate to narrowly obovate, apically acuminate, the lateral veins prominent; petioles amplexicaul, winged. Inflorescences terminal or axillary, composed of twice to ternately compound dichasia, rarely reduced, usually loosely arranged; bracts opposite, 2–5 mm long. Flowers horizontal, or more often nodding; calyx 7–13 mm long, lobes long acuminate, 5–9 mm long, scariously margined, weakly carinate; corolla tubular, thickened and waxy, constricted apically and distally, tube 2.1–3.5 cm long, sometimes greenish tipped, lobes 4–6 mm long, triangular, to 3 mm wide. Stamens inserted on corolla at apex of ovary; filaments 1.5–3 cm long, the longest ones long exserted past corolla lobes; anthers 2.5–3.5 mm long, yellow, bilobate at base. Style to 3.5 cm long, conspicuously exserted past anthers; stigma peltate, to 1 mm broad. Capsule shortly fusiform, 1–1.6 cm long, beaked; seeds asymmetrical, corrugated. Chromosome number, $n = 18$.

Distribution. *Lisianthius jefensis* is known only from the Cerro Jefe region of the Province of Panamá, elevation 800–900 m. This species is widespread near the rounded peak but can be found scattered at lower elevations. Cerro Jefe is subjected to alternating periods of wet cloud cover and intense sunlight due to an unusual combination of local topography and climate. *Lisianthius jefensis* is a conspicuous and locally widespread member of the floristically diverse and predominantly shrubby flora of Cerro Jefe that contains numerous other local endemics. This forest is dominated by species of *Clusia* and *Calopothrinax cookii.*

Two populations of *Lisianthius skinneri* are found immediately below the cloud forest zone. The transition between the two life zones is abrupt, with the change readily perceived. In one locality individuals of *L. skinneri* and *L. jefensis* are only meters apart, with no hybrids reported or seen (see also Weaver, 1972). DNA analysis clearly indicates that *L. jefensis* has been derived recently from eastern populations of *L. skinneri. Lisianthius jefensis* is morphologically similar to *L. weaveri* in floral characters and might have been involved in the origin of the latter species by hybridization with *L. skinneri.*

Representative specimens examined. PANAMA. PANAMÁ: Cerro Jefe, 6–8 mi. past Goofy Lake, 3–4 mi. past Cerro Azul, 800–900 m elevation; *Almeda & Nakai 3452* (F, MO); *Antonio et al. 3402* (MO); *Antonio 4699* (MO); *Busey 798* (MO); *Correa & Dressler 1154* (MO, NY); *Correa et al. 1617* (DUKE, MO); *Croat 14435, 17341* (MO); *D'Arcy & Hamilton 14801* (MO); *D'Arcy et al. 15516* (MO); *Duke 8010* (MO), *9413* (MO, US); *Dwyer et al. 5035* (MO); *Dwyer & Hayden 8087* (MO); *Folsom et al. 5655* (MO); *Foster 1164* (DUKE); *Gentry 2115* (DUKE, F, MO), *6771* (F, MO); *Hammel 3716, 4817* (MO); *Hamilton & D'Arcy 602* (MO); *Hayden 1008* (DUKE, MO); *Kirkbride & Crebbs 16* (F, MO); *Knapp 925, 2225, 3509, 3538, 5202* (MO); *Luteyn 3200* (DUKE, F, MO); *Luteyn & Kennedy 3959* (DUKE); *McPherson 6878* (MO); *Miller & Miller 896* (MO, WIS); *Mori & Kallunki 2376* (MO, US); *Mori 7129* (MO); *Nee 11456* (MO); *Robyns 4438* (MO); *Skog et al. 4219* (MO, US); *Stimson 5390* (DUKE); *Sullivan 218* (MO); *Sytsma 1399, 2025* (MO); *Sytsma et al. 2902* (MO); *Sytsma & Antonio 3829* (MO); *Sytsma & D'Arcy 3695, 3696* (MO); *Sytsma & Knapp 4798, 4799* (MO); *Sytsma 4105* (MO); *Tyson et al. 3203* (MO); *van der Werff & van Herdeveld 6972* (MO, WIS); *Weaver & Foster 1481* (DUKE, MO); *Weaver & Wilbur 2241, 2243, 2250* (DUKE, F, MO, NY, US); *Webster et al. 16457* (DUKE, MO); *Wilbur & Teeri 13604* (DUKE, MO, NY); *Wilbur et al. 15524* (DUKE, F, MO, NY, US); *Wilbur 24126* (DUKE, F); *Witherspoon & Witherspoon 8484* (US).

4. **Lisianthius habuensis** K. J. Sytsma, sp. nov. TYPE: Panama. Comarca de San Blas: Cerro Habu, vicinity of peak, cloud forest, 800 m, 78°49′W, 9°23′N, *Sytsma, Antonio & Dressler 2685* (holotype, MO). Figure 5.

Frutex 1–4 m altus. Folia obovata-elliptica, 13–19.5 cm longa, 3.5–5.8 cm lata. Inflorescentiae axillares et terminales, dichasio reducto, 3–7-floribus; pedunculis elongatis. Calyx viridis, tubularis, 6–8 mm longis; lobi 4–5 mm longi. Corolla aurea, cerea, 4.9–6.1 cm longa; lobi triangulares, virides, cerescens ad margineum, 3.5–5 mm longi et lati. Stamina filamentis ± exsertis. Stilus antherae superans 1–3 mm; stigma grande, conicum, corrugatum, ad 3–3.5 mm longa. Capsulae fusiformes, ad 2 cm longa.

Shrub or subshrub, 1–4 m tall; stem terete, erect. Leaves membranaceous, usually pale green to green; petiole 1.3–2.5 cm long, amplexicaul; blade obovate to obovate-elliptic, basally attenuate, apically long acuminate to attenuate, 13–19.5 cm long and 3.5–5.8 cm wide, with 2–4 ascending lateral veins, the costa prominent beneath. Inflorescences of reduced dichasia, usually once compound, or reduced, on long axillary or terminal peduncles, 14–30 cm long; bracts opposite, over 2 mm long. Flowers nodding; calyx tubular, green, 6–8 mm long, the lobes lanceolate, acuminate, scariously margined, strongly carinate, 4–5 mm long; corolla bright yellow, waxy, the tube funnelform, inflated, 4.9–6.1 cm long, the lobes dark green with yellow border, broadly deltoid or triangular ovate, 3.5–5 mm long and broad, recurved slightly. Stamens inserted within corolla tube at apex of ovary; filaments exserted just past corolla lobes; anthers 2–3 mm long, bilobate at base; pollen

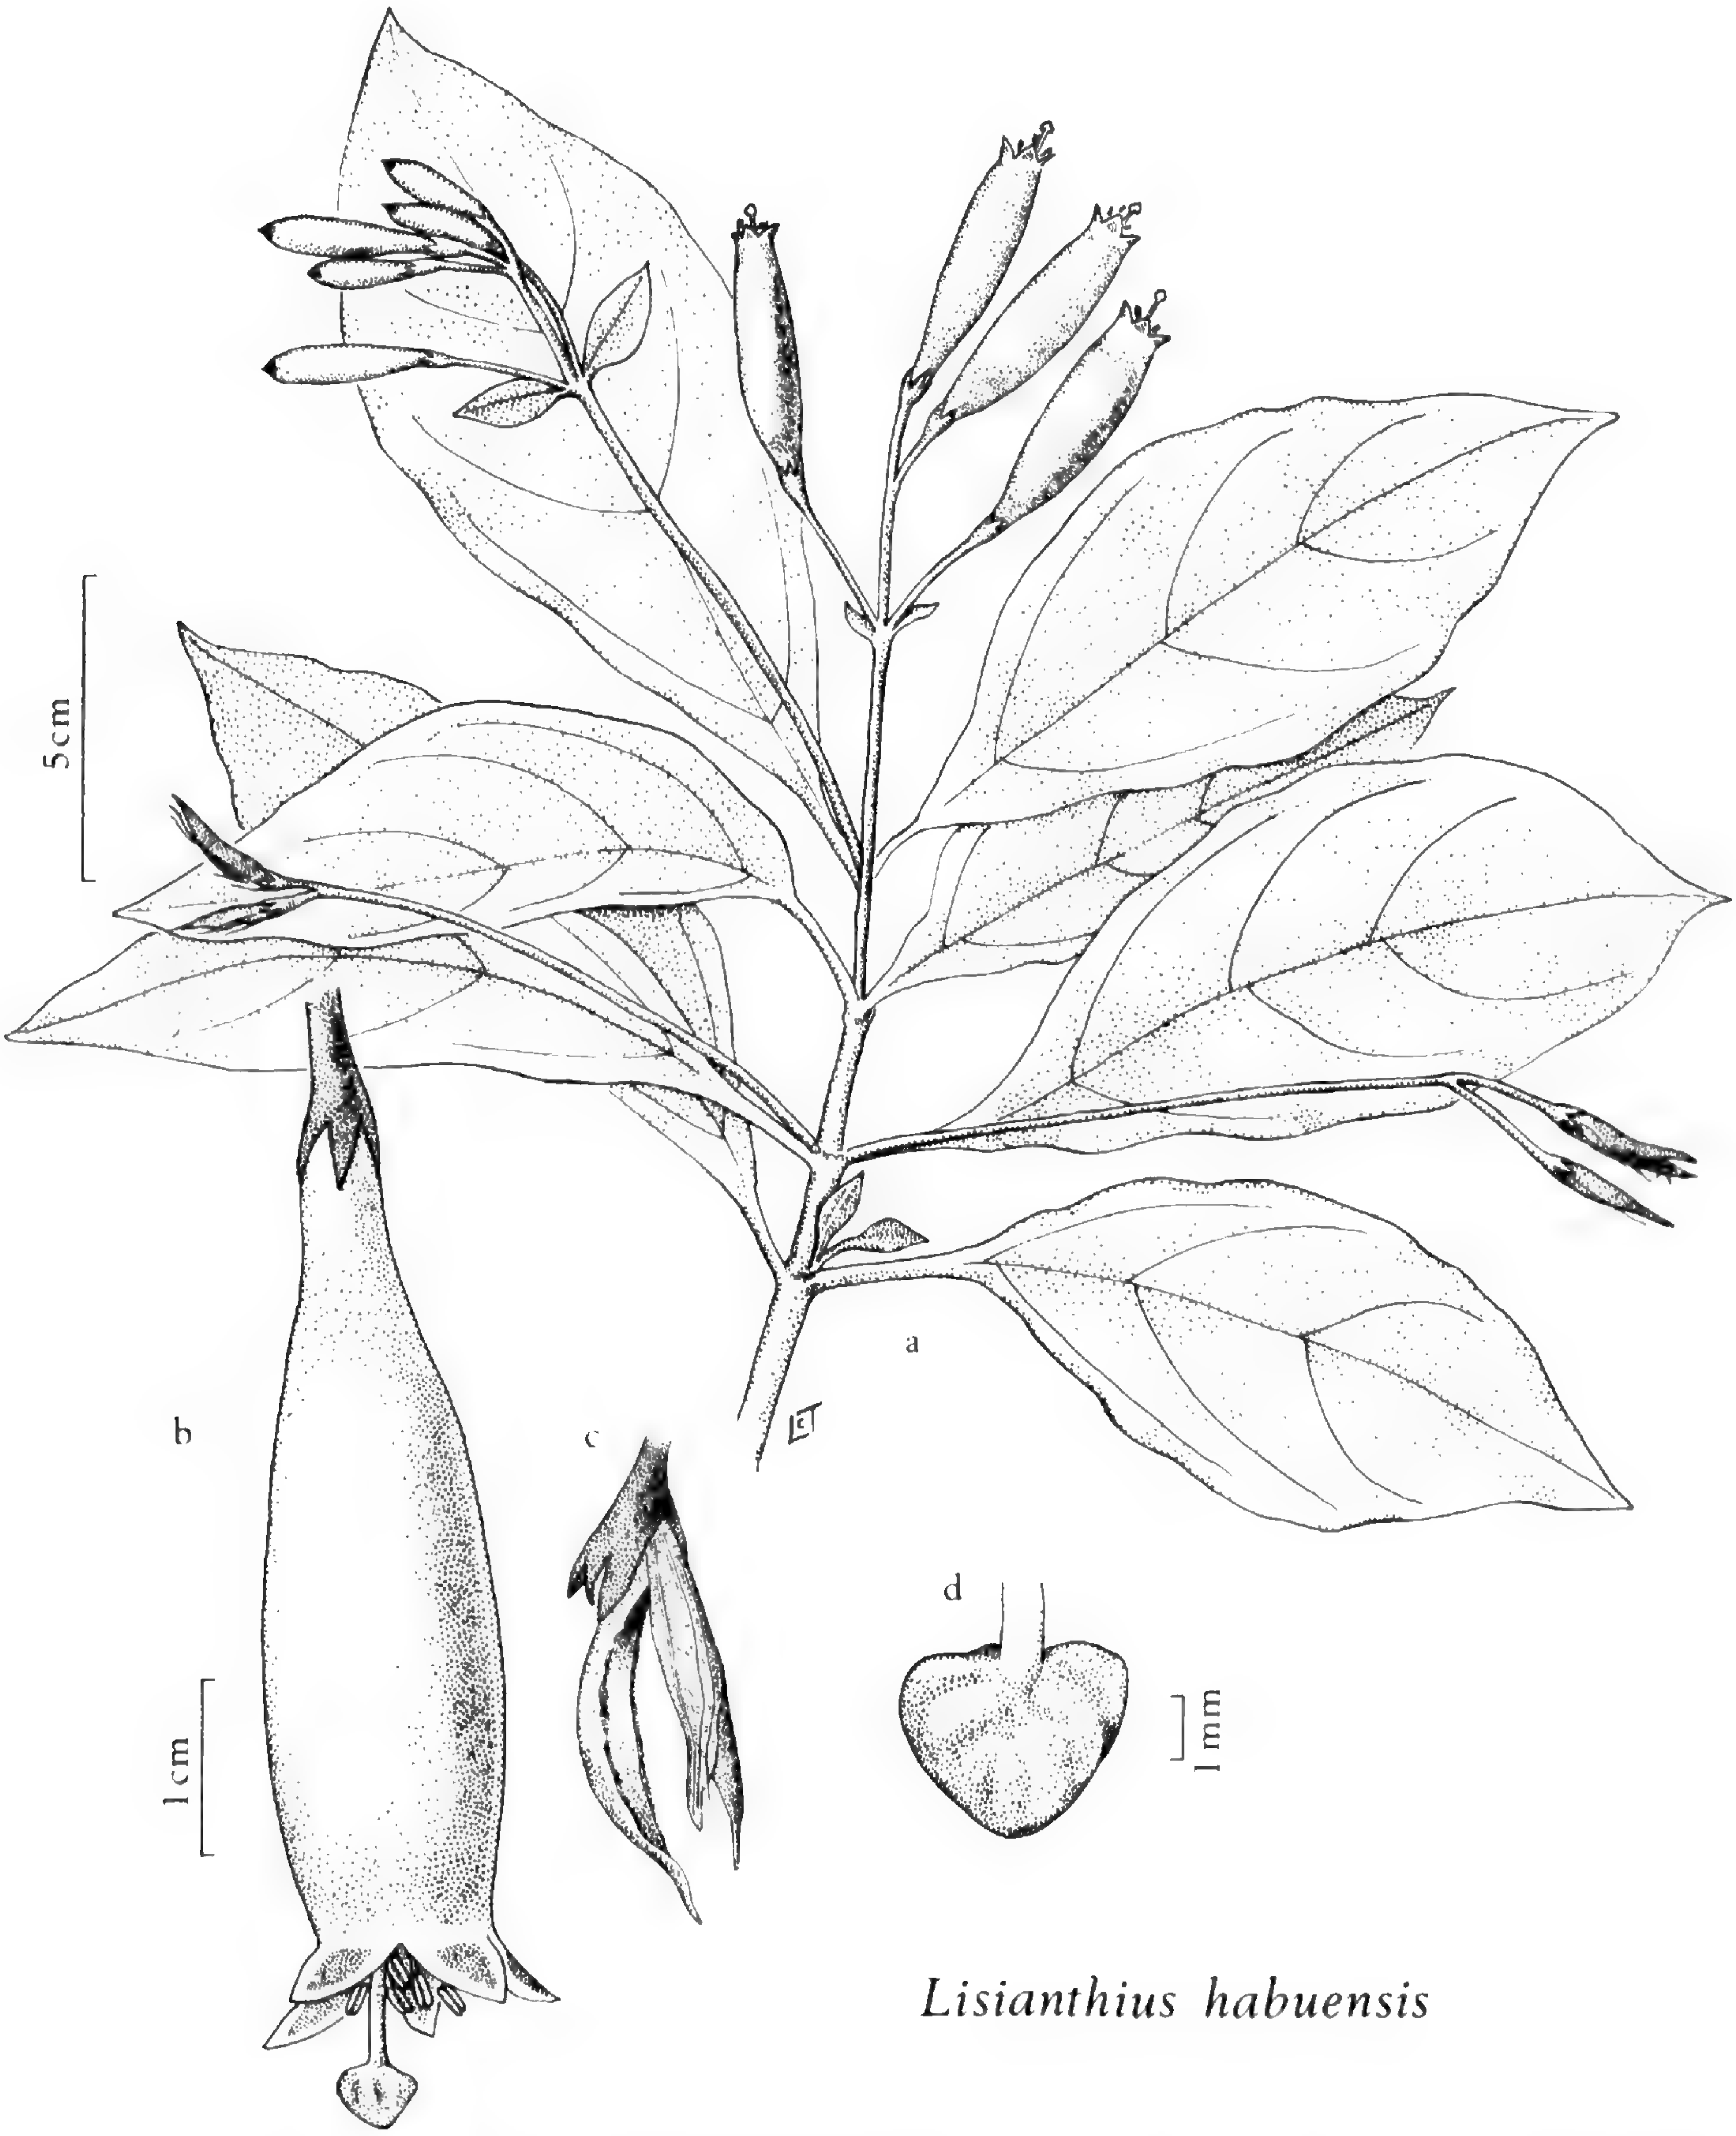

FIGURE 5. Lisianthius habuensis (Sytsma et al. 2685 (MO)).—*a. Habit.—b. Flower.—c. Dehisced fruit.—d. Stigma.*

yellowish. Style surpassing anthers; stigma large, conical, to 3.5 mm long, contorted, almost corrugated. Capsule fusiform, to 2 cm long, with short beak; seeds asymmetrical, seed texture corrugated.

Distribution. *Lisianthius habuensis* occurs near the eastern range of the species complex in the province of Panamá and in the Comarca de San Blas. A large population was discovered at the very top of Cerro Habu (800 m), Comarca de San Blas. This peak is located on the Cordillera de San Blas adjacent to the Atlantic coast and receives extremely abundant rainfall. *Lisianthius habuensis* dominates the shrub layer on the very tip of Cerro Habu but is not found more than 50 m below the summit. A second population was found near the Continental Divide on the the road from El Llano to Cartí, Province of Panamá, approximately 20 km from Cerro Habu. A large portion of this population grows on the roadside, with a few scattered individuals in the forest interior. Several populations of *L. skinneri* are located 3–5 km south of (below) *L. habuensis* along the El Llano–Cartí road. A third population was discovered at the headwaters of three rivers in the Province of Panamá at elevations of 100–400 m.

Lisianthius habuensis is distinct from all other species of *Lisianthius* by having an unusual stigma. The large ovoid stigma is obvious in the field, although not as noticeable on dried herbarium specimens. The unique corolla and lobes further distinguish it from all other species. DNA evidence indicates that this species is most closely related to a lineage giving rise to *L. peduncularis* and *L. aurantiacus.*

Additional specimens examined. PANAMA. PANAMÁ: headwaters of Río Chagres, Río Esperanza and Río Piedras, 79°20′W, 9°20′N, *de Nevers 4086* (MO); 8 mi. along El Llano–Cartí road from Pan American Highway, 300–400 m, *Sytsma 4002* (MO, WIS); *Sytsma et al. 5003* (MO, WIS).

5. **Lisianthius peduncularis** L. O. Williams, Fieldiana, Bot. 31: 408, fig. 1. 1968 (as "*Lisianthus*"). TYPE: Panama. Coclé: El Valle de Antón, *Allen 3410* (MO).

Shrub or subshrub, occasionally large, to 3.5 m tall; stems terete, distinctly woody below, herbaceous above. Leaves petiolate, the petiole amplexicaul; blades dark green above, paler below, 6–20 cm long, to 7.5 cm broad, broadly ovate, abruptly acuminate to acute; the lateral veins prominent, strongly ascending. Inflorescences longly pedunculate, loose and open, once compound dichasia, sometimes reduced; bracts opposite, lanceolate to sublinear. Flowers nodding, the pedicels 6–13 mm long. Calyx 7.5–13 mm long, the lobes lanceolate, carinate, scariously margined, long acuminate at the apex, 5.5–10 mm long. Corolla tube funnelform, 4.5–6 cm long, bright yellow, inflated in the middle; the lobes dark green, 6–10 mm long, long acuminate, usually spreading. Stamens inserted in the corolla tube at the apex of the ovary; filaments 3.2–4 cm long, just surpassing the corolla tube but not the lobes; anthers 2–3 mm long, yellow, bilobed at the base. Style to 5 cm long, just exceeding the corolla lobes, always surpassing the anthers; stigma peltate. Capsule fusiform, to 1.5 cm long, sharply beaked; seeds irregular in shape, corrugated in texture. Chromosome number, $n = 18$.

Distribution. *Lisianthius peduncularis*, endemic to the north rim and adjacent ridges of El Valle de Antón, Coclé Province, is now known to be composed of three small populations. Two populations are restricted to exposed elfin forest ridges (900–1,000 m) and usually are found associated with *Symbolanthus pulcherrimus* Gilg, a lisianthioid shrub characteristic of such habitats. A third population is found on the northern lower flanks of the El Valle crater (800 m). This large population of approximately 80 individuals grows on a soft porous rhyolite bedrock in association with a low *Clusia*-dominated scrubby open forest similar to the vegetation type on Cerro Jefe. *Lisianthius skinneri* has been collected on the road from El Valle leading up to these *L. peduncularis* sites. P. Allen (*2369*) collected it in 1941, but the species has not been collected since from the region despite extensive searches and collecting through the Flora of Panama project.

Morphologically, *Lisianthius peduncularis* most closely resembles the new *L. aurantiacus* with which it shares long corolla tubes and lobes, and reduced inflorescences. They differ strikingly in habit and corolla color. Both occur at the western edge of the species complex in Panama. DNA analysis clearly indicates that these two species form a close pair of "sister species."

Representative specimens examined. PANAMA. COCLÉ: N rim, El Valle de Antón, *Allen 1793* (MO, US); La Mesa, N of El Valle, *Allen 2369* (US); Cerro Pajita, *Allen & Allen 4187* (MO); El Valle, Club Campestre, *Croat 14288* (F, MO); Cerro Pilón, *Croat 22945* (DUKE, F, MO, WIS); Cerro Pilón, *Duke 12192* (MO); Cerro Carocoral, *Duke & Dwyer 15094* (MO); Cerro Carocoral, *Kirkbride 1094* (MO); trail past La Mesa, *Clusia* forest, *Luteyn 4082* (DUKE); Cerro Pilón, *Mori 6631* (MO); Cerro Gaital, *Reveal & Balogh 4945* (MO); Divide SW of La Mesa at end of logging road, *Stein & Hamilton 1002* (MO, WIS); Cerro Carocoral, *Sytsma 3815* (MO); Las Minas, N of El Valle, *Sytsma 4039* (MO); La Mesa, N of El Valle, *Sytsma et al. 4367* (MO); inside crater at El Valle de Antón at La Mesa, *Weaver et al. 2247* (DUKE, F, NY, US); trail to La Mesa, 4.5 mi. past El Valle, *Wilbur & Luteyn 11696* (DUKE, MO, NY); trail past La Mesa, *Clusia* thicket, *Wilbur et al. 15622* (DUKE).

6. **Lisianthius aurantiacus** K. J. Sytsma, sp. nov. TYPE: Panama. Coclé: Mountains between La Pintada and Cascajal, *Dressler 5625* (holotype, MO; isotype, WIS). Figure 6.

Frutex vel arbor, ad 6.5 m alta; truncus ad 7 cm latis, ramosis aequaliter apicem versus. Folia obovata-elliptica, ad 25 cm longa et 6.5 cm lata. Inflorescentiae axillares, dichasio reducto, 1–2-floribus; pedunculis elongatis, ad 12 cm longis. Calyx viridis, tubularis, 10–16 mm longis; lobi 8–13 mm longi, acuminati longe. Corolla aurea, au-

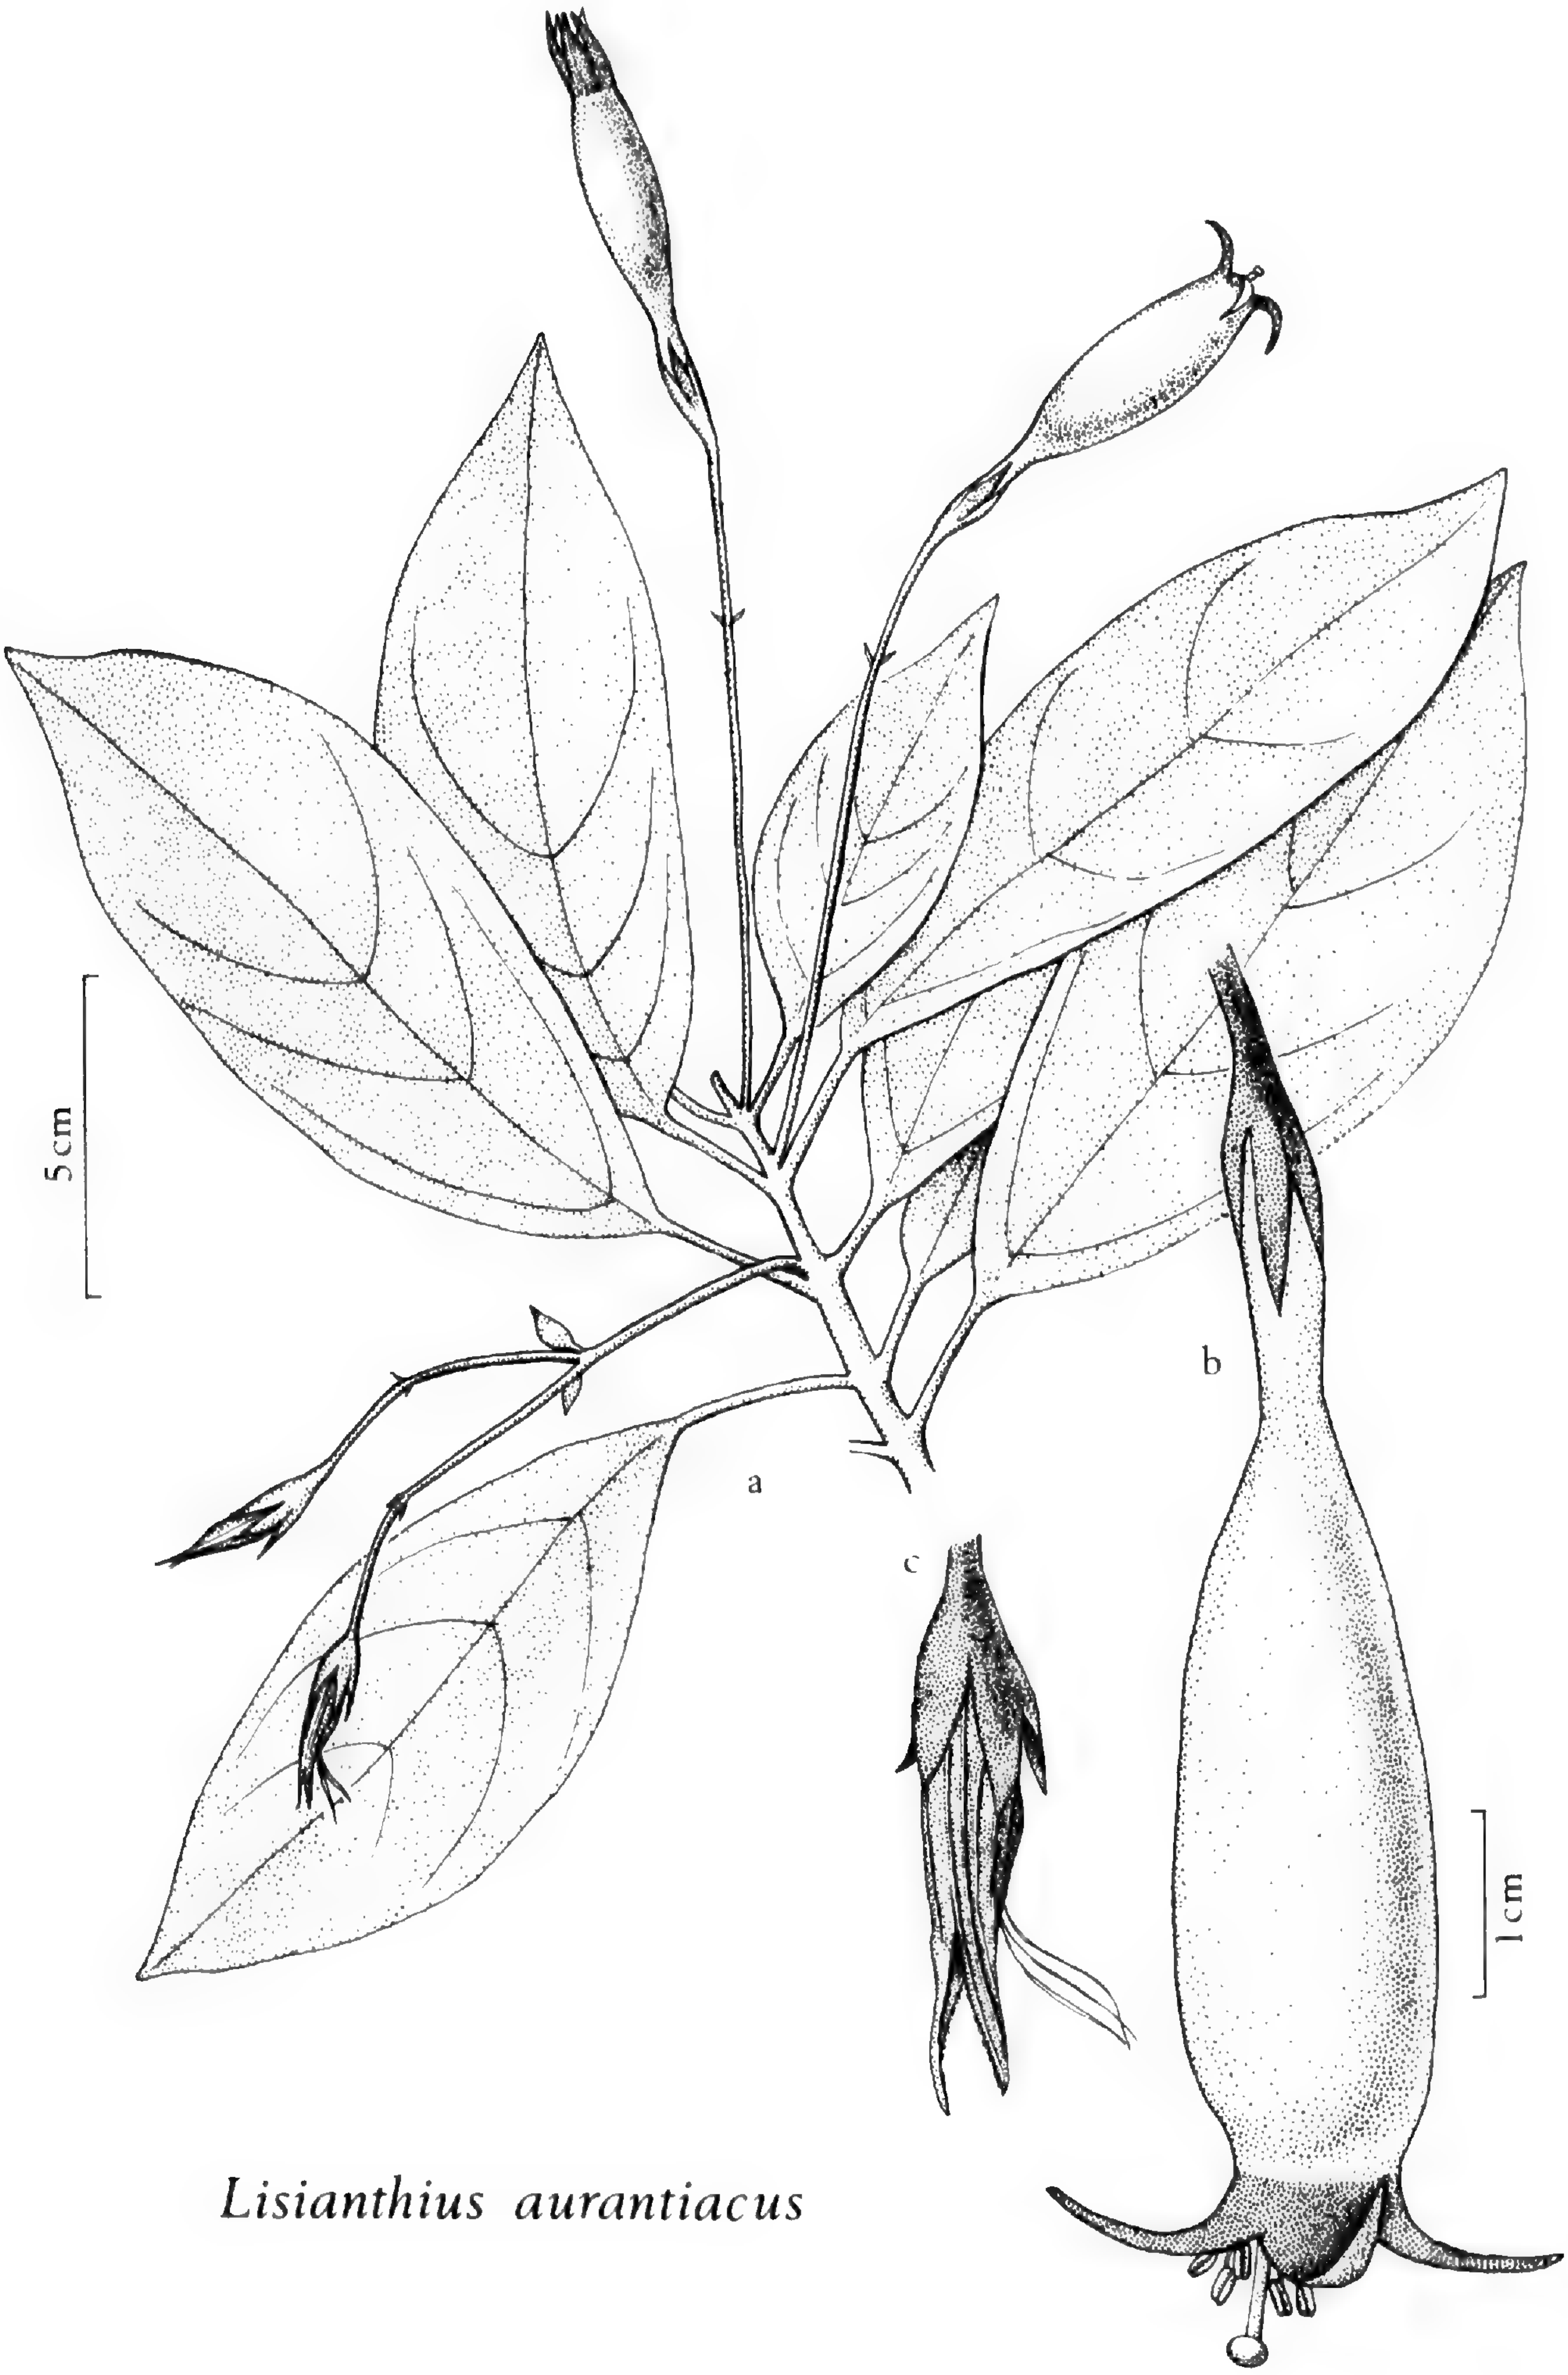

FIGURE 6. Lisianthius aurantiacus (Hammel 2508 *(MO))*.—*a. Habit.—b. Flower.—c. Dehisced fruit.*

rantiacus, 5.5–7.8 cm longa; lobi triangulares, virides, 10–14(–17) mm longi, 3–5 mm lati. Stamina filamentis ± exsertis; antherae 2.5–5 mm longae. Stilus antherae superans 1–3 mm; stigma peltatum, aquamarinum. Capsulae fusiformes, 1.8–2.5 cm longa.

Shrub or slender-trunked tree, to 6.5 m tall. Stem to 7 cm wide, terete, evenly branched to the top. Leaves petiolate, the petiole 5–15 mm long, amplexicaul; blade glossy dark green above, slightly paler below, 2–3 lateral veins conspicuous, strongly ascending, the costa prominent below, membranaceous; to 25 cm long and 6.5 cm broad, obovate to obovate-elliptic, basally cuneate to slightly attenuate, apically acuminate. Inflorescence axillary, opposite, consisting of 1 or 2 flowers; the peduncles to 12 cm long, containing 1–3 sets of foliaceous to linear bracts, the larger bracts to 15 mm long; the pedicels to 2 cm long. Flowers strongly nodding. Calyx tubular, dark green, 10–16 mm long, the lobes lanceolate, long acuminate, scariously margined, carinate at the base only, 8–13 mm long. Corolla 5.5 –7.8 cm long, tubular-funnelform, inflated, the tube bright pumpkin orange, the lower ⅙ narrowly constricted, the lobes dark green, triangular, acuminate and spreading, 10–14(–17) mm long and 3–5 mm wide at the base. Stamens 4.5–6.3 cm long, exserted to the midpoint of the lobes; filaments filiform, inserted on the corolla tube at the apex of the ovary; anthers 2.5–5 mm long, slightly sagittate at base, yellow. Style 4.7–6.7 mm long, slightly exserted past the anthers; stigma blue-green, capitate, slightly bilobed at apex. Capsule fusiform, 1.8–2.5 cm long, 5–7 mm diam., with a beak 4 mm long.

Distribution. *Lisianthius aurantiacus* has the most widespread distribution of the cloud-forest species. It has been collected in three localities: on the continental divide near Cascajal, Coclé Province (650 m); below the continental divide on the Atlantic watershed north of El Cope, Coclé Province (800–900 m); and the Cerro Tífe region 15 km west of El Cope (400–450 m). *Lisianthius aurantiacus* usually occurs sporadically in closed forests, with only a few individuals seen together. Populations in the more disturbed Cascajal area are large and more treelike (to 6 m), effectively forming a canopy. *Lisianthius aurantiacus* is found at lower elevations than the other cloud-forest species. The cloud forests in this region of Coclé Province are lower in elevation than in other areas of central Panama because of local climatic conditions. The forests are floristically more similar to mid-elevation moist forests where *L. skinneri* thrives. Indeed, a population of *L. skinneri* was discovered growing sympatrically with *L. aurantiacus* in the Cascajal area.

Lisianthius aurantiacus is undoubtedly the most spectacular member of the genus. Its arboreal habit, very large pumpkin orange corolla (thus the specific epithet), and highly reduced inflorescence distinguish it from all other *Lisianthius* species. A more northern species, *L. axillaris,* is strikingly similar to *L. aurantiacus.* The only species with red or orange flowers known prior to *L. aurantiacus* was *Lisianthius axillaris,* a common roadside plant in Belize and surrounding regions. It exhibits not only a reddish corolla, but also an axillary inflorescence of a single flower as well. This is a clear case of floral convergence. *Lisianthius aurantiacus* is most closely related to *L. peduncularis,* with which it shares several other floral characters.

Representative specimens examined. PANAMA. CHROMOSOME NUMBERS IN *LOTONONIS* AND *BUCHENROEDERA* (FABACEAE—CROTALARIEAE)[1]

Ben-Erik Van Wyk
and Anne Lise Schutte[2]

ABSTRACT

Original chromosome counts for Buchenroedera *(new generic report) and* Lotononis *(44 new specific reports) are presented. The most common somatic number in* Lotononis, *18, was found in 29 species. Three species of* Buchenroedera *and nine species of* Lotononis *have* $2n = 28$. *In* Lotononis *section* Krebsia $2n = 28, 42, 56$, *and 84 were found in a closely related species group. This is the first report of a polyploid series in the Crotalarieae and includes the highest numbers recorded in the tribe. The chromosome numbers indicate anomalies in the existing sectional classification of* Lotononis *and may provide evidence for a more natural generic and infrageneric classification.*

The genera *Lotononis* (DC.) Eckl. & Zeyh. and *Buchenroedera* Eckl. & Zeyh. are poorly known cytologically, with only six species of the former and none of the latter having been investigated previously. As part of an ongoing taxonomic study of these genera, chromosome counts were made for 47 species, representing almost the full range of variation in *Lotononis* (ca. 120 species centered in southern Africa, with a few extending into Asia) and *Buchenroedera* (ca. 16 species restricted to the eastern parts of southern Africa). The results are presented here, and their systematic significance in terms of an improved generic and infrageneric classification is discussed.

MATERIALS AND METHODS

Mitotic counts were made from root tips of germinated seeds. Standard methods of pretreatment in hydroxyquinoline (0.02% mass/volume) and staining in lacto-propionic orcein were used. The duration of hydrolysis (1–8 minutes) and the concentration of HCl (0.2–0.5 N) proved to be important. The chromosomes are small (ca. 1–3 μm long). Voucher specimens (listed in Table 1) are housed at the Rand Afrikaans University Herbarium (JRAU). A list of the species studied and voucher specimen details are given in the Appendix. Our efforts to collect seeds have been rewarded by numerous rediscoveries of rare species and have provided a fairly representative sample of the two genera.

RESULTS AND DISCUSSION

The results listed in Table 1 are arranged according to Duemmer's (1913) sectional classification. Where morphologically heterogenous sections of *Lotononis* have been subdivided into two or more groups, or where species have been moved to more appropriate positions, the reasons for doing so are given in the footnotes. The arrangement of species in Table 1 is aimed at facilitating the discussion that follows and is not intended as a formal infrageneric classification, but it nevertheless reflects major discontinuities and shows basic affinities.

Several morphological characters provide links among the species of *Lotononis* with $2n = 28$ and among those with $2n = 18$. The latter are presently placed in various sections, indicating that Duemmer's infrageneric treatment is artificial; that the same chromosome number has evolved independently in several different groups seems unlikely. Section *Krebsia*, for example, presently comprises three distinct groups, two of which have obvious

[3] Species added to *Krebsia* by Duemmer (1913).
[4] Position in section *Polylobium* was based on a superficial characterization.
[5] An anomalous species. Dahlgren (1964) suggested similarities with *L. involucrata.*
[6] Species added to section *Polylobium* by Baker (1871) and related species.
[7] Superficially similar to *L. laxa* and previously associated with the section *Leptis.*
[8] This section was referred to the genus *Crotalaria* by Duemmer (1913).
[9] Better known as *L. micrantha* (E. Mey.) Benth.
[10] A distinct group of *Lipozygis* with indehiscent, wind-dispersed fruit.
[11] A distinct group of pyrophytes from grassland areas of the eastern parts of southern Africa.
[12] Perennial herbs with acute keel petals as in section *Oxydium.*
[13] Annuals with acute keel petals as in section *Oxydium.*
[14] Annuals and perennials with obtuse keel petals as in the *L. eriantha* group of section *Lipozygis.*

affinities elsewhere in the genus. The woody habit of *L. digitata* and *L. transvaalensis* was used to place them in *Krebsia,* but both are morphologically very similar to various species of section *Leptis.* Another example is section *Polylobium*; *Lotononis umbellata* and its allies are closely related to section *Aulacinthus* and perhaps not distinct from it at the sectional level. The *L. angolensis* group is quite different from other species of section *Polylobium* and its position in this section is unsatisfactorily artificial.

Two separate phylogenetic lines with base numbers of $x = 9$ and $x = 7$ are suggested, and further research will show if other evidence supports such a dichotomy in the genus. Not a single count of $2n = 16$ or 32 has been made, so that a base number of 8, which is common in some of the other genera, so far appears to be totally absent in *Lotononis*.

At the generic level, the data also give some indications of affinity. *Buchenroedera* is so closely related to *Lotononis* (especially to section *Krebsia*) that its generic status has been questioned (Polhill, 1976, 1981). The shared chromosome number of $2n = 28$ (and presumably a base number of 7) agrees with chemical evidence (Van Wyk & Verdoorn, 1988) that *Buchenroedera* is perhaps best considered a section of *Lotononis*.

The remarkable similarities between species of *Crotalaria* and *Lotononis* have caused confusion in past taxonomic treatments. For example, most species of *Lotononis* section *Oxydium* were transferred to *Crotalaria* by Duemmer (1913). The presence of macrocyclic pyrrolizidine alkaloids in both genera (Van Wyk & Verdoorn, in prep.) indeed indicates that *Lotononis* is more closely related to *Crotalaria* than to other genera of the tribe, all of which seem to contain only quinolizidine alkaloids. *Crotalaria*, however, have $2n = 16$, 32, or rarely 14 (Goldblatt, 1981a), while those species of *Lotononis* that closely resemble *Crotalaria* (section *Oxydium* and some groups of *Leptis*) all have $2n = 18$. The morphological distinction between *Lotononis* and *Crotalaria* (Polhill, 1968) is therefore strongly supported by the data at hand.

Some of the woody species of *Lotononis* (sections *Aulacinthus* and *Krebsia*) are very similar to species of *Lebeckia*. *Lotononis caerulescens* (E. Mey.) B-E. van Wyk, for example, has until recently been known as *Lebeckia microphylla* E. Mey., but morphological and chemical evidence (Van Wyk, 1988; Van Wyk & Verdoorn, 1988) clearly showed it to be misplaced in *Lebeckia*. The sections *Aulacinthus* and *Krebsia* sensu stricto have $2n = 28$, 42, 56, and 84, while four counts of $2n = 18$ are known for *Lebeckia* (Dahlgren, 1967). Here again, the cytological data agree with the morphological distinction between *Lotononis* and *Lebeckia*. *Lotononis angolensis* and related species (section *Polylobium*) are chemically similar to *Lebeckia* and also have the same chromosome number. Morphological characters such as the zygomorphic calyx and dimorphic stipules, however, are typical of *Lotononis*.

Not a single count of $2n = 14$ is known for *Lotononis*; so it seems to be cytologically different from the genus *Pearsonia*. The only available count for the latter genus was by Frahm-Leliveld (1969), who reported $2n = 14$ for *P. flava* (Bak. f.) Polhill. The species of *Pearsonia* are similar to *Lotononis* except for their highly modified flowers (Polhill, 1973), and the shared chromosome base number of $x = 7$ may indeed indicate a common ancestry.

From a phylogenetic point of view, the different base numbers in *Lotononis* suggest interesting questions about generic relationships in the Crotalarieae. The base number of the tribe is almost certainly $x = 9$ (Goldblatt, 1981a), and $2n = 18$ in some species of *Lotononis* is presumably the ancestral condition. The only way to achieve $2n = 28$ (if *Lotononis* is monophyletic) is to postulate descending aneuploidy from $n = 9$ to 8 and 7 and subsequent polyploidy. Since $2n = 16$ and 14 appear to be totally absent in *Lotononis*, it may be argued that *Crotalaria* and *Pearsonia* form part of the lineage that gave rise to the group of species with $2n = 28$, 42, 56, and 84. If *Lotononis* proves to be polyphyletic, this possibility can be seriously considered, but the generic characters of the current concept of *Lotononis* are present in at least some species of each major group. Although there are marked phenetic similarities linking all the major groups, *Lotononis* as a whole is not monothetic. It is defined by combinations of apomorphic tendencies, such as single stipules, suffrutescent or herbaceous habit, absence of bracteoles, fusion of the lateral calyx lobes, verrucose upper suture of the fruit, tuberculate testa, elongated funicles, flower dimorphism associated with cleistogamy, ability to produce HCN, and presence of macrocyclic pyrrolizidine alkaloids. There is not a single apomorphy known to us that would unambiguously support monophyly. A possible solution would be to separate the lineage with $2n = 28$ from the one with $2n = 18$ and to split the latter into several smaller groups. Despite conflicting character information, there are some indications from the morphology that the geographically widespread and generally herbaceous $2n = 18$ lineage is more primitive than the predominantly woody and essentially southern African $2n = 28$ lineage.

In a tribal context, the occurrence of polyploidy in *Lotononis* (section *Krebsia*) is of some interest. Polyploidy and high chromosome numbers are typical of the Genisteae but have never been reported from any genus of the Crotalarieae (Goldblatt, 1981a). It is also noteworthy that polyploidy should occur in an essentially woody group (previously considered to be one of the basal groups of *Lotononis*) and not in the supposedly more derived herbaceous groups. Unlike the situation in the other large genera of the Crotalarieae (*Aspalathus* and to some extent *Crotalaria*), there is no direct evidence of aneuploidy, although it must have played a significant role in the phylogeny of *Lotononis.*

GEORGE ENGELMANN TYPE SPECIMENS IN THE HERBARIUM OF THE MISSOURI BOTANICAL GARDEN[1]

Steven J. Wolf[2]

ABSTRACT

Eight hundred ninety-two type specimens (in 62 families) representing 589 taxa described by George Engelmann have been located in the herbarium of the Missouri Botanical Garden. For each specimen the following are given: literature citation, kind of type, locality and date of collection, collector, and name it is currently filed under in the herbarium.

Asa Gray once remarked that George Engelmann had the potential to become the "gatekeeper for all scientists going into the wilderness" (Dupree, 1959). Engelmann, a well-trained botanist and physician, on the edge of the American frontier in mid-19th century St. Louis, the gateway to the West, was indeed the right man in the right place at the right time. Some of the first botanical expeditions to the American West were organized, outfitted, and coordinated by Engelmann, who then received and processed the incoming plant specimens and sent them on to Gray (Timberlake, 1984). Among these early expeditions were Geyer's to Illinois, Missouri, and Iowa; Lindheimer's to Texas; Wislizenus's to the New Mexico Territory and northern Mexico, and Fendler's to the southern Rocky Mountains. By the 1850s most expeditions to the West were government supported; however, the plant specimens from them continued to be funneled through Engelmann in St. Louis (Timberlake, 1984). As a result, his herbarium, which consisted of about 97,000 specimens at his death, contained collections from more than 30 collecting expeditions. Although largely from the American West and Mexico, collections also came from South America and Asia.

Engelmann, a prolific and industrious scientist, was much more than a gatekeeper. In addition to maintaining a full-time medical practice, he published more than 100 botanical papers (Sargent, 1884; Timberlake, 1984), described more than 600 new taxa of plants (Trelease & Gray, 1887), founded the Academy of Science of St. Louis, and was largely responsible for the foundation of what later became the herbarium of the Missouri Botanical Garden. It was Engelmann who convinced Henry Shaw, a wealthy St. Louis businessman planning a botanical garden, that to be scientifically credible his garden must have a library and herbarium (Timberlake, 1984). In fact it was Engelmann who purchased the Bernhardi Herbarium for Shaw, which comprised the first specimens of this herbarium. After Engelmann's death in 1884, his entire herbarium was added to Shaw's herbarium which, upon Shaw's death, became known as the herbarium of the Missouri Botanical Garden.

On the 100th anniversary of the death of George Engelmann, it seemed appropriate to re-examine his herbarium, particularly with respect to possible type specimens it might contain. Complete lists of Engelmann's publications, including his contributions to the works of others, are provided in Sargent (1884) and Timberlake (1984), and references to and reprints of most of his newly described taxa are included in Trelease & Gray (1887). The only major omissions in the latter are Engelmann's contributions to Coulter's (1894, 1896) revision of North American cacti. In the present study, a search for type specimens of Engelmann's more than 600 described taxa was conducted. An un-

---

ANN. MISSOURI BOT. GARD. 75: 1608–1636. 1988.

derstanding of some of Engelmann's habits was most helpful in locating types. He sometimes wrote "n. sp." on newly named specimens or wrote the descriptions on the sheet itself. Although he sometimes did not mention a specific collection or collector, it is often apparent which ones he had seen and used for his descriptions. For example, if his protologue stated "Battlefields of Buena Vista, near Saltillo, Flowers May," there is often a specimen with this exact wording on the label, collected in May by one of the collectors of that particular expedition. Additionally, if in describing a new taxon he had stated that it resembled or was related to taxon "X," the type would often have been initially labeled taxon "X," but this epithet would later have been crossed out and the new epithet penciled in by Engelmann.

The purpose of the present paper is to provide a list of types or possible type material contained in Engelmann's herbarium. Since many of the collections examined by Engelmann were widely distributed, and since only specialists should designate lectotypes, I have adopted a conservative type terminology. The only exception is that I have adopted Rollins's (1972) view that "the existence of a holotype in the institution where the author worked is assumed until proven otherwise." If Engelmann cited only one specimen and that specimen has been located in his herbarium, it is considered a holotype and supersedes previously designated lectotypes. Annotations by specialists on the sheets themselves, as well as known lectotypifications in the monographs listed below, have been accepted unless a holotype has been located. I have adopted the term "type material" in cases in which it is not clear what kind of type the specimen is but in which it is apparent that Engelmann did see it and may have used it in making his descriptions. This term is especially useful in dealing with Lindheimer's collections from Texas because they were apparently widely distributed and the exsiccatae numbers often consisted of mixed material collected in different locales, in different years, and sometimes even after the date of publication of Engelmann & Gray (1845). It is therefore suggested that specialists examine these specimens, some of which bear Lindheimer's original collection label and number, in order to determine if they are heterogeneous material and/or what kind of types they are.

In the present paper a total of 892 types, representing 589 taxa in 62 families, described by or attributed to George Engelmann are presented. In the following list the name of the taxon, its authorship, and place of publication are given, followed by the kind of type, location and date of collection, and the collector(s) and collection number if known. Also given is the current name under which it is filed in the herbarium. Taxa for which works containing numerous lectotypifications have been consulted, and for which synonymies have been followed, include: *Agave* (Gentry, 1982), *Arceuthobium* (Hawksworth & Weins, 1972), *Asclepias* (Woodson, 1954), Cactaceae (Benson, 1982), *Cuscuta* (Yuncker, 1932), *Euphorbia* (Wheeler, 1941), *Isoetes* (Pfeiffer, 1922), *Phoradendron* (Trelease, 1916), *Quercus* (Trelease, 1924), *Sagittaria* (Bogin, 1955), *Vitis* (Bailey, 1934), and *Yucca* (McKelvey, 1938, 1947). The taxa are arranged by family according to Kartesz & Kartesz (1980).

ACANTHACEAE

Dianthera humilis Engelm. & Gray, Boston J. Nat. Hist. 5: 55. 1845. SYNTYPE: west of Houston, Texas, 1845, *F. Lindheimer 159.* = *Justicia ovata* (Walt.) Lindau.

Dipteracanthus nudiflorus Engelm. & Gray, Boston J. Nat. Hist. 5: 229. 1845. HOLOTYPE: Sim's Bayou, near Houston, Texas, 1842, *F. Lindheimer s.n.*

AGAVACEAE

Agave angustissima Engelm., Trans. Acad. Sci. St. Louis 3: 306. 1876. HOLOTYPE: Octillo, Mexico, 1849, *J. Gregg 959.*

Agave couessii Engelm. in Trelease, Annual Rep. Missouri Bot. Gard. 22: 94. 1911. HOLOTYPE: Ft. Whipple, Arizona, 1865, *E. Coues & E. Palmer 253,* "couessi" added by Engelm. = *A. Parryi* Engelm. var. *couessii* (Engelm. ex Trel.) Kearny & Peables.

Agave desertii Engelm., Trans. Acad. Sci. St. Louis 3: 310. 1875. HOLOTYPE?: San Felipe, California, 1875, *E. Palmer & G. Hitchcock s.n.,* annotated "n. sp." by Engelm.

Agave falcata Engelm., Trans. Acad. Sci. St. Louis 3: 304. 1875. LECTOTYPE: Saltillo, Mexico, 1847, *A. Wislizenus 312* (2 sheets). = *A. striata* Zucc. subsp. *falcata* (Engelm.) Gentry.

Agave maculata Engelm. in Torr., Bot. Mex. Bound. Surv. 214. 1859. HOLOTYPE: Rio Grande, 1847, *A. Wislizenus 373* (3 sheets). = *Manfreda maculosa* (Hook.) Rose.

Agave maculosa Hook. var. *brevituba* Engelm., Trans. Acad. Sci. St. Louis 3: 301. 1875. LECTOTYPE: below El Paso, Texas, 1851–1852,

C. *Wright 1905.* = *Manfreda maculosa* (Hook.) Rose.

Agave newberryi Engelm., Trans. Acad. Sci. St. Louis 3: 309. 1879. HOLOTYPE: northwestern Arizona, 1858, *J. S. Newberry s.n.* = *A. utahensis* Engelm.

Agave palmeri Engelm., Trans. Acad. Sci. St. Louis 3: 319. 1875. SYNTYPE: southern Arizona, 1869, *E. Palmer s.n.* (3 sheets).

Agave parryi Engelm., Trans. Acad. Sci. St. Louis 3: 312. 1875. SYNTYPES: Arizona Territory, 1871, *F. Bischoff s.n.*; 1846, *Emory s.n.*; 1874, *J. T. Rothrock 274* (3 sheets).

Agave schottii Engelm., Trans. Acad. Sci. St. Louis 3: 306. 1875. HOLOTYPE: Sierra del Pajarito, Arizona, 1855, *A. Schott s.n.*

Agave shawii Engelm., Trans. Acad. Sci. St. Louis 3: 314. 1875. SYNTYPE: San Diego, California, *s.d., G. N. Hitchcock s.n.* (2 sheets).

Agave utahensis Engelm. in Watson, Bot. King's Expl. 497. 1871. LECTOTYPE: St. George, Utah, 1870, *E. Palmer s.n.* (2 sheets). Syntype: *J. E. Johnson s.n.*

Agave virginica L. var. *tigrina* Engelm., Trans. Acad. Sci. St. Louis 3: 302. 1875. HOLOTYPE: South Carolina, 1873, *Mellichamp s.n.* = *Manfreda virginica* (L.) Rose.

Agave wislizenii Engelm., Trans. Acad. Sci. St. Louis 3: 320. 1875. HOLOTYPE: San Sebastino, Mexico, 1847, *A. Wislizenus 280* (2 sheets). = *A. parrasana* Berger.

Asyliron leiophyllum Engelm. ex Trelease, Proc. Am. Phil. Soc. 50: 433. 1911. HOLOTYPE: Presidio del Norte, Texas, 1880, *D. Harvard s.n.*

Yucca angustifolia Pursh var. *radiosa* Engelm. in Watson, Bot. King's Expl. 496. 1871. LECTOTYPE: Arizona, 1867, *E. Palmer 201.* = *Y. elata* Engelm.

Yucca angustissima Engelm. ex Trelease, Annual Rep. Missouri Bot. Gard. 13: 58. 1902. LECTOTYPE: deserts of the Colorado River, 1853 & 1854, *J. M. Bigelow s.n.* (2 sheets).

Yucca brevifolia Engelm. in Watson, Bot. King's Expl. 496. 1871. LECTOTYPE: Date Creek, *s.d., E. Palmer?*, MO Nos. 135643 & 135646.

Yucca elata Engelm., Bot. Gaz. 7: 17. 1882. LECTOTYPE: Camp Grant, Arizona, *s.d., J. T. Rothrock 382.*

Yucca macrocarpa Engelm., Bot. Gaz. 6: 244. 1881. LECTOTYPE: Santa Rita Mts., Arizona, 1880, *G. Engelmann s.n.* = *Y. schottii* Engelm.

Yucca schottii Engelm., Trans. Acad. Sci. St. Louis 3: 46. 1873. LECTOTYPE: Santa Cruz River, Arizona, 1855, *A. Schott s.n.*

Yucca yucatana Engelm., Trans. Acad. Sci. St. Louis 3: 37. 1873. HOLOTYPE: Nohpat, Yucatán, Mexico, 1865, *A. Schott s.n.* = *Y. aloifolia* L.

ALISMATACEAE

Sagittaria calycina Engelm. in Torr., Bot. Mex. Bound. Surv. 212. 1859. LECTOTYPE: Alexandria, Louisiana, *s.d., J. Hale s.n.* Syntypes: banks of Missouri, 1856, *G. Engelmann s.n.*; Kimms Salt Pond, Missouri, 1856, *G. Engelmann s.n.* = *S. montevidensis* Cham. & Schlecht. subsp. *calycina* (Engelm.) Bogin.

Sagittaria calycina Engelm. var. *fluitans* Engelm. in Torr., Bot. Mex. Bound. Surv. 212. 1859. HOLOTYPE: western Texas, 1851–1852, *C. Wright 1899.* = *S. montevidensis* Cham. & Schlecht. subsp. *calycina* (Engelm.) Bogin.

Sagittaria calycina Engelm. var. *spongiosa* Engelm. in Gray, Man. Bot. 5: 493. 1868. HOLOTYPE: Wilmington, Delaware, 1860, *Tatnall s.n.* = *S. montevidensis* Cham. & Schlecht. subsp. *spongiosa* (Engelm.) Bogin.

Sagittaria cristata Engelm. in Arthur, Contr. Flor. Iowa 5: 3. 1882. LECTOTYPE & 2 ISOLECTOTYPES: Armstrong, Iowa, 1881, *Cratty s.n.* = *S. graminea* Michx. subsp. *cristata* (Englem.) Bogin.

Sagittaria graminea Michx. var. *platyphylla* Engelm. in Gray, Man. Bot. 5: 494. 1868. LECTOTYPE & ISOLECTOTYPE: Texas, *s.d., F. Lindheimer 713.* Syntype?: Mississippi, 1860, "ex herb *A. Wood.*"

Sagittaria heterophylla Pursh var. *angustifolia* Engelm. in Gray, Man. Bot. 5: 494. 1868. TYPE MATERIAL?: Lakes, American Bottom (in Illinois, near St. Louis), 1846, *N. Riehl s.n.* = *S. rigida* Pursh.

Sagittaria recurva Engelm. ex Patterson, Checklist 130. 1887. LECTOTYPE & ISOLECTOTYPE: Texas, *s.d., F. Lindheimer 713.* = *S. graminea* Engelm. var. *platyphylla* Engelm.

Sagittaria trachysepala Engelm. ex Michelin in DC., Monogr. Phan. 3: 74. 1881. ISOTYPE: Texas, *s.d., Drummond 423.*

Sagittaria variabilis Engelm. in Gray, Man. Bot. 1: 461. 1848. LECTOTYPE: St. Louis, Missouri, 1846, *G. Engelmann s.n.* = *S. latifolia* Willd.

ANACARDIACEAE

Rhus microphylla Engelm. ex Gray, Pl. Wrightiana 1: 31. 1852. SYNTYPE: Texas, 1850, *F. Lindheimer 734.*

APIACEAE

Apium butleri Engelm. in Watson, Proc. Amer. Acad. Arts 21: 453. 1887. ISOLECTOTYPE: eastern Texas, *s.d.*, *E. Hall 244*. = *Ammoselinum butleri* (Engelm.) Coult. & Rose.

Cynosciadium pinnatum var. *pumilum* Engelm. & Gray, Boston J. Nat. Hist. 5: 218. 1845. TYPE MATERIAL: no locale but collected by *F. Lindheimer s.n.*, 1843; prairie west of the Brazos, Texas, *F. Lindheimer s.n.* Annotated "n. sp." by Engelmann.

Daucosma laciniata Englem. & Gray in Gray, Boston J. Nat. Hist. 6: 211. 1850. TYPE MATERIAL: upper Guadalupe, Texas, 1846, *F. Lindheimer s.n.*

Eryngium heterophyllum Engelm. in Wisliz., Mem. Tour. No. Mex. 107. 1848. HOLOTYPE: Cosihuiriachi, Mexico, 1846, *A. Wislizenus 176.*

ARISTOLOCHIACEAE

Aristolochia longiflora Engelm. & Gray, Boston J. Nat. Hist. 5: 259. 1845. HOLOTYPE: Texas, 1844, *F. Lindheimer s.n.*

ASCLEPIADACEAE

Asclepias brachystephana Engelm. in Torr., Bot. Mex. Bound. Surv. 163. 1859. LECTOTYPE: New Mexico, 1851–1852, *C. Wright 1692.*

Asclepias euphorbiifolia Engelm. ex Gray, Proc. Amer. Acad. Arts 16: 104. 1881. LECTOTYPE: San Luis Potosí, Mexico, *s.d.*, *Schaffner 55.*

Asclepias involucrata Englem. in Torr., Bot. Mex. Bound. Surv. 163. 1859. LECTOTYPE: Copper Mines, New Mexico, 1851–1852, *C. Wright 1690.*

Asclepias leucophylla Engelm. in Parry, Amer. Naturalist 9: 348. 1875. HOLOTYPE: southern Utah, 1874, *C. C. Parry 207*. = *A. erosa* Torr.

Asclepias lindheimeri Engelm. & Gray, Boston J. Nat. Hist. 5: 250. 1845. SYNTYPE: Industry, Texas, 1844, *F. Lindheimer 272*. = *A. oenotheroides* Cham. & Schlecht.

Asclepias sullivantii Engelm. ex Gray, Man. Bot. 1: 366. 1848. SYNTYPE: St. Louis, Missouri, 1834, *G. Engelmann 451.*

Astephanus utahensis Englem in Parry, Amer. Naturalist 9: 347. 1875. PROBABLE HOLOTYPE: southern Utah, 1874, *C. C. Parry 209*. Engelmann wrote "spec. nov." on it.

Gonolobus curtisii Engelm. in Parry, apparently not published, but annotated "n. sp." by Engelm. TYPE MATERIAL: North Carolina, 1844, *Curtis s.n.* = *Matelea gonocarpa* (Walt.) Shinners.

Gonolobus cynanchoides Engelm. & Gray, Boston J. Nat. Hist. 5: 251. 1845. TYPE MATERIAL: Industry, Texas, 1844, *F. Lindheimer 273.* = *Matelea cynanchoides* (Engelm.) Woods.

Gonolobus reticulatus Engelm. ex Gray, Proc. Amer. Acad. Arts 12: 75. 1877. TYPE MATERIAL: Guadalupe, Texas, 1846, *F. Lindheimer 461*. = *Matelea reticulatus* (Engelm.) Woods.

Mellichampia filifolia Engelm., apparently not published, but annotated "n. sp." by Engelm. TYPE MATERIAL: St. George, Utah, July 1874, *Parry s.n.*

Sarcostemma heterophyllum Engelm. in Torr., Bot. Mex. Bound. Surv. 362. 1859. HOLOTYPE: New Mexico, 1851–1852, *C. Wright 1681.*

ASTERACEAE

Agassiza suavis Gray & Engelm., Proc. Amer. Acad. Arts 1: 46. 1847. SYNTYPE: San Antonio, Texas, 1845, *F. Lindheimer 351* distributed as No. 437 for 1846 (2 sheets). = *Gaillardia suavis* (Gray & Englem.) Britton & Rusby.

Aster anomalus Engelm. in Torrey & Gray, Fl. N. Amer. 2: 503. 1843. TYPE MATERIAL: Rockspring near Prairie du Pont, Sept. 1842, *G. Engelmann s.n.* The only prepublication dated specimen.

Aster azureus Lindl. ex Hook. var. *vernalis* Engelm. ex Small, Fl. S.E. U.S. 1215. 1903. HOLOTYPE: prairies west of Houston, Texas, 1842, *F. Lindheimer s.n* (2 sheets).

Keerlia bellidifolia Gray & Engelm., Proc. Amer. Acad. Arts 1: 47. 1846. SYNTYPE: Guadalupe, Texas, 1845, *F. Lindheimer 415.*

Liatris acidota Engelm. & Gray, Boston J. Nat. Hist. 5: 218. 1845. ISOTYPES: Texas, 1843, *F. Lindheimer 72, 73.*

Lindheimera texana Gray & Engelm., Proc. Amer. Acad. Arts 1: 47. 1847. SYNTYPES: New Braunfels, Texas, 1846, *F. Lindheimer 424* (2 sheets); New Braunfels, Texas, 1847, *F. Lindheimer 638.*

Porophyllum amplexicaule Engelm. ex Gray, Pl. Wrightiana 1: 120. 1852. HOLOTYPE?: near Messillas, Mexico, *s.d.*, *J. Gregg s.n.*, annotated "n. sp." by Engelm.

Rudbeckia missouriensis Engelm. ex Boynton & Beadle, Biltmore Bot. Stud. 1: 17. 1901. TYPE MATERIAL: Meramec Station, Missouri, July 1879, *H. Eggert s.n.*; Allentown, Missouri, Sept. 1879, *G. Letterman s.n;* Allentown, Missouri, July 1879, *G. Letterman s.n.*

Sanvitalia angustifolia Engelm. ex Gray, Pl.

Wrightiana 1: 112. 1852. HOLOTYPE?: Buena Vista, Mexico, *s.d.*, *J. Gregg 274*, annotated "n. sp." by Engelm.

Vernonia lettermanii Engelm. ex Gray, Proc. Amer. Acad. Arts 16: 78. 1881. LECTOTYPE: Washita, Arkansas, 1879, *G. W. Letterman s.n.* Syntypes: Arkansas, 1879 & 1880, *G. W. Letterman s.n.* (2 sheets).

Vernonia lindheimeri Gray & Engelm., Proc. Amer. Acad. Arts 1: 46. 1848. HOLOTYPE: New Braunfels, Texas, 1846, *F. Lindheimer 408.*

Zinnia intermedia Engelm. in Wisliz., Mem. Tour. No. Mex. 107. 1848. HOLOTYPE: Cosihuiriachi, Mexico, 1846, *A. Wislizenus 182.* = *Z. peruviana* (L.) L.

BORAGINACEAE

Lithospermum breviflorum Engelm., Trans. Amer. Philos. Soc. 12: 203. 1861. HOLOTYPE?: 200 miles above Fort Pierre, 1853–1854, *F. V. Hayden s.n.*, only Hayden specimen and "breviflorum" added by Engelm.

Myosotis inflexa Engelm., Amer. J. Sci. 46: 98. 1844. HOLOTYPE?: no locale, 1842, *C. A. Geyer s.n.*, annotated "n. sp." by Engelm.

Myosotis macrosperma Engelm., Amer. J. Sci. 46: 98. 1844. HOLOTYPE: Prairies, Texas, 1839, *F. Lindheimer s.n.*, annotated "n. sp." by Engelm.

BRASSICACEAE

Dithyrea wislizenii Englem. in Wisliz., Mem. Tour. No. Mex. 97. 1848. TYPE MATERIAL: Mexico, 1846, *A. Wislizenus 63* (2 sheets).

Nasturtium calycinum Engelm., Trans. Amer. Philos. Soc. 12: 184. 1859. LECTOTYPE: Yellowstone River, 1853–1854, *F. V. Hayden 93.* Syntype: Ft. Union, mouth of Yellowstone, 1855?, *F. V. Hayden s.n.* = *Rorippa calycinum* (Engelm.) Rydb.

Sisymbrium incisum Engelm. ex Gray, Mem. Amer. Acad. Arts. II. 4: 8. 1849. SYNTYPES: Santa Fe Creek, New Mexico, 1847, *A. Fendler 30 & 31*; Moro, New Mexico, 1847, *A. Fendler 29.* = *Descuriana richardsonii* (Sweet) O. E. Schulz. subsp. *incisa* (Engelm.) Delting.

Vesicaria auriculata Englem. & Gray, Boston J. Nat. Hist. 5: 240. 1845. ISOTYPE: Brazos, Texas, 1844, *F. Lindheimer 271* (2 sheets). = *Lesquerella auriculata* (Englem. & Gray) S. Wats.

Vesicaria recurvata Englem. ex Gray, Boston J. Nat. Hist. 6: 240. 1850. ISOLECTOTYPE: New Braunfels, Texas, 1846, *F. Lindheimer 8.* Syntype: New Braunfels, Texas, 1846, *F. Lindheimer 330.* = *Lesquerella recurvata* (Englem. ex Gray) S. Wats.

CACTACEAE

Cactus gabbii Englem. in Coult., Contr. U.S. Natl. Herb. 3: 109. 1894. HOLOTYPE: Peninsula of California, Mexico, 1867, *W. Gabb 19.* = *Mammillaria brandegeei* (Coult.) K. Brandegee.

Cereus berlandieri Englem., Proc. Amer. Acad. Arts 3: 286. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 38. 1859. LECTOTYPE: southern Texas, 1834, *Berlandier 2433.* = *Echinocereus berlandieri* (Englem.) Engelm. ex Rumpler.

Cereus caespitosus Engelm. in Engelm. & Gray, Boston J. Nat. Hist. 5: 247. 1845. LECTOTYPE: cult. from Industry, Texas, 1845, *F. Lindheimer s.n.* = *Echinocereus reichenbachii* (Tenscheck) Haage, f., ex Britt. & Rose.

Cereus caespitosus Engelm. var. *castaneus* Engelm. in Gray, Boston J. Nat. Hist. 6: 202. 1850. LECTOTYPE: Liano, Texas, 1847, *F. Lindheimer s.n.* = *Echinocereus reichenbachii* (Tenscheck) Haage, f., ex Britt. & Rose.

Cereus caespitosus Engelm. var. *major* Engelm., Proc. Amer. Acad. Arts 3: 280. 1856. LECTOTYPE: Texas, 1851, *F. Lindheimer s.n.* = *Echinocereus reichenbachii* (Tenscheck) Haage, f., ex Britt. & Rose.

Cereus calvus Engelm. in Coult., Contr. U.S. Natl. Herb. 3: 409. 1896. HOLOTYPE: Peninsula of California, Mexico, 1867, *W. Gabb 2.*

Cereus chloranthus Engelm., Proc. Amer. Acad. Arts 3: 278. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 29. 1859. LECTOTYPE: El Paso and Stony Hills at Frontera, Texas, 1852, *C. Wright 95* (3 sheets, 1 box). = *Echinocereus chloranthus* Engelm.

Cereus coccineus Engelm. in Gray, Mem. Amer. Acad. Arts. II. 4: 51. 1849. LECTOTYPE: Wolf Creek, Mexico, 1846, *A. Wislizenus s.n.* (2 sheets). Syntype: Santa Fe, New Mexico, *s.d.*, *A. Fendler 272.* = *Echinocereus triglochidiatus* Engelm. var. *melanacanthus* (Engelm.) L. Benson.

Cereus coccineus Engelm. var. *cylindricus* Engelm. in Gray, Mem. Amer. Acad. Arts. II.

4: 51. 1849. LECTOTYPE: Santa Fe, New Mexico, 1846, *A. Fendler s.n.* = *Echinocereus triglochidiatus* Engelm. var. *melanacanthus* (Engelm.) L. Benson.

Cereus coccineus Englem. var. *melanacanthus* Engelm. in Gray, Mem. Amer. Acad. Arts. II. 4: 51. 1849. LECTOTYPE: Santa Fe, New Mexico, 1846, *A. Fendler 4.* = *Echinocereus triglochidiatus* Engelm. var. *melanacanthus* (Engelm.) L. Benson.

Cereus conoides Engelm. & Bigelow, Proc. Amer. Acad. Arts 3: 284. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 35. 1857. LECTOTYPE: Anton Chico, New Mexico, 1853, *J. M. Bigelow s.n.* Syntype: 1853, *J. M. Bigelow s.n.* = *Echinocereus triglochidiatus* Englem. var. *melanacanthus* (Engelm.) L. Benson.

Cereus ctenoides Engelm., Proc. Amer. Acad. Arts 3: 279. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 31. 1859. LECTOTYPE: Santa Rosa, Mexico, 1853, *J. M. Bigelow s.n.* (2 sheets). Syntypes: Pecos, 1851, *C. Wright s.n.*; Rio Grande, 1853, *J. M. Bigelow s.n.* = *Echinocereus pectinatus* (Scheidw.) Engelm.

Cereus dasycanthus Engelm. in Gray, Mem. Amer. Acad. Arts. II. 4: 50. 1849. NEOTYPE: between San Antonio and El Paso, Texas, 1849, *C. Wright s.n.* = *Echinocereus pectinatus* (Scheidw.) Engelm. var. *neomexicanus* (Standl.) L. Benson.

Cereus dasycanthus Engelm. var. *minor* Engelm., Proc. Amer. Acad. Arts 3: 279. 1856. LECTOTYPE: Frontera, Texas, 1851, *C. Wright s.n.* (2 sheets). Syntype: Chihuahua, Mexico, 1852, *J. M. Bigelow s.n.* = *Echinocereus pectinatus* (Scheidw.) Englem. var. *minor* (Engelm.) L. Benson.

Cereus dubius Engelm., Proc. Amer. Acad. Arts 3: 282. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 36. 1859. LECTOTYPE: Rio Grande, Texas, 1852, *C. Wright 410.* = *Echinocereus enneancanthus* Engelm. var. *dubia* (Engelm.) L. Benson.

Cereus emoryi Engelm., Amer. J. Sci. 14: 338. 1852. LECTOTYPE: San Diego, California, 1850, *C. C. Parry s.n.*

Cereus engelmannii Parry var. *chrysocentrus* Engelm. & Bigelow, in Engelm., Proc. Amer. Acad. Arts 3: 283. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 35. 1857. LECTOTYPE: Bill Williams River, California, 1854, *J. M. Bigelow s.n.* = *Echinocereus engelmannii* Parry var. *chrysocentrus* (Engelm. & Bigelow) Engelm. ex Rumpler.

Cereus engelmannii Parry var. *variegatus* Engelm. & Bigelow, in Engelm., Proc. Amer. Acad. Arts 3: 283. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 35. 1857. LECTOTYPE: Bill Williams Fork, California, 1854, *J. M. Bigelow s.n.* = *Echinocereus engelmannii* Parry var. *variegatus* (Engelm. & Bigelow) Engelm. ex Rumpler.

Cereus fendleri Engelm. in Gray, Mem. Amer. Acad. Arts. II. 4: 51. 1849. HOLOTYPE: Santa Fe, New Mexico, 1846, *A. Fendler 3.* = *Echinocereus fendleri* (Engelm.) Engelm. ex Rumpler.

Cereus fendleri Engelm. var. *pauperculus* Engelm. in Gray, Mem. Amer. Acad. Arts. II. 4: 51. 1849. HOLOTYPE: Santa Fe, New Mexico, 1846, *A. Fendler s.n.* = *Echinocereus fendleri* (Engelm.) Engelm. ex Rumpler.

Cereus flaviflorus Engelm. ex Coult., Contr. U.S. Natl. Herb. 3: 391. 1896. HOLOTYPE: Santa Borga, Mexico, 1867, *W. Gabb 10.* = *Echinocereus maritimus* (Jones) Schumann.

Cereus flexuosus Engelm. ex Coult., Contr. U.S. Natl. Herb. 3: 411. 1896. HOLOTYPE: Peninsula of California, Mexico, 1867, *W. Gabb 5.* = *Machaerocereus gummosus* (Engelm.) Britt. & Rose.

Cereus gonacanthus Engelm. & Bigelow, in Engelm., Proc. Amer. Acad. Arts 3: 285. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 33. 1857. LECTOTYPE: Cedar Woods, west of Zuni, New Mexico, 1853, *J. M. Bigelow s.n.* = *Echinocereus triglochidiatus* Engelm. var. *gonacanthus* (Engelm. & Bigelow) L. Benson.

Cereus greggii Engelm. var. *cismontanus* Engelm. in Wisliz., Mem. Tour. No. Mex. 102. 1848. LECTOTYPE: Cadena, Mexico, 1847, *J. Gregg s.n.* Syntype: Paso del Norte, Mexico, 1846, *A. Wislizenus 222.*

Cereus hexaedrus Engelm., Proc. Amer. Acad. Arts 3: 285. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 34. 1857. LECTOTYPE: near Zuni, New Mexico, 1853, *J. M. Bigelow s.n.* = *Echinocereus triglochidiatus* Engelm. var. *mojavensis* (Engelm. & Bigelow) L. Benson.

Cereus longisetus Engelm., Proc. Amer. Acad. Arts 3: 280. 1856. HOLOTYPE: Santa Rosa, Mexico, 1853, *J. M. Bigelow s.n.* = *Echinocereus longisetus* (Engelm.) Engelm.

Cereus mamillatus Engelm. ex Coult., Contr. U. S. Natl. Herb. 3: 405. 1896. HOLOTYPE: Peninsula of California, Mexico, 1867, *W. Gabb 16.* = *Echinocereus mamillatus* (Engelm. ex Coult.) Britt. & Rose.

Cereus mojavensis Engelm. & Bigelow in Engelm., Proc. Amer. Acad. Arts 3: 281. 1857 (preprint, 1956); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 33. 1857. HOLOTYPE: Mojave Creek, California?, 1854, *J. M. Bigelow s.n.* = *Echinocereus triglochidiatus* Engelm. var. *mojavensis* (Engelm. & Bigelow) L. Benson.

Cereus mojavensis Engelm. var. *zuniensis* Engelm. & Bigelow in Engelm., Proc. Amer. Acad. Arts 3: 281. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 33. 1857. LECTOTYPE: Colorado Chiquito, Arizona, 1853, *J. M. Bigelow s.n.* = *Echinocereus triglochidiatus* Engelm. var. *melanacanthus* (Engelm. & Bigelow) L. Benson.

Cereus paucispinus Engelm., Proc. Amer. Acad. Arts 3: 285. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 37. 1859. LECTOTYPE: cultivated from *C. Wright & J. M. Bigelow s.n.* = *Echinocereus triglochidiatus* Engelm. var. *paucispinus* (Engelm.) Engelm. ex W. T. Marshall.

Cereus pectinatus Scheidw. var. *rigidissimus* Engelm., Proc. Amer. Acad. Arts 3: 279. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 31. 1859. LECTOTYPE: Sonora, Mexico, 1855, *A. Schott s.n.* = *Echinocereus pectinatus* (Scheidw.) Engelm. var. *rigidissimus* (Engelm.) Engelm. ex Rumpler.

Cereus procumbens Engelm. in Gray, Mem. Amer. Acad. Arts. II. 4: 50. 1849. LECTOTYPE: near the mouth of the Rio Grande below Matamoras by the Missouri Volunteers, 1846, and cult. St. Louis May 1848. = *Echinocereus pentalophus* (DC.) Rumpler.

Cereus roemeri Engelm. in Gray, Mem. Amer. Acad. Arts. II. 4: 51. 1849. LECTOTYPE: Liano River, Texas, 1847, *F. Lindheimer s.n.* (2 sheets). = *Echinocereus triglochidiatus* Engelm. var. *melanacanthus* (Engelm. & Bigelow) L. Benson.

Cereus schottii Engelm., Proc. Amer. Acad. Arts 3: 288. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 44. 1859. HOLOTYPE: Sierra de Sonoyita, Mexico, *s.d.*, *A. Schott 3.*

Cereus stramineus Engelm., Proc. Amer. Acad. Arts 3: 282. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 35: 1859. LECTOTYPE: near El Paso, Texas, 1851, *C. Wright s.n.* Syntype: *J. M. Bigelow s.n.* = *Echinocereus enneacanthus* Engelm.

Cereus thurberi Engelm., Amer. J. Sci. II. 17: 234. 1854. LECTOTYPE: Sonora, Mexico, 1851, *G. Thurber s.n.*

Cereus titan Engelm. in Coult., Contr. U. S. Natl. Herb. 3: 409. 1896. HOLOTYPE: Cape San Lucas to San Quentin, Mexico, 1867, *W. Gabb 1.* = *Pachycereus pringlei* (S. Wats.) Britt. & Rose.

Cereus viridiflorus Engelm. var. *cylindricus* Engelm., Proc. Amer. Acad. Arts 3: 278. 1856. LECTOTYPE: New Mexico, 1851, *C. Wright s.n.*

Echinocactus bicolor Galeotti var. *schottii* Engelm., Proc. Amer. Acad. Arts 3: 277. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 27. 1859. HOLOTYPE: Cretaceous hills, near Mier, Mexico, 1853, *A. Schott s.n.* = *Thelocactus bicolor* Galeotti var. *schottii* (Engelm.) Krainz.

Echinocactus dasycanthus Engelm., Proc. Amer. Acad. Arts 3: 277. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 28. 1859. LECTOTYPE: El Paso, Texas, 1852, *C. Wright s.n.* (2 sheets). Syntype: Frontera, 1852, *C. Wright 86?* = *Neolloydia intertexta* (Engelm.) L. Benson var. *dasycanthus* (Engelm.) L. Benson.

Echinocactus emoryi Engelm. var. *rectispinus* Engelm. ex Coult., Contr. U.S. Natl. Herb. 3: 362. 1896. HOLOTYPE: Peninsula of California, Mexico, 1867, *W. Gabb 12.* = *Ferocactus wislizenii* Engelm.

Echinocactus flexispinus Engelm. in Wisliz., Mem. Tour. No. Mex. 112. 1848. HOLOTYPE: Pelayo, between Chihuahua and Parras, Mexico, 1847, *A. Wislizenus s.n.* = *Ferocactus hamatacanthus* Muhlenpfordt var. *crassispinus* (Engelm.) L. Benson. On same sheet as *E. hamatacanthus* (Muhlenpfordt) Britt. & Rose var. *crassispinus* Engelm.

Echinocactus hamatacanthus Muhlenpfordt var. *crassispinus* Engelm., Proc. Amer. Acad. Arts 3: 273. 1856. HOLOTYPE: Pelayo, between Chihuahua and Parras, Mexico, 1847, *A. Wislizenus s.n.* On same sheet as *E. flexispinus* Engelm. = *Ferocactus hamatacanthus* (Muhlenpfordt) Britt. & Rose var. *crassispinus* Engelm.

Echinocactus horizonthalonius Lem. var. *centrispinus* Engelm., Proc. Amer. Acad. Arts 3:

276. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 26. 1859. LECTOTYPE: Frontera, New Mexico Territory, 1851–1852, *C. Wright s.n.* (2 sheets) = *Echinocactus horizonthalonius* Lem.

Echinocactus intertextus Engelm., Proc. Amer. Acad. Arts 3: 277. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 27. 1859. LECTOTYPE: El Paso, Texas, *s.d.*, *C. Wright* or *J. M. Bigelow* (no coll.), *s.n.* (2 sheets). Syntype: Chihuahua, 1846, *A. Wislizenus s.n.* = *Neolloydia intertextus* (Engelm.) L. Benson.

Echinocactus lecontei Engelm., Proc. Amer. Acad. Arts 3: 274. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 29. 1857. LECTOTYPE: Bill Williams Fork, Arizona, 1854, *J. M. Bigelow s.n.* Syntype: Gilia, *Leconte s.n.* = *Ferocactus acanthodes* (Lemaire) Britt. & Rose var. *lecontei* (Engelm.) Lindsay.

Echinocactus limitus Engelm. in Coult., Contr. U.S. Natl. Herb. 3: 374. 1896. LECTOTYPE: south of San Diego, 1878, *Parker & Hitchcock s.n.* (2 sheets). = *Ferocactus viridescens* (Nutt.) Britt. & Rose.

Echinocactus longehamatus Galeotti var. *brevispinus* Engelm., Proc. Amer. Acad. Arts 3: 273. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 22. 1859. LECTOTYPE: rocky mountains of the Limpia, Texas, 1852, *J. M. Bigelow s.n.* = *Ferocactus hamatacanthus* (Muhlenpfordt) Britt. & Rose.

Echinocactus orcuttii Engelm., West. Amer. Sci. 2: 46. 1886. HOLOTYPE: Palm Valley, northern Lower California, 1883, *C. R. Orcutt 641* (2 sheets). = *Ferocactus orcuttii* (Engelm.) Britt. & Rose.

Echinocactus peninsulae Engelm. ex Coult., Contr. U.S. Natl. Herb. 3: 361. 1896. HOLOTYPE: Cape San Lucas to San Diego, 1867, *W. Gabb 11*.

Echinocactus polyancistrus Engelm. & Bigelow in Engelm., Proc. Amer. Acad. Arts 3: 272. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 29. 1857. HOLOTYPE: head of the Mojave, California?, 1854, *J. M. Bigelow s.n.* = *Sclerocactus polyancistrus* (Engelm. & Bigelow) Britt. & Rose.

Echinocactus polycephalus Engelm. & Bigelow in Engelm., Proc. Amer. Acad. Arts 3: 276. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 31. 1857. LECTOTYPE: on Mojave River and Mojave Valley, California?, 1854, *J. M. Bigelow s.n.* (3 sheets).

Echinocactus polycephalus Engelm. & Bigelow var. *xeranthemoides* Engelm. in Coult., Contr. U.S. Natl. Herb. 3: 358. 1859. LECTOTYPE: northern Arizona, 1881, *A. L. Siler s.n.*

Echinocactus pubispinus Engelm., Trans. Acad. Sci. St. Louis 2: 199. 1863. HOLOTYPE: Utah, 1851, *H. Engelmann 1.* = *Sclerocactus pubispinus* (Engelm.) L. Benson.

Echinocactus setispinus Engelm. in Engelm. & Gray, Boston J. Nat. Hist. 5: 246. 1845. LECTOTYPE: Colorado River, 1844, *F. Lindheimer s.n.* = *Ferocactus setispinus* (Engelm.) L. Benson.

Echinocactus sileri Engelm. ex Coult., Contr. U.S. Natl. Herb. 3: 376. 1896. HOLOTYPE: Cottonwood Springs and Pipe Springs, Arizona, 1883, *A. L. Siler s.n.* (2 sheets). = *Pediocactus sileri* (Engelm.) L. Benson.

Echinocactus simpsonii Engelm., Trans. Acad. Sci. St. Louis 2: 197. 1863. LECTOTYPE: Kobe Valley, Nevada, 1859, *H. Engelmann s.n.* Syntype: Utah Desert, *s.d.*, *H. Engelmann s.n.* = *Pediocactus simpsonii* (Engelm.) Britt. & Rose.

Echinocactus simpsonii Engelm. var. *minor* Engelm., Trans. Acad. Sci. St. Louis. 2: 197. 1863. LECTOTYPE: Mt. Vernon, *Parry, Hall & Harbour s.n.* = *Pediocactus simpsonii* Engelm. var. *minor* (Engelm.) Cockerell.

Echinocactus uncinatus Hopf. ex Foerst. var. *wrightii* Engelm., Proc. Amer. Acad. Arts 3: 272. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 20. 1859. LECTOTYPE: Frontera, Texas, 1852, *C. Wright 88*. Syntype: Frontera, Texas, 1852, *J. M. Bigelow s.n.* = *Ancistrocactus uncinatus* (Galeotti) Benson var. *wrightii* (Engelm.) L. Benson.

Echinocactus unquispinus Engelm. in Wisliz., Mem. Tour. No. Mex. 12. 1848. LECTOTYPE: Pelayo, Mexico, *s.d.*, *A. Wislizenus s.n.* = *Echinomastus unquispinus* (Engelm.) Britt. & Rose.

Echinocactus viridescens Nutt. var. *cylindraceus* Engelm., Amer. J. Sci. II. 14: 338. 1852. HOLOTYPE: San Felipe, California, 1850, *C. C. Parry s.n.* = *Ferocactus acanthodes* (Lemaire) Britt. & Rose.

Echinocactus whipplei Engelm. & Bigelow in Engelm., Proc. Amer. Acad. Arts 3: 271. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 28. 1857. HOLOTYPE: Colorado Chiquito, Arizona, 1853, *J. M. Bigelow s.n.* = *Sclero-*

cactus whipplei (Engelm. & Bigelow) Britt. & Rose.

Echinocactus whipplei Engelm. var. *spinosior* Engelm., Trans. Acad. Sci. St. Louis 2: 199. 1863. LECTOTYPE: Camp Floyd, Utah, 1859, *H. Engelmann s.n.* (2 sheets). = *Sclerocactus spinosior* (Engelm.) Woodruff & L. Benson.

Echinocactus wislizenii Engelm. in Wisliz., Mem. Tour. No. Mex. 96. 1848. LECTOTYPE: Doñana, Mexico, 1846, *A. Wislizenus s.n.* (3 sheets). = *Ferocactus wislizenii* Engelm.

Echinocactus wislizenii Engelm. var. *decipiens* Engelm. in Rothr., Bot. Wheeler's Surv. 128. 1878. HOLOTYPE: Camp Bowie, Arizona, 1874, *J. T. Rothrock 492.* = *Ferocactus wislizenii* Engelm.

Echinocereus adustus Engelm. in Wisliz., Mem. Tour. No. Mex. 104. 1848. HOLOTYPE: Cosihuiriachi, Mexico, 1846, *A. Wislizenus s.n.* (2 sheets).

Echinocereus chloranthus Engelm. ex Rumpler in Forster, Handb. Cact. 2nd edition: 812. 1885. SYNTYPE: Texas, 1852, *J. M. Bigelow s.n.*

Echinocereus coccineus Engelm. in Wisliz., Mem. Tour. No. Mex. 100. 1848. HOLOTYPE: Wolf Creek, Santa Fe, New Mexico, 1846, *A. Wislizenus s.n.* (2 sheets). = *E. triglochidiatus* Engelm. var. *melanacanthus* (Engelm.) L. Benson.

Echinocereus dasyacanthus Engelm. in Wisliz., Mem. Tour. No. Mex. 100. 1848. NEOTYPE: San Antonio to El Paso, Texas, 1849, *C. Wright s.n.* = *E. pectinatus* Scheidw. var. *neomexicanus* (Coult.) L. Benson.

Echinocereus enneacanthus Engelm. in Wisliz., Mem. Tour. No. Mex. 112. 1848. HOLOTYPE: south of Chihuahua, Mexico, 1847, *A. Wislizenus 244.*

Echinocereus polyacanthus Engelm. in Wisliz., Mem. Tour. No. Mex. 104. 1848. LECTOTYPE: Cosihuiriachi, Mexico, 1847, *A. Wislizenus s.n.* (2 sheets + 1 box). = *E. triglochidiatus* Engelm. var. *neomexicanus* (Standley) Benson.

Echinocereus radians Engelm. in Wisliz., Mem. Tour. No. Mex. 104. 1848. HOLOTYPE: Cosihuiriachi, Mexico, 1846, *A. Wislizenus s.n.* = *E. adustus* Engelm.

Echinocereus rufispinus Engelm. in Wisliz., Mem. Tour. No. Mex. 106. 1848. HOLOTYPE: Cosihuiriachi, Mexico, 1846, *A. Wislizenus s.n.*

Echinocereus triglochidiatus Engelm. in Wisliz., Mem. Tour. No. Mex. 93. 1848. LECTOTYPE: Wolf Creek, New Mexico, 1846, *A. Wislizenus s.n.* (2 sheets + 1 box).

Echinocereus viridiflorus Engelm. in Wisliz., Mem. Tour. No. Mex. 91. 1848. LECTOTYPE: Wolf Creek, New Mexico, 1846, *A. Wislizenus 514* (2 sheets).

Mammillaria applanata Engelm. in Wisliz., Mem. Tour. No. Mex. 105. 1848. LECTOTYPE: western Texas, 1845, *F. Lindheimer s.n.* = *M. gummifera* Engelm. var. *applanata* (Engelm.) L. Benson.

Mammillaria arizonica Engelm. in Brewer & Watson, Bot. Calif. 1: 244. 1876. LECTOTYPE: Arizona, *s.d.*, *Coues & E. Palmer s.n.* Syntype: Arizona, 1871, *Bischoff s.n.* = *Coryphantha vivipara* (Nutt.) Britt. & Rose var. *arizonica* (Engelm.) W. T. Marshall.

Mammillaria barbata Engelm. in Wisliz., Mem. Tour. No. Mex. 105. 1848. HOLOTYPE: Cosihuiriachi, Mexico, *s.d.*, *A. Wislizenus s.n.* = *Neomammillaria barbata* (Engelm.) Britt. & Rose.

Mammillaria chlorantha Engelm. in Rothr., Bot. Wheeler's Surv. 128. 1878. LECTOTYPE: St. George, Utah, 1874, *C. C. Parry s.n.* = *Coryphantha vivipara* (Nutt.) Britt. & Rose var. *desertii* (Engelm.) W. T. Marshall.

Mammillaria compacta Engelm. in Wisliz., Mem. Tour. No. Mex. 105. 1848. Cosihuiriachi, Mexico, 1846, *A. Wislizenus s.n.*

Mammillaria dasyacantha Engelm., Proc. Amer. Acad. Arts 3: 269. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 15. 1859. LECTOTYPE & PROBABLE ISOLECTOTYPE: El Paso, Texas, *C. Wright s.n.* = *Coryphantha dasyacantha* (Engelm.) Orcutt.

Mammillaria desertii Engelm. in Watson, Bot. Calif. 2: 449. 1880. LECTOTYPE: "Ivanpah," 1880, *S. B. & W. F. Parish 455* (3 sheets). = *Coryphantha vivipara* (Nutt.) Britt. & Rose var. *desertii* (Engelm.) W. T. Marshall.

Mammillaria echinus Engelm., Proc. Amer. Acad. Arts 3: 267. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 13. 1859. LECTOTYPE: western Texas, 1849, *C. Wright s.n.* (2 sheets). Syntypes: Presidio del Norte, 1852, *J. M. Bigelow s.n.* (2 sheets); western Texas, 1852, *C. Wright s.n.*; east of El Paso, Texas, *s.d.*, *C. Wright s.n.* = *Coryphantha cornifera* DC. var. *echinus* (Engelm.) L. Benson.

Mammillaria fissurata Engelm., Proc. Amer. Acad. Arts 3: 270. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 18. 1859. LECTOTYPE: Rio Bravo del Norte, Texas, 1852, *A. Schott s.n.* Syntype: Pecos, 1852, *J. M. Bigelow s.n.* = *Ariocarpus fissurata* (Engelm.) K. Schumann.

Mammillaria grahamii Engelm., Proc. Amer. Acad. Arts 3: 262. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 7. 1859. LECTOTYPE: El Paso, Texas, 1852, *C. Wright s.n.* (2 sheets). Syntypes: Colorado Basin, 1855, *A. Schott s.n.*; Gila, *C. C. Parry s.n.*

Mammillaria gummifera Engelm. in Wisliz., Mem. Tour. No. Mex. 106. 1848. LECTOTYPE: Cosihuiriachi, Mexico, 1848, *A. Wislizenus s.n.* = *M. heyderi* Muhlenpfordt var. *gummifera* (Engelm.) L. Benson.

Mammillaria hemisphaerica Engelm. in Wisliz., Mem. Tour. No. Mex. 106. 1848. LECTOTYPE: cult. in St. Louis, Missouri from Matamoras, 1846, *St. Louis Volunteers.* = *M. heyderi* Muhlenpfordt var. *hemisphaerica* Engelm.

Mammillaria lasiacantha Engelm. var. *denuta* Engelm., Proc. Amer. Acad. Arts 3: 261. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 5. 1859. LECTOTYPE: west of the Pecos, 1852, *C. Wright s.n.* = *M. lasiacantha* Engelm.

Mammillaria lasiacantha Engelm. var. *minor* Engelm., Proc. Amer. Acad. Arts 3: 261. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 5. 1859. LECTOTYPE: west of the Pecos, *s.d.*, *C. Wright s.n.* = *M. lasiacantha* Engelm.

Mammillaria macromeris Engelm. in Wisliz., Mem. Tour. No. Mex. 98. 1848. LECTOTYPE: Donana, New Mexico, 1846, *A. Wislizenus s.n.* (2 sheets). = *Coryphantha macromeris* (Engelm.) Orcutt.

Mammillaria meiacantha Engelm., Proc. Amer. Acad. Arts 3: 263. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 27. 1857. LECTOTYPE: east of the Pecos, 1853, *J. M. Bigelow s.n.* = *M. gummifera* Engelm. var. *meiacantha* (Engelm.) L. Benson.

Mammillaria micromeris Engelm., Proc. Amer. Acad. Arts 3: 260. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 3. 1859. LECTOTYPE: San Filipe to the Pecos, Texas, 1851, *C. Wright s.n.* Syntypes: western Texas, 1852, *C. Wright s.n.* (2 sheets) & 1849, *C. Wright s.n.* = *Epithelantha micromeris* (Engelm.) Weber.

Mammillaria micromeris Engelm. var. *greggii* Engelm., Proc. Amer. Acad. Arts 3: 261. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 4. 1859. LECTOTYPE: Saltillo, Mexico, 1848, *J. Gregg 508.* = *Epithelantha micromeris* L. Benson.

Mammillaria nuttallii Engelm. in Gray, Mem. Amer. Acad. Arts. II. 4: 49. 1849. LECTOTYPE & PROBABLE ISOLECTOTYPE: Ft. Pierre, South Dakota, 1847, *F. V. Hayden s.n.* = *Coryphantha missouriensis* (Sweet) Britt. & Rose.

Mammillaria papyracanthus Engelm. in Gray, Mem. Amer. Acad. Arts. II. 4: 49. 1849. LECTOTYPE: Santa Fe, New Mexico, 1857, *A. Fendler s.n.* = *Pediocactus papyracanthus* (Engelm.) L. Benson.

Mammillaria pectinata Engelm., Proc. Amer. Acad. Arts 3: 266. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 12. 1859. LECTOTYPE: on the Pecos, Texas, 1849, *C. Wright* (3 sheets). = *Coryphantha cornifera* (DC.) L. Benson.

Mammillaria phellosperma Engelm., Proc. Amer. Acad. Arts 3: 262. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 6. 1859. LECTOTYPE: Mojave Creek, 1854, *J. M. Bigelow s.n.* Syntypes: Gila, *s.d.*, *LeConti s.n.*; Bill Williams Fork, 1854, *J. M. Bigelow s.n.* = *M. tetrancistra* Engelm.

Mammillaria pusilla Sweet var. *texana* Engelm., Proc. Amer. Acad. Arts 3: 261. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 5. 1859. SYNTYPES: Eagle Pass to Santa Rosa, *s.d.*, *J. M. Bigelow s.n.*; Rio Grande, *s.d.*, *Poselger s.n.* = *M. prolifera* (Miller) Haw. var. *texana* (Engelm.) Borg.

Mammillaria radiosa Engelm. in Gray, Boston J. Nat. Hist. 6: 196. 1850. LECTOTYPE: western Texas, 1846, cult. St. Louis, Missouri, *F. Lindheimer s.n.* (2 sheets). = *Coryphantha vivipara* (Nutt.) Britt. & Rose var. *radiosa* (Engelm.) Backeberg.

Mammillaria recurvispina Engelm., Proc. Amer. Acad. Arts 3: 266. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 12. 1859. LECTOTYPE: Sierra del Pajarito, Mexico, 1855, *A. Schott s.n.* = *Coryphantha recurvata* (Engelm.) Britt. & Rose.

Mammillaria scheeri Muhlenpfordt var. *valida* Engelm., Proc. Amer. Acad. Arts 3: 265. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 10. 1859. LECTOTYPE: Limpio, Mexico, 1852, *C. Wright s.n.* Syntype: El Paso, *s.d.*, *C. Wright s.n.* (2 sheets). = *Coryphantha scheeri* Muhlenpfordt.

Mammillaria similis Engelm. & Gray. var. *caespitosa* Engelm. in Engelm. & Gray, Boston

J. Nat. Hist. 5: 246. 1845. LECTOTYPE: cultivated St. Louis, from Industry, Texas, 1846, *F. Lindheimer s.n.* (2 sheets). = *Coryphantha missouriensis* (Sweet) Britt. & Rose var. *similis* (Engelm.) L. Benson.

Mammillaria similis Engelm. & Gray var. *robustior* Engelm. in Gray, Boston J. Nat. Hist. 6: 200. 1850. LECTOTYPE: cult. St. Louis from Pierdenales River, Texas, *F. Lindheimer s.n.* = *Coryphantha missouriensis* (Sweet) Britt. & Rose var. *robustior* (Engelm.) L. Benson.

Mammillaria strobiliformis Engelm. in Wisliz., Mem. Tour. No. Mex. 115. 1848. HOLOTYPE: Rinconda, on rocks, 1847, *A. Wislizenus s.n.* = *Neolloydia conoidea* (DC.) Britt. & Rose.

Mammillaria sulcata Engelm. in Engelm. & Gray, Boston J. Nat. Hist. 5: 246. 1845. LECTOTYPE: Industry, Texas, 1844, *F. Lindheimer s.n.* = *Coryphantha sulcata* (Engelm.) Britt. & Rose.

Mammillaria tuberculosa Engelm., Proc. Amer. Acad. Arts 3: 268. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 14. 1859. LECTOTYPE: Flounce Mts., Chihuahua, Mexico, 1852, *J. M. Bigelow s.n.* (2 sheets). Syntypes: El Paso, 1851 & 1852, *C. Wright & J. M. Bigelow s.n.* (2 sheets). = *Coryphantha strobiliformis* (Poselger) Moran.

Mammillaria vivipara Haw. var. *radiosa* Engelm. subvar. *borealis* Engelm., Proc. Amer. Acad. Arts 3: 269. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 15. 1859. LECTOTYPE: Santa Fe, New Mexico, 1847, *A. Fendler 271* (2 sheets). Syntype: New Mexico, 1846, *A. Wislizenus s.n.* = *Coryphantha vivipara* (Nutt.) Britt. & Rose.

Mammillaria vivipara Haw. var. *radiosa* Engelm. subvar. *neomexicana* Engelm., Proc. Amer. Acad. Arts 3: 269. 1857 (preprint 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 15. 1859. LECTOTYPE: southern New Mexico, 1849, *C. Wright s.n.* Syntypes: San Pedro, on the Pecos, *s.d.*, *C. Wright & J. M. Bigelow s.n.* (5 sheets); Sonora, 1855?, *A. Schott s.n.* = *Coryphantha vivipara* (Nutt.) Britt. & Rose. var. *radiosa* (Engelm.) Backeberg.

Mammillaria vivipara Haw. var. *radiosa* Engelm. subvar. *texana* Engelm., Proc. Amer. Acad. Arts 3: 269. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 15. 1859. LECTOTYPE: Pierdenales, in sterile sandy plains in western Texas, cult. St. Louis, 1846, *F. Lindheimer s.n.* = *Coryphantha vivipara* (Nutt.) Britt. & Rose var. *radiosa* (Engelm.) Backeberg.

Mammillaria wrightii Engelm., Proc. Amer. Acad. Arts 3: 262. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 27. 1857. LECTOTYPE: Copper Mines, New Mexico, 1851, *C. Wright s.n.* = *M. barbata* Engelm.

Opuntia angustata Engelm. & Bigelow in Engelm., Proc. Amer. Acad. Arts 3: 292. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 39. 1857. LECTOTYPE: Bill Williams Fork, 1854, *J. M. Bigelow s.n.* Syntypes: Inscription Rock, 1853, *J. M. Bigelow s.n.*; Cajon Pass, 1854, *J. M. Bigelow s.n.* = *O. phaeacantha* Engelm. var. *major* Engelm.

Opuntia arborescens Engelm. in Wisliz., Mem. Tour. No. Mex. 90. 1848. LECTOTYPE: Santa Fe, New Mexico, 1847, *A. Fendler 277.* Syntype: no locale, *A. Wislizenus s.n.* = *O. imbricata* Haw.

Opuntia arbuscula Engelm., Proc. Amer. Acad. Arts 3: 309. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 60. 1859. LECTOTYPE: Gilia, Arizona, *s.d.*, *A. Schott s.n.*

Opuntia arenaria Engelm. & Bigelow, Proc. Amer. Acad. Arts 3: 301. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 52. 1859. LECTOTYPE: Frontera, near El Paso, Texas, 1852, *C. Wright 311.*

Opuntia basilaris Engelm. & Bigelow in Engelm., Proc. Amer. Acad. Arts 3: 298. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 43. 1857. LECTOTYPE: Cactus Pass, Bill Williams Fork, 1854, *J. M. Bigelow s.n.*

Opuntia bernardina Engelm. ex Parish, Bull. Torrey Bot. Club 19: 92. 1892. LECTOTYPE: San Bernardino, California, 1880, *G. Engelmann s.n.* = *O. parryi* Engelm.

Opuntia brachyathra Engelm. & Bigelow in Engelm., Proc. Amer. Acad. Arts 3: 302. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 47. 1857. HOLOTYPE: Zuni, New Mexico, 1853, *J. M. Bigelow s.n.* = *O. fragilis* (Nutt.) Haw. var. *brachyathra* (Engelm. & Bigelow) Coult.

Opuntia bulbispina Engelm., Proc. Amer. Acad. Arts 3: 304. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 55. 1859. HOLOTYPE: near Perros Bravos, Mexico, 1848, *J. Gregg probably 669.* Photo only, type has not been located.

Opuntia californica Engelm. in Emory, Notes Mil. Reconn. Ft. Leavenworth to San Diego, App. 2: 158. 1848. LECTOTYPE: Arizona, 1846?, *Emory? s.n.* = *O. kleiniae* Englem. var. *tetracantha* (Toumey) W. T. Marshall.

Opuntia camanchica Engelm. & Bigelow in Engelm., Proc. Amer. Acad. Arts 3: 293. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 40. 1857. LECTOTYPE: plains, Tucumcari, New Mexico, 1853, *J. M. Bigelow s.n.* = *O. phaeacantha* Engelm. var. *camanchica* (Engelm. & Bigelow) L. Benson.

Opuntia chlorotica Engelm. & Bigelow in Engelm., Proc. Amer. Acad. Arts 3: 291. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 38. 1857. LECTOTYPE: Bill Williams Mt., Arizona, 1853, *J. M. Bigelow s.n.* Syntype: Mojave Creek, 1854, *J. M. Bigelow s.n.*

Opuntia clavata Engelm. in Wisliz., Mem. Tour. No. Mex. 95. 1848. LECTOTYPE: Santa Fe, New Mexico, 1846, *A. Fendler s.n.*

Opuntia clavellina Engelm. in Coult., Contr. U.S. Natl. Herb. 3: 444. 1896. LECTOTYPE: Peninsula of California, 1867, *W. Gabb 23.*

Opuntia cymochila Engelm. & Bigelow in Engelm., Proc. Amer. Acad. Arts 3: 295. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 42. 1857. LECTOTYPE: Tucumcari Hills, New Mexico, 1853, *J. M. Bigelow s.n.* Syntype: Camanche Springs, 1853, *J. M. Bigelow s.n.* = *O. macrorhiza* Engelm.

Opuntia cymochila Engelm. & Bigelow var. *montana* Engelm. & Bigelow in Engelm., Proc. Amer. Acad. Arts 3: 296. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 42. 1857. LECTOTYPE: Sandia Mts., New Mexico, 1853, *J. M. Bigelow s.n.* = *O. macrorhiza* Engelm.

Opuntia dulcis Engelm., Proc. Amer. Acad. Arts 3: 291. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 48. 1859. LECTOTYPE: El Paso, Texas, 1852, *C. Wright s.n.* = *O. phaeacantha* Engelm.

Opuntia emoryi Engelm., Proc. Amer. Acad. Arts 3: 303. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 53. 1859. LECTOTYPE: seeds from Chihuahua, 1852, *A. Schott s.n.* = *O. stanlyi* Engelm.

Opuntia engelmannii Salm-Dyck var. *cyclodes* Engelm. & Bigelow in Engelm., Proc. Amer. Acad. Arts 3: 291. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 37. 1857. LECTOTYPE: Hunah Creek near the Pecos, 1853, *J. M. Bigelow s.n.* = *O. phaeacantha* Engelm. var. *major* Engelm.

Opuntia engelmannii Salm-Dyck var. *littoralis* Engelm. in Brewer & Watson, Bot. Calif. 1: 248. 1876. LECTOTYPE: Santa Barbara, California, 1874, *O. Tittmann s.n.* Syntype: Santa Cruz Island, California, 1874, *O. Tittman s.n.* = *O. littoralis* Engelm.

Opuntia erinacea Engelm. & Bigelow in Engelm., Proc. Amer. Acad. Arts 3: 301. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 47. 1857. HOLOTYPE: Mojave Creek, 1854, *J. M. Bigelow s.n.*

Opuntia filipendula Engelm., Proc. Amer. Acad. Arts 3: 294. 1857. LECTOTYPE: near San Elizario, 1852, *C. Wright s.n.* = *O. macrorhiza* Engelm. var. *pottsii* (Salm-Dyck) L. Benson.

Opuntia fragilis Haw. var. *frutescens* Engelm. in Engelm. & Gray, Boston J. Nat. Hist. 5: 245. 1845. LECTOTYPE: Colorado bottom prairie, 1844, *F. Lindheimer 244.* = *O. leptocaulis* DC.

Opuntia frutescens Engelm. in Engelm. & Gray, Boston J. Nat. Hist. 5: 245. 1845. LECTOTYPE: Colorado bottom prairie, 1844, *F. Lindheimer 244.* = *O. leptocaulis* DC.

Opuntia frutescens Engelm. var. *brevispina* Engelm., Proc. Amer. Acad. Arts 3: 309. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 53. 1857. LECTOTYPE: Texas, 1845, *F. Lindheimer s.n.* = *O. leptocaulis* DC.

Opuntia frutescens Engelm. var. *longispina* Engelm., Proc. Amer. Acad. Arts 3: 309. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 53. 1857. LECTOTYPE: Laguna, Colorado, 1853, *J. M. Bigelow s.n.* = *O. leptocaulis* DC.

Opuntia fulgida Engelm., Proc. Amer. Acad. Arts 3: 306. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 57. 1859. LECTOTYPE: western Sonora, Mexico, *s.d.*, *A. Schott 8.*

Opuntia fusco-atra Engelm., Proc. Amer. Acad. Arts 3: 297. 1856. LECTOTYPE: prairies west of Houston, Texas, 1842, *F. Lindheimer 33.*

Opuntia fusiformis Engelm. & Bigelow in Engelm., Proc. Amer. Acad. Arts 3: 297. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 43. 1857. LECTOTYPE: Deer Creek, Missouri?, 1853, *J. M. Bigelow s.n.* Syntype: Cow Creek, 1846, *A. Wislizenus 417.* = *O. macrorhiza* Engelm.

Opuntia grahamii Engelm., Proc. Amer. Acad. Arts 3: 304. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 55. 1859. LECTOTYPE: Rio Grande, near El Paso, Texas, 1851, *C. Wright s.n.* = *O. schottii* Engelm. var. *grahamii* (Engelm.) L. Benson.

Opuntia grandiflora Engelm., Proc. Amer. Acad. 3: 295. 1857 (preprint, 1856). LECTOTYPE: cultivated St. Louis, Missouri from Industry, Texas, 1847, *F. Lindheimer s.n.* = *O. macrorhiza* Engelm.

Opuntia hystricina Engelm. & Bigelow in Engelm., Proc. Amer. Acad. Arts 3: 299. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 44. 1857. LECTOTYPE: Colorado Chiquito, Arizona, 1853, *J. M. Bigelow s.n.* = *O. erinacea* Engelm. & Bigelow var. *hystricina* (Engelm. & Bigelow) L. Benson.

Opuntia lindheimeri Engelm. in Gray, Boston J. Nat. Hist. 6: 207. 1850. LECTOTYPE: New Braunfels, Texas, 1845, *F. Lindheimer s.n.*

Opuntia macrocentra Engelm., Proc. Amer. Acad. Arts 3: 292. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 49. 1859. LECTOTYPE: Rio Grande, near El Paso, Texas, 1852, *C. Wright s.n.* (2 sheets). = *O. violacea* Engelm. var. *macrocentra* (Engelm.) L. Benson.

Opuntia macrorhiza Engelm. in Gray, Boston J. Nat. Hist. 6: 206. 1850. LECTOTYPE: between the Picardinales & Guadalupe, 1847, *F. Lindheimer 1251.*

Opuntia missouriensis DC. var. *albispina* Engelm. & Bigelow in Engelm., Proc. Amer. Acad. Arts 3: 300. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 46. 1857. LECTOTYPE: Canadian River, Texas?, 1853, *J. M. Bigelow s.n.* = *O. polyacantha* Haw.

Opuntia missouriensis DC. var. *microsperma* Engelm., Proc. Amer. Acad. Arts 3: 300. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 46. 1857. LECTOTYPE: specimens from Ft. Pierre, South Dakota, cult. St. Louis, Missouri in 1854, no collector (2 sheets). = *O. polyacantha* Haw.

Opuntia missouriensis DC. var. *platycarpa* Engelm., Proc. Amer. Acad. Arts 3: 300. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 45. 1857. LECTOTYPE: Yellowstone River, 1854, *F. V. Hayden s.n.* = *O. polyacantha* Haw.

Opuntia missouriensis DC. var. *rufispina* Engelm. & Bigelow in Engelm., Proc. Amer. Acad. Arts 3: 300. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 45. 1857. LECTOTYPE: Pecos, New Mexico, 1853, *J. M. Bigelow s.n.* = *O. polyacantha* Haw. var. *rufispina* (Engelm. & Bigelow) L. Benson.

Opuntia missouriensis DC. var. *subinermis* Engelm., Proc. Amer. Acad. Arts 3: 300. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 46. 1857. LECTOTYPE: Ft. Pierre, South Dakota, 1853, *F. V. Hayden s.n.* = *O. polyacantha* Haw.

Opuntia missouriensis DC. var. *trichophora* Engelm. & Bigelow in Engelm., Proc. Amer. Acad. Arts 3: 300. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 46. 1857. LECTOTYPE: Santa Fe Creek, New Mexico, 1853, *J. M. Bigelow s.n.* = *O. polyacantha* Haw. var. *trichophora* (Engelm. & Bigelow) Coult.

Opuntia mojavensis Engelm., Proc. Amer. Acad. Arts 3: 293. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 40. 1857. LECTOTYPE: Mojave Creek, 1854, *J. M. Bigelow s.n.* = *O. phaeacantha* Haw. var. *mojavensis* (Engelm.) Fosberg.

Opuntia occidentalis Engelm. & Bigelow in Engelm., Proc. Amer. Acad. Arts 3: 279. 1857 (preprint, 1856); U.S. Senate Rept. Expl & Surv. R.R. Route Pacific Ocean. Botany 4: 38. 1857. LECTOTYPE: Los Angeles, California, 1852, *J. M. Bigelow s.n.* Syntype: southern California, 1855, *A. Schott s.n.* = *O. ficus-indica* (L.) Miller.

Opuntia parkeri Engelm. in Coult., Contr. U.S. Natl. Herb. 3: 446. 1896. HOLOTYPE: San Diego, California, 1879, *C. F. Parker s.n.* = *O. parryi* Engelm.

Opuntia phaeacantha Engelm. var. *brunnea* Engelm., Proc. Amer. Acad. Arts 3: 293. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 50. 1859. LECTOTYPE: Rio Grande, near El Paso, Texas, 1852, *C. Wright s.n.* = *O. phaeacantha* Engelm. var. *major* Engelm.

Opuntia phaeacantha Engelm. var. *major* Engelm., Proc. Amer. Acad. Arts 3: 293. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 50. 1857. LECTOTYPE: Santa Fe, New Mexico, 1846, *A. Fendler s.n.*

Opuntia phaeacantha Engelm. var. *nigricans* Engelm. in Gray, Mem. Amer. Acad. Arts. II. 4: 52. 1849. LECTOTYPE: Santa Fe, New Mexico, *A. Fendler 8.* = *O. phaeacantha* Engelm.

Opuntia procumbens Engelm. & Bigelow in Engelm., Proc. Amer. Acad. Arts 3: 292. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 39. 1857. LECTOTYPE: Aztec Pass, Arizona, 1853, *J. M. Bigelow s.n.* Syntypes: San Francisco Mts., Arizona, 1853, *J. M. Bigelow s.n.*; Cactus Pass, 1854, *J. M. Bigelow s.n.* = *O. phaeacantha* Engelm. var. *discata* (Griffiths) L. Benson & Walkington.

Opuntia prolifera Engelm., Amer. J. Sci. II. 14: 338. 1852. NEOTYPE: Mission Hills, San Diego, California, 1903, *Leroy Abrams 3394.*

Opuntia pulchella Engelm., Trans. Acad. Sci. St. Louis 2: 201. 1863. LECTOTYPE: Walker River, Nevada, 1859, *H. Engelmann s.n.*

Opuntia rafinesquei Engelm., Proc. Amer. Acad. Arts 3: 295. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 41. 1857. LECTOTYPE: St. Louis, Missouri, no collector. = *O. humifusa* (Raf.) Raf.

Opuntia rafinesquei Engelm. var. *arkansana* Engelm. ex Rumpler in Forster, Handb. Cact. 2nd edition: 922. 1885. LECTOTYPE: Fort Smith, 1853, *J. M. Bigelow s.n.* = *O. humifusa* (Raf.) Raf.

Opuntia rafinesquei Engelm. var. *microsperma* Engelm. & Bigelow in Engelm., Proc. Amer. Acad. Arts 3: 295. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 41. 1857. LECTOTYPE: cultivated St. Louis, Missouri, April 1854, no collector. = *O. humifusa* (Raf.) Raf.

Opuntia rafinesquei Engelm. var. *minor* Engelm., U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany. 4: 55. 1857. LECTOTYPE: naked sandstone ledges at Mine la Motte, Missouri, 1845, *G. Engelmann s.n.* = *Opuntia humifusa* (Raf.) Raf.

Opuntia ramosissima Engelm., Amer. J. Sci. II. 14: 339. 1852. NEOTYPE: Sonora, Mexico, 1855, *A. Schott 2.*

Opuntia rufida Engelm., Proc. Amer. Acad. Arts 3: 298. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 51. 1859. LECTOTYPE: Presidio del Norte, Mexico, 1852, *J. M. Bigelow s.n.*

Opuntia schottii Engelm., Proc. Amer. Acad. Arts 3: 304. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 54. 1859. LECTOTYPE: near mouth of Pecos and San Pedro, 1853, *A. Schott s.n.*

Opuntia setispina Engelm. in Salm-Dyck, Cact. Hort. Dyck. 1849: 239. 1850. LECTOTYPE & SYNTYPE: Cosihuiriachi, Mexico, 1846, *A. Wislizenus s.n.* = *O. macrorhiza* Engelm. var. *pottsii* (Salm-Dyck) L. Benson.

Opuntia sphaerocarpa Engelm. & Bigelow in Engelm., Proc. Amer. Acad. Arts 3: 300. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 47. 1857. LECTOTYPE: near Albuquerque, New Mexico, 1853, *J. M. Bigelow s.n.* = *O. polyacantha* Haw. var. *junipera* (Engelm. & Bigelow) L. Benson.

Opuntia sphaerocarpa Engelm. var. *utahensis* Engelm., Trans. Acad. Sci. St. Louis 11: 199. 1863. HOLOTYPE: Steptoe Valley, Utah, 1859, *H. Engelmann s.n.* = *O. erinacea* Engelm. & Bigelow var. *utahensis* (Engelm. & Bigelow) L. Benson.

Opuntia stenochila Engelm. & Bigelow in Engelm., Proc. Amer. Acad. Arts 3: 296. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 43. 1857. LECTOTYPE: Cañon de Zuñi, 1853, *J. M. Bigelow s.n.* = *O. macrorhiza* Engelm.

Opuntia stenopetala Engelm., Proc. Amer. Acad. Arts 3: 289. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 46. 1859. HOLOTYPE: Buena Vista, Mexico, 1848, *J. Gregg 295* (2 sheets).

Opuntia strigil Engelm., Proc. Amer. Acad. Arts 3: 290. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 47. 1859. LECTOTYPE: 6 mi. west of the Pecos, Texas, 1851, *C. Wright s.n.*

Opuntia tapona Engelm. in Coult., Contr. U.S. Natl. Herb. 3: 423. 1896. HOLOTYPE: Peninsula of California, 1867, *W. Gabb 20a.*

Opuntia tenuispina Engelm. & Bigelow in Engelm., Proc. Amer. Acad. Arts 3: 294. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 50. 1859. LECTOTYPE: below El Paso, 1852, *C. Wright 332.* = *O. macrorhiza* Engelm. var. *pottsii* (Salm-Dyck) L. Benson.

Opuntia thurberi Engelm., Proc. Amer. Acad. Arts 3: 308. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae

59. 1859. HOLOTYPE: near Bacuachi, Sonora, 1851, *G. Thurber s.n.*

Opuntia tortispina Engelm. & Bigelow in Engelm., Proc. Amer. Acad. Arts 3: 293. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 41. 1859. LECTOTYPE: Camanche Plains, 1853, *J. M. Bigelow s.n.*

Opuntia vaginata Engelm. in Wisliz., Mem. Tour. No. Mex. 100. 1848. LECTOTYPE: mountains near El Paso, 1846, *A. Wislizenus s.n.* Syntype: between Albuquerque and El Paso, 1846, *A. Wislizenus s.n.* = *O. leptocaulis* DC.

Opuntia versicolor Engelm. in Coult, Contr. U.S. Natl. Herb. 3: 452. 1896. LECTOTYPE: mesas and foothills, near Tucson, Arizona, 1881, *C. G. Pringle s.n.* Syntype: same locale, 1881, *C. G. Pringle 13712.*

Opuntia whipplei Engelm. & Bigelow in Engelm., Proc. Amer. Acad. Arts 3: 307. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 50. 1857. LECTOTYPE: Zuñi, New Mexico, 1853, *J. M. Bigelow s.n.*

Opuntia whipplei Engelm. var. *spinosior* Engelm. & Bigelow in Engelm., Proc. Amer. Acad. Arts 3: 307. 1857 (preprint, 1856); U.S. Senate Rept. Expl. & Surv. R.R. Route Pacific Ocean. Botany 4: 51. 1857. LECTOTYPE: Santa Cruz River Valley, *s.d.*, *A. Schott 5.* = *O. spinosior* (Engelm.) Toumey.

Opuntia wrightii Engelm., Proc. Amer. Acad. Arts 3: 308. 1857 (preprint, 1856); in Emory, Rept. U.S. & Mex. Bound. Surv. 2: Cactaceae 59. 1859. LECTOTYPE: Presidio del Norte, Texas, 1851–1852, *C. Wright s.n.* Syntypes: Presidio del Norte, 1852, *C. C. Parry s.n.*; mountain sides of the Limpia, 1852, *C. Wright 490.* = *O. kleiniae* DC.

CALLITRICHACEAE

Callitriche antarctica Engelm. ex Hegelm., Verh. Bot. Ver. Brandenburg 9: 20. 1867. SYNTYPE: Kerguelen's Land, 1839–1843, *J. D. Hooker s.n.*

Callitriche austinii Engelm. in Gray, Man. Bot. 5: 428. 1868. TYPE MATERIAL: New Jersey, *s.d.*, *Austin s.n.* = *C. terrestris* Raf.

Callitriche heteropoda Engelm. ex Hegelm., Verh. Bot. Ver. Brandenburg 9: 40. 1867. SYNTYPES: Bolivia, *s.d.*, *G. Mandon 1456 & 1496.*

Callitriche japonica Engelm. ex Hegelm., Verh. Bot. Ver. Brandenburg 10: 113. 1868. TYPE MATERIAL: Hakodadi, Japan, 1853–1856, *C. Whipple s.n.*

CAMPANULACEAE

Campanula planifolia Engelm. in Coult., Bot. Gaz. 7: 5. 1882. SYNTYPES: Empire, Colorado, 1881, *G. Engelmann s.n.* (6 sheets); Clear Creek, Colorado, 1881, *G. Engelmann s.n.* (2 sheets); Middle Park, Colorado, 1881, *G. Engelmann s.n.*

Campanula scabella Engelm. in Coult., Bot. Gaz. 6: 237. 1881. LECTOTYPE: Scotts Mountain, California, 1880, *G. Engelmann s.n.*

Lobelia mucronata Engelm. in Wisliz., Mem. Tour. No. Mex. 108. 1848. HOLOTYPE & ISOTYPE: Cosihuiriachi, Mexico, 1846, *A. Wislizenus 177.* = *L. fulgens* Willd.

Lobelia pectinata Engelm. in Wisliz., Mem. Tour. No. Mex. 108. 1848. HOLOTYPE & ISOTYPE: Cosihuiriachi, Mexico, 1846, *A. Wislizenus 192.* = *L. fenestralis* Car.

Lobelia phyllostachya Engelm. in Wisliz., Mem. Tour. No. Mex. 108. 1848. HOLOTYPE & ISOTYPE: between Monterey and Cerralbo, Mexico, 1847, *A. Wislizenus 337.* = *L. fulgens* Willd.

CAPPARACEAE

Wislizenia refracta Engelm. in Wisliz., Mem. Tour. No. Mex. 99. 1848. HOLOTYPE: Rio Grande, near El Paso, Texas, 1846, *C. Wright 88.*

CAPRIFOLIACEAE

Symphoricarpos spicatus Engelm. ex Gray, Boston J. Nat. Hist. 6: 215. 1850. SYNTYPE: Texas, 1849, *F. Lindheimer 846.* = *S. orbiculatus* Moench.

CARYOPHYLLACEAE

Cerastium nutans Raf. var. *brachypodum* Engelm., Proc. Amer. Acad. Arts 29: 277. 1894. SYNTYPE: banks of Chouteair's Pond, *s.d.*, *G. Engelmann s.n.*

Drymaria nodosa Engelm. in Gray, Mem. Amer. Acad. Arts. II. 4: 12. 1849. HOLOTYPE: cult. St. Louis, Missouri from Cosihuiriachi, Mexico, 1848. = *D. leptophylla* (Cham. & Schlecht.) Fenzl ex Rohrb. var. *nodosa* (Engelm.) J. Duke.

Paronychia lindheimeri Engelm. in Gray, Boston J. Nat. Hist. 6: 152. 1850. TYPE MATERIAL:

Texas, 1845 and 1846, *F. Lindheimer 335* (2 sheets).

CLUSIACEAE

Hypericum gymnanthum Engelm. & Gray, Boston J. Nat. Hist. 5: 212. 1845. TYPE MATERIAL: Texas, 1844, *F. Lindheimer 17.* = *H. multilum* L.

CONVOLVULACEAE

Cuscuta acuta Engelm., Trans. Acad. Sci. St. Louis 1: 497. 1859. HOLOTYPE: Chatham Island, Galapagos, Ecuador, 1852, *Andersson s.n.*

Cuscuta angulata Engelm., Trans. Acad. Sci. St. Louis 1: 474. 1859. LECTOTYPE: Dutuitskloff, South Africa, *Drege s.n.*

Cuscuta applanata Engelm., Trans. Acad. Sci. St. Louis 1: 479. 1859. LECTOTYPE: Arizona Territory, *s.d., C. Wright Mexican Boundary Survey 1623–541.*

Cuscuta arvensis Bayrich ex Hook. var. *pubescens* Engelm., Trans. Acad. Sci. St. Louis 1: 495. 1859. LECTOTYPE: western Texas, 1847, *F. Lindheimer s.n.* = *C. glabrior* Engelm. var. *pubescens* (Engelm.) Yuncker.

Cuscuta bracteata Engelm., Trans. Acad. Sci. St. Louis 1: 509. 1859. ISOTYPE: Goyaz, Brazil, *s.d., Gardner 3348.*

Cuscuta californica Choisy var. *apiculata* Engelm., Trans. Acad. Sci. St. Louis 1: 499. 1859. HOLOTYPE: Colorado River, California, 1854, *J. M. Bigelow s.n.*

Cuscuta californica Choisy var. *squamigera* Engelm., Trans. Acad. Sci. St. Louis 1: 499. 1859. HOLOTYPE: Rio Virgen, Utah, *s.d., Remy s.n.*

Cuscuta cephalanthi Engelm., Amer. J. Sci. 43: 336. 1842. LECTOTYPE: near St. Louis, Missouri, *s.d., G. Engelmann s.n.*

Cuscuta chinensis Lam. var. *ciliaris* Engelm., Trans. Acad. Sci. St. Louis 1: 480. 1859. LECTOTYPE: Mosul, Kurdistan, *s.d., Kotschy 431* (3 sheets).

Cuscuta corniculata Engelm. var. *sphaerocyma* Engelm., Trans. Acad. Sci. St. Louis 1: 504. 1859. LECTOTYPE: Goyaz Province, *s.d.*, Brazil, *Weddell s.n.* Syntype: Rio Meta, *s.d., Karsten s.n.*

Cuscuta coryli Engelm., Amer. J. Sci. 43: 337. 1842. LECTOTYPE: American Bottom, St. Louis, Missouri, 1841, *G. Engelmann s.n.*

Cuscuta corymbosa Choisy var. *grandiflora* Engelm., Trans. Acad. Sci. St. Louis 1: 483. 1859. LECTOTYPE: Popayán, Columbia, *s.d., Humboldt s.n.*

Cuscuta corymbosa Choisy var. *stylosa* Engelm., Trans. Acad. Sci. St. Louis 1: 484. 1859. ISOLECTOTYPE: Mexico, 1846, *Berlandier 822.*

Cuscuta cristata Engelm., Trans. Acad. Sci. St. Louis 1: 507. 1859. ISOTYPE: Argentina, *s.d., Tweedy 1191.*

Cuscuta cuspidata Engelm. & Gray var. *pratensis* Engelm. in Engelm. & Gray, Boston J. Nat. Hist. 5: 224. 1845. LECTOTYPE: west of the Brazos, Texas, 1843, *F. Lindheimer 125.*

Cuscuta decora Choisy ex Engelm. var. *integriuscula* Engelm., Trans. Acad. Sci. St. Louis 1: 502. 1859. HOLOTYPE: Mendoza, Argentina, *Gilles s.n.* = *C. indecora* Choisy var. *integriuscula* (Engelm.) Yuncker.

Cuscuta denticulata Engelm., Amer. Naturalist 9: 348. 1875. HOLOTYPE: St. George, Utah, *C. C. Parry 205.*

Cuscuta epithymum Murr. var. *angustata* Engelm. subvar. *angustissima* Engelm., Trans. Acad. Sci. St. Louis 1: 463. 1859. HOLOTYPE: Padua, Italy, *s.d., Visiani s.n.* = *C. epithymum* Murr. var. *angustissima* Engelm.

Cuscuta epithymum Murr. var. *kotschyi* Engelm. subvar. *scabrella* Engelm., Trans. Acad. Sci. St. Louis 1: 464. 1859. LECTOTYPE: Sicily, *s.d., Gussone s.n.* = *C. epithymum* Murr. var. *scabrella* (Engelm.) Yuncker.

Cuscuta epithymum Murr. var. *obtusata* Engelm. subvar. *apoda* Engelm., Trans. Acad. Sci. St. Louis 1: 462. 1859. HOLOTYPE: Koniah, Asia Minor, 1845, *Heldreich s.n.* = *C. obtusata* (Engelm.) Traub.

Cuscuta epithymum Murr. var. *obtusata* Engelm., subvar. *macropoda* Engelm., Trans. Acad. Sci. St. Louis 1: 462. 1859. HOLOTYPE: Sierra Nevada, Spain, *s.d., Funk s.n.* = *C. triumvirati* Lange.

Cuscuta epithymum Murr. var. *sagittanthera* Engelm., Trans. Acad. Sci. St. Louis 1: 462. 1859. HOLOTYPE: Tunis, *s.d., Kralik s.n.*

Cuscuta exaltata Engelm., Trans. Acad. Sci. St. Louis 1: 513. 1859. LECTOTYPE: New Braunfels, Texas, *s.d., F. Lindheimer 472* (3 sheets).

Cuscuta globiflora Engelm., Trans. Acad. Sci. St. Louis 1: 520. 1859. ISOTYPE: Cuzo, Brazil, *s.d., Pentland s.n.*

Cuscuta gracillima Engelm., Trans. Acad. Sci. St. Louis 1: 488. 1859. ISOLECTOTYPE: Mexico, *s.d., Mornay s.n.*

Cuscuta gracillima Engelm. var. *saccharata* Engelm., Trans. Acad. Sci. St. Louis 1: 489. 1859. ISOLECTOTYPE: Oaxaca, Mexico, *s.d.*, *Liebman s.n.* = *C. saccharata* (Engelm.) Yuncker.

Cuscuta gronovii Willd. var. *calyptrata* Engelm., Trans. Acad. Sci. St. Louis 1: 508. 1859. LECTOTYPE: western Louisiana, *s.d.*, *J. Gregg s.n.*

Cuscuta gronovii Willd. var. *curta* Engelm., Trans. Acad. Sci. St. Louis 1: 508. 1859. ISOLECTOTYPE: northwest America, *s.d.*, *Douglas s.n.* = *C. curta* (Engelm.) Rydb.

Cuscuta japonica Choisy var. *fissistyla* Engelm., Trans. Acad. Sci. St. Louis 1: 517. 1859. HOLOTYPE: Hong Kong, China, *s.d.*, *Wright 486.*

Cuscuta japonica Choisy var. *paniculata* Engelm., Trans. Acad. Sci. St. Louis 1: 517. 1859. LECTOTYPE: Pekin (sic), China, *s.d.*, *Kirilow s.n.*

Cuscuta japonica Choisy var. *thyrsoidea* Engelm., Trans. Acad. Sci. St. Louis 1: 517. 1859. ISOTYPE: Japan, *s.d.*, *Zollinger 355.*

Cuscuta kurdica Engelm., Trans. Acad. Sci. St. Louis 1: 470. 1859. HOLOTYPE?: Gara Mts., Kurdistan, *Kotschy 388b.*

Cuscuta lehmanniana Bunge var. *esquamata* Engelm., Trans. Acad. Sci. St. Louis 1: 515. 1859. HOLOTYPE: Mont Sipyle, Persia, *s.d.*, *Balansa 411.*

Cuscuta leptantha Engelm., Trans. Acad. Sci. St. Louis 1: 489. 1859. LECTOTYPE: western Texas to El Paso, Texas, 1849, *C. Wright 522.*

Cuscuta lupuliformis Krock var. *asiatica* Engelm., Trans. Acad. Sci. St. Louis 1: 516. 1859. LECTOTYPE: Volga River, Russia, *s.d.*, *Fischer s.n.*

Cuscuta micrantha Choisy var. *latiflora* Engelm., Trans. Acad. Sci. St. Louis 1: 501. 1859. LECTOTYPE: Concon, Chile, *s.d.*, *Poeppig 89.* Syntype: 1827, *Poeppig 159.*

Cuscuta mitraeformis Engelm. in Hemsley, Diag. Pl. Nov. 54. 1880. HOLOTYPE: San Luis Potosí to Tampico, Mexico, 1878–1879, *E. Palmer s.n.*

Cuscuta neuropetala Engelm., Amer. J. Sci. 45: 75. 1843. LECTOTYPE: near Houston, Texas, 1843, *F. Lindheimer 124.* = *C. indecora* Choisy var. *neuropetala* (Engelm.) Hitchcock.

Cuscuta obtusiflora H.B.K. var. *australis* Engelm., Trans. Acad. Sci. St. Louis 1: 492. 1859. LECTOTYPE: New Holland, Australia, *s.d.*, *R. Brown s.n.* = *C. australis* R. Br.

Cuscuta obtusiflora H.B.K. var. *cesatiana* Engelm., Trans. Acad. Sci. St. Louis 1: 493. 1859. LECTOTYPE: Vercelli, Italy, *s.d.*, *Cesati 83?.* = *C. australis* R. Br. var. *cesatiana* (Bertoloni) Yuncker.

Cuscuta obtusiflora H.B.K. var. *cordofana* Engelm., Trans. Acad. Sci. St. Louis 1: 493. 1859. HOLOTYPE: Kordofan, Africa, 1844, *Figari s.n.* = *C. cordofana* (Engelm.) Yuncker.

Cuscuta obtusiflora H.B.K. var. *glandulosa* Engelm., Trans. Acad. Sci. St. Louis 1: 492. 1859. LECTOTYPE: Columbus, Georgia, 1838, *Boykin s.n.*

Cuscuta obtusiflora H.B.K. var. *vera* Engelm., Trans. Acad. Sci. St. Louis 1: 493. 1859. LECTOTYPE: Andes, Peru, *s.d.*, *Humboldt s.n.* = *C. obtusiflora* H.B.K.

Cuscuta odontolepis Engelm., Trans. Acad. Sci. St. Louis 1: 486. 1859. HOLOTYPE: Arizona, 1851–1852, C. Wright 1642.

Cuscuta parviflora Engelm., Trans. Acad. Sci. St. Louis 1: 506. 1859. LECTOTYPE: Minas Geraes, Brazil, *s.d.*, *Ackerman s.n.* Syntype: Villa Rica, Brazil, *s.d.*, *Pohl 5726.*

Cuscuta parviflora Engelm. var. *elongata* Engelm., Trans. Acad. Sci. St. Louis 1: 506. 1859. HOLOTYPE: Goyaz, Brazil, *s.d.*, *Weddell 2125.*

Cuscuta pentagona Engelm., Amer. J. Sci. 43: 340. 1842. HOLOTYPE: Norfolk, Virginia, 1841, *Rugel s.n.*

Cuscuta pentagona Engelm. var. *calycina* Engelm., Amer. J. Sci. 45: 76. 1845. SYNTYPE: Texas, *F. Lindheimer 126.* = *C. campestris* Yuncker.

Cuscuta planiflora Tenore var. *tenorii* Engelm., Trans. Acad. Sci. St. Louis 1: 466. 1859. LECTOTYPE: Naples, Italy, *s.d.*, *Tenore s.n.* = *C. planiflora* Tenore.

Cuscuta planiflora Tenore var. *papillosa* Engelm., Trans. Acad. Sci. St. Louis 1: 467. 1859. LECTOTYPE: Djebel Zaghouan, Tunis, 1854, *Kralik 410a.*

Cuscuta polygonorum Engelm., Amer. J. Sci. 43: 342. LECTOTYPE: west of St. Louis, Missouri, *s.d.*, *G. Engelmann s.n.* Syntype: west of St. Louis, Missouri, *F. Lindheimer s.n.*

Cuscuta racemosa Mart. var. *brasiliana* Engelm., Trans. Acad. Sci. St. Louis 1: 505. 1859. SYNTYPE: Rio de Janeiro, Brazil, 1817, *Martius s.n.*

Cuscuta racemosa Mart. var. *miniata* Engelm., Trans. Acad. Sci. St. Louis 1: 505. 1859. SYNTYPE: Brazil, 1857, *Martius 1292.*

Cuscuta racemosa Mart. var. *nuda* Engelm., Trans.

Acad. Sci. St. Louis 1: 505. 1859. SYNTYPE: near Rio, Brazil, *s.d.*, *Sellow s.n.*

Cuscuta reflexa Roxb. var. *brachystigma* Engelm., Trans. Acad. Sci. St. Louis 1: 519. 1859. LECTOTYPE: Calcutta, India, *s.d.*, *Gaudichaud 129.* = *C. reflexa* Wallich var. *anguina* (Edgeworth) Yuncker.

Cuscuta saururi Engelm., Amer. J. Sci. 43: 339. 1842. LECTOTYPE: St. Louis, Missouri, 1841, *C. A. Geyer s.n.* = *C. gronovii* Willd. var. *saururi* (Engelm.) MacMillan.

Cuscuta squamata Engelm., Trans. Acad. Sci. St. Louis 1: 510. 1859. LECTOTYPE: western Texas to El Paso, Texas, 1849, *C. Wright 518.*

Cuscuta stenolepis Engelm., Trans. Acad. Sci. St. Louis 1: 500. 1859. HOLOTYPE: Mare Island, San Francisco, California, 1855, *C. Wright s.n.*

Cuscuta trichostyla Engelm., Trans. Acad. Sci. St. Louis 1: 495. 1859. ISOTYPE: Parana, *s.d.*, *Tweedie s.n.* Syntype: Santatem, Brazil, *s.d.*, Spruce 854.

Cuscuta umbellata H.B.K. var. *desertorum* Engelm., Trans. Acad. Sci. St. Louis 1: 488. 1859. LECTOTYPE: Piauhy Province, Brazil, 1847, *Martius s.n.*

Cuscuta verrucosa Engelm. var. *glabrior* Engelm., Amer. J. Sci. 43: 341. 1842. LECTOTYPE: west of Houston, Texas, *s.d.*, *F. Lindheimer s.n.* Syntype: Texas, 1833, *Drummond 247.* = *C. glabrior* (Engelm.) Yuncker.

Lepidanche compositarum Engelm., Amer. J. Sci. 43: 344. 1842. LECTOTYPE: American Bottom, St. Louis, Missouri, 1841, *G. Engelmann s.n.*

CUPRESSACEAE

Juniperus occidentalis Hook. var. *monosperma* Engelm., Trans. Acad. Sci. St. Louis 3: 590. 1877. SYNTYPES: Cañon City & Manitou, Colorado, 1874, *G. Engelmann s.n.* (5 sheets).

CYPERACEAE

Cyperus refractus Engelm. in Boeckl., Linnaea 36: 369. 1870. HOLOTYPE: Merimac, *s.d.*, *N. Riel Herbarium 496.*

EPHEDRACEAE

Ephedra aspera Engelm. ex Watson, Proc. Amer. Acad. Arts 18: 157. 1883. TYPE MATERIAL: Sierra Madre, west of Saltillo, Mexico, 1880, *E. Palmer 1288.*

Ephedra pedunculata Engelm. ex Watson, Proc. Amer. Acad. Arts 18: 157. 1883. TYPE MATERIAL: Nvalde, west of San Antonio, Texas, 1880, *E. Palmer 1291.*

EQUISETACEAE

Equisetum laevigatum A. Braun var. *elatum* Engelm. in A. Braun, Amer. J. Sci. 46: 87. 1843. TYPE MATERIAL: banks of Mississippi, below Jefferson Barracks, St. Louis, Missouri, 1843, *G. Engelmann s.n.* (7 sheets).

Equisetum laevigatum A. Braun var. *scabrellum* Engelm. in A. Braun, Amer. J. Sci. 46: 87. 1843. LECTOTYPE: Jefferson Barracks, St. Louis, Missouri, 1843, *G. Engelmann s.n.*

Equisetum robustum A. Braun var. *affine* Engelm. in A. Braun, Amer. J. Sci. 46: 88. 1843. LECTOTYPE: below Jefferson Barracks, St. Louis, Missouri, 1843, *G. Engelmann s.n.* = *E. hyemale* L. var. *affine* (Engelm.) A. A. Eaton.

Equisetum robustum A. Braun var. *minus* Engelm. in A. Braun, Amer. J. Sci. 46: 88. 1843. LECTOTYPE: banks of Mississippi, below St. Louis, Missouri, 1843, *G. Engelmann s.n.* = *E. hyemale* L. var. *affine* (Engelm.) A. A. Eaton.

EUPHORBIACEAE

Aphora humilis Engelm. & Gray, Boston J. Nat. Hist. 5: 54. 1845. ISOTYPE: west of Brazos, Texas, 1844, *F. Lindheimer 306.* = *Argythamnia humilis* (Engelm. & Gray) Muell.-Arg.

Croton corymbulosus Engelm. in Rothr., Bot. Wheeler's Surv. 242. 1878. SYNTYPES: Camp Bowie, New Mexico, 1874, *J. T. Rothrock 506*; Buena Vista, Mexico, 1848, *J. Gregg 71 & 288*; west Texas, 1849, *C. Wright 641*, and 1851–1852, *C. Wright 1805.* = *C. pottsii* (Klotzsch) Muell.-Arg.

Croton fruticulosus Engelm. in Torr., Bot. Mex. Bound. Surv. 194. 1859. SYNTYPES: Texas, 1849, *F. Lindheimer 134* (2 sheets), *176, 177, 297a.* Published as *C. fruticulosum.*

Euphorbia acuta Engelm. in Torr., Bot. Mex. Bound. Surv. 189. 1859. LECTOTYPE: "N. Mex.," 1851, *C. Wright 1839.*

Euphorbia angusta Engelm. in Torr., Bot. Mex. Bound. Surv. 189. 1859. LECTOTYPE: San Pedro River, Texas, 1851, *C. Wright 1828.*

Euphorbia arizonica Engelm. in Torr., Bot. Mex. Bound. Surv. 186. 1859. LECTOTYPE: Arizona, 1856, *A. Schott s.n.*

Euphorbia arkansas Engelm. & Gray, Boston J. Nat. Hist. 5: 261. 1845. SYNTYPES: near

Houston, Texas, 1843 and 1845, *F. Lindheimer s.n.* (2 sheets).

Euphorbia astyla Engelm. ex Boiss. in DC., Prod. 15(2): 40. 1862. HOLOTYPE: Nazas River, Mexico, 1847, *J. Gregg 457. = Chamaesyce albomarginata* (Torr. & Gray) Small.

Euphorbia barbellata Engelm. in Torr., Bot. Mex. Bound. Surv. 190. 1859. LECTOTYPE: Rio Grande, 1848, *C. Wright s.n.*

Euphorbia baueri Engelm. ex Boiss. in DC., Prod. 15(2): 27. 1862. TYPE MATERIAL: "Nov. Holland," *s.d., Bauer s.n.*

Euphorbia bicolor var. *bicolor* Engelm. & Gray, Boston J. Nat. Hist. 5: 233. 1845. SYNTYPE: west of Houston, Texas, 1841, *F. Lindheimer 174.*

Euphorbia bicolor Engelm. & Gray var. *concolor* Engelm. & Gray, Boston J. Nat. Hist. 5: 233. 1845. TYPE MATERIAL: Lynchburg, Texas, 1842, *F. Lindheimer s.n.*

Euphorbia bifurcata Engelm. in Torr., Bot. Mex. Bound. Surv. 190. 1859. HOLOTYPE OR ISOTYPE: valley of the Limpio, 1852, *J. M. Bigelow s.n.*

Euphorbia bilobata Engelm. in Torr., Bot. Mex. Bound. Surv. 190. 1859. LECTOTYPE: Santa Cruz, Sonora, Mexico, 1851–1852, *C. Wright 1831.*

Euphorbia blodgettii Engelm. ex Hitchcock, Annual Rep. Missouri Bot. Gard. 4: 126. 1893. LECTOTYPE: Key West, Florida, *s.d., Blodgett s.n. = Chamaesye blodgettii* (Engelm. ex Hitchcock) Small.

Euphorbia brachycera Engelm. in Torr., Bot. Mex. Bound. Surv. 192. 1859. HOLOTYPE: Donana, above El Paso, Texas, 1851, *C. Wright 1821.*

Euphorbia capitellata Engelm. in Torr., Bot. Mex. Bound. Surv. 188. 1859. HOLOTYPE: San Bernardino, Arizona, 1851, *C. Wright 1849.*

Euphorbia cinerascens Engelm. in Torr., Bot. Mex. Bound. Surv. 186. 1859. LECTOTYPE: Monterrey, Mexico, 1847, *J. Gregg 215.* Syntype: western Texas to El Paso, 1849. *C. Wright 559.*

Euphorbia cinerascens Engelm. var. *appendiculata* Engelm. in Torr., Bot. Mex. Bound. Surv. 186. 1859. LECTOTYPE: San Felipe, California, 1852, *G. Thurber 628. = E. melanadenia* Torr.

Euphorbia commutata Engelm. in Gray, Man. Bot. 2: 389. 1856. TYPE MATERIAL: "Gasconade," May 1835, number 35, illegible but "commutata" added to label by Engelm.

Euphorbia crenulata Engelm. in Torr., Bot. Mex. Bound. Surv. 192. 1859. TYPE MATERIAL: no locale, *s.d., Hartweg 1950.*

Euphorbia curtisii Engelm. in Chapman, Fl. S. U.S. 401. 1860. LECTOTYPE: North Carolina, *s.d., Curtiss s.n.*

Euphorbia deltoidea Engelm. in Chapman, Fl. S. U.S. 2nd edition. 647. 1883. LECTOTYPE: Florida, 1880, *Curtiss 162.*

Euphorbia dentata Michx. var. *cuphosperma* Engelm. in Torr., Bot. Mex. Bound. Surv. 190. 1859. LECTOTYPE: Copper Mines, New Mexico, 1851–1852, *C. Wright 1834.*

Euphorbia dentata Michx. var. *rigida* Engelm. in Torr., Bot. Mex. Bound. Surv. 190. 1859. LECTOTYPE: San Pedro River, New Mexico, 1851–1852, *C. Wright 1837.*

Euphorbia dictyosperma Fisch. & Mey. var. *leiococca* Engelm. in Torr., Bot. Mex. Bound. Surv. 191. 1859. LECTOTYPE: Texas, 1835, *Drummond 327.*

Euphorbia dictyosperma Fisch. & Mey. var. *mexicana* Engelm. in Torr., Bot. Mex. Bound. Surv. 191. 1859. LECTOTYPE: Balson de Mapimi, 1847, *J. Gregg 456. = E. mexicana* (Norton) Engelm.

Euphorbia dioeca H.B.K. var. *indivisa* Engelm. in Torr., Bot. Mex. Bound. Surv. 187. 1859. ISOTYPE: near the Copper Mines, New Mexico, 1851, *C. Wright 1845. = E. indivisa* (Engelm.) Tidstrom.

Euphorbia exstipulata Engelm. in Torr., Bot. Mex. Bound. Surv. 189. 1859. LECTOTYPE: Santa Fe, New Mexico, 1847, *A. Fendler 790.* Syntypes: eastern Sonora, *C. Wright 1833 & 1838.*

Euphorbia floribunda Engelm. ex Boiss. in DC., Prod. 15(2): 39. 1862. LECTOTYPE: east of Guadalahara, Mexico, 1849, *J. Gregg 856a.*

Euphorbia florida Engelm. in Torr., Bot. Mex. Bound. Surv. 189. 1859. LECTOTYPE: west of Chiricahua Mountains, Arizona, 1851, *C. Wright 1829.*

Euphorbia fruticulosa Englem. ex Boiss. in DC., Proc. 15(2): 38. 1862. ISOTYPE: Coahuila, Mexico, *s.d., J. Gregg 506.*

Euphorbia garberi Engelm. ex Chapman, Fl. S. U.S. 2nd edition. 646. 1883. LECTOTYPE: coast of Florida, *s.d., Garber s.n.*

Euphorbia geyeri Engelm. in Engelm. & Gray, Boston J. Nat. Hist. 5: 260. 1845. LECTOTYPE: Beardstown, Illinois, 1842, *C. A. Geyer s.n.*

Euphorbia glyptosperma Engelm. in Torr., Bot. Mex. Bound. Surv. 187. 1859. LECTOTYPE: Fort Kearney, Nebraska, 1856, *H. Engelmann s.n.*

Euphorbia glyptosperma Engelm. var. *tenerrima* Engelm. in Torr., Bot. Mex. Bound. Surv. 187. 1859. LECTOTYPE: Nueces River, Texas, 1851, *C. Wright 1853.* = *E. glyptosperma* Engelm.

Euphorbia grisea Engelm. ex Boiss. in DC., Prod. 15(2): 41. 1862. LECTOTYPE: Cerralro, Nuevo Leon, Mexico, 1847, *J. Gregg 837.*

Euphorbia hirtula Engelm. in Watson, Bot. Calif. 2: 74. 1880. LECTOTYPE: southern California, 1880, *E. Palmer 140.*

Euphorbia humistrata Engelm. ex Gray, Man. Bot. 2: 386. 1856. LECTOTYPE: St. Louis, Missouri, 1833, *G. Engelmann 1139.*

Euphorbia lata Engelm. in Torr., Bot. Mex. Bound. Surv. 189. 1859. LECTOTYPE: western Texas, 1851, *C. Wright 1841.* Syntype: the Cimarron to Sand Creek 1847, *A. Fendler s.n.*

Euphorbia leptocera Engelm. ex Torr., Pacif. Rail. Rep. 4: 135. 1857. TYPE MATERIAL: Grass Valley, California, *s.d., J. M. Bigelow s.n.*

Euphorbia lurida Engelm. in Ives, Rep. Colo. River Bot. 4: 26. 1861. LECTOTYPE: Bill Williams Mt., Arizona, 1858, *Newberry s.n.*

Euphorbia marginata Pursh var. *uloleuca* Engelm. & Gray, Boston J. Nat. Hist 5: 261. 1845. LECTOTYPE: prairies in the Colorado bottom, 1844, *F. Lindheimer 303.*

Euphorbia montana Engelm. var. *gracilor* Engelm. in Torr., Bot. Mex. Bound. Surv. 192. 1859. LECTOTYPE: Santa Fe Creek, New Mexico, 1847, *A. Fendler 786.*

Euphorbia multicaulis Engelm. in Torr., Bot. Mex. Bound. Surv. 191. 1859. HOLOTYPE: Las Playas, Sonora, 1851, *G. Thurber 381.*

Euphorbia palmeri Engelm. in Watson, Bot. Calif. 2: 75. 1880. LECTOTYPE: at Tally's, California, 1875, *E. Palmer s.n.*

Euphorbia parryi Engelm., Amer. Naturalist 9: 350. 1875. LECTOTYPE: St. George, Utah, 1874, *C. C. Parry 247.*

Euphorbia pediculifera Engelm. in Torr., Bot. Mex. Bound. Surv. 186. 1859. LECTOTYPE: Sonoita Creek, Arizona, 1851, *C. Wright 1848.*

Euphorbia peplidion Engelm. in Torr., Bot. Mex. Bound. Surv. 191. 1859. HOLOTYPE: San Pedro, Texas, 1851, *C. Wright 1823.*

Euphorbia petaloidea Engelm. in Torr., Bot. Mex. Bound. Surv. 185. 1859. LECTOTYPE: Platte River, Nebraska Territory, 1858, *H. Engelmann s.n.* = *E. missurica* Raf. var. *intermedia* (Engelm.) L. C. Wheeler.

Euphorbia petaloidea Engelm. var. *flagelliformis* Engelm. in Torr., Bot. Mex. Bound. Surv. 185. 1859. HOLOTYPE: near Frontera, Texas, 1851, *C. Wright 1826.* = *E. parryi* Engelm.

Euphorbia petaloidea Engelm. var. *intermedia* Engelm. in Torr., Bot. Mex. Bound. Surv. 185. 1859. LECTOTYPE: Ft. Pierre, South Dakota, 1853, *F. V. Hayden s.n.* = *E. missurica* Raf. var. *intermedia* (Engelm.) L. C. Wheeler.

Euphorbia petaloidea Engelm. var. *nicollettii* Engelm. in Torr., Bot. Mex. Bound. Surv. 185. 1859. LECTOTYPE: Powder River, Montana, 1854. *F. V. Hayden s.n.* = *E. missurica* Raf. var. *intermedia* (Engelm.) L. C. Wheeler.

Euphorbia pilulifera L. var. *discolor* Engelm. in Torr., Bot. Mex. Bound. Surv. 188. 1859. LECTOTYPE: Sonoita Creek, Arizona, 1842, *C. Wright s.n.* = *E. hirta* L.

Euphorbia platysperma Engelm. in Watson, Bot. Calif. 2: 482. 1880. LECTOTYPE: mouth of Colorado River, 1869, *E. Palmer s.n.*

Euphorbia pringlei Engelm. in Patterson, Check list 115. 1887. LECTOTYPE: Canyon of Santa Rita, Arizona, 1881. *C. G. Pringle 138.*

Euphorbia pycnanthema Engelm. in Torr., Bot. Mex. Bound. Surv. 188. 1859. HOLOTYPE: Lake Santa Maria, Chihuahua, Mexico, 1852, *C. Wright 186.* = *E. capitellata* Engelm.

Euphorbia revoluta Engelm. in Torr., Bot. Mex. Bound. Surv. 186. 1859. LECTOTYPE: between Santa Fe and Moro River, New Mexico, 1847, *A. Fendler 789.*

Euphorbia schizoloba Engelm. in Ives, Rep. Colorado River Bot. 4: 27. 1861. HOLOTYPE: western Arizona, 1858, *Newberry s.n.*

Euphorbia serrula Engelm. in Torr., Bot. Mex. Bound. Surv. 188. 1859. LECTOTYPE: Guadalupe Pass, Sonora, Mexico, 1851, *C. Wright 1843.*

Euphorbia setiloba Engelm. in Torr., Pacif. Rail. Rep. 5: 364. 1857. ISOTYPE: Fort Yuma, California, *G. H. Thomas s.n.*

Euphorbia stictospora Engelm. in Torr., Bot. Mex. Bound. Surv. 187. 1859. LECTOTYPE: Pawnee River, Kansas, 1847, *A. Fendler 798.*

Euphorbia subpubens Engelm. in Watson, Bot. Calif. 2: 76. 1880. ISOTYPE & FRAGMENT OF HOLOTYPE FROM GH: Prescott, Arizona, 1876, *E. Palmer 512.*

Euphorbia tetrapora Engelm. in Torr., Bot. Mex. Bound. Surv. 191. 1859. SYNTYPE: west of Brazos, Texas, 1839, *F. Lindheimer s.n.*

Euphorbia tomentella Engelm. ex Boiss. in DC., Prod. 15(2): 32. 1862. LECTOTYPE: San Luis Potosi, Mexico, 1827, *Berlandier 1358.*

Euphorbia trachysperma Engelm. in Torr., Bot. Mex. Bound. Surv. 189. 1859. HOLOTYPE: San Pedro River, Arizona, 1851, *C. Wright 1832.*

Euphorbia umbellata Engelm. ex Boiss. in DC., Prod. 15(2): 127. 1862. LECTOTYPE: Guadalahara, Mexico, 1849, *J. Gregg 856.*

Euphorbia villifera Scheele var. *nuda* Engelm. ex Boiss. in DC., Prod. 15(2): 45. 1862. LECTOTYPE: New Braunfels, Texas, 1850, *C. Wright s.n.*

Euphorbia xantii Engelm. ex Boiss. in DC., Prod. 15(2): 62. 1862. LECTOTYPE: Cape St. Lucas, California, 1859–1860, *L. T. Xantus s.n.*

Jatropha macrorhiza Benth. var. *septemfida* Engelm. in Rothr., Bot. Wheeler's Surv. 244. 1878. SYNTYPE: Sulphur Springs, Arizona, 1874, *J. T. Rothrock 546.*

Pilinophytum lindheimeri Engelm. & Gray, Boston J. Nat. Hist. 5: 232. 1845. SYNTYPE: Texas, 1843, *F. Lindheimer 171.*

Stillingia angustifolia Engelm. ex Watson, Proc. Amer. Acad. Arts 18: 154. 1883. HOLOTYPE: Comfort, Texas, 1879, *E. Palmer 1256.* = *S. texana* I. M. Johnston.

Tetracoccus dioicus Engelm. ex Parry, West Am. Sci. 1: 13. 1885. PARATYPE: Table Mountain, Northern Lower California, 1883, *C. C. Parry & H. C. Orcutt 313.*

Tragia brevispica Engelm. & Gray, Boston J. Nat. Hist. 5: 226. 1845. SYNTYPE: Texas, 1848, *F. Lindheimer 307.*

FABACEAE

Amorpha canescens Nutt. var. *leptostachya* Engelm. in Gray, Mem. Amer. Acad. Arts. II. 4: 31. 1849. HOLOTYPE?: in woods between San Miguel and Vegas, 1847, *A. Fendler 125.*

Amorpha incana Engelm., apparently not published. HOLOTYPE?: Texas, 1842, *F. Lindheimer 153,* annotated "n. sp." by Engelm.

Astragalus lindheimeri Engelm. in Gray, Pl. Wrightiana 1: 52. 1852. LECTOTYPE: Texas, *s.d., F. Lindheimer 746.*

Baptisia sulphurea Engelm. Bot. Gaz. 3: 65. 1878. HOLOTYPE: Oklahoma, 1877, *Butler s.n.* (2 sheets). = *B. lactea* (Raf.) Thieret × *B. sphaerocarpa* Nutt.

Calliandra chamaedrys Engelm. ex Gray, Mem. Amer. Acad. Arts. II. 4: 39. 1849. SYNTYPES: Chihuahua, Mexico, 1847, *J. Gregg 529, A. Wislizenus 251.*

Calliandra herbacea Engelm. ex Gray, Mem. Amer. Acad. Arts. II. 4: 39. 1849. LECTOTYPE: New Mexico, *s.d., A. Fendler 180.*

Cercis reniformis Engelm. ex Gray, Boston J. Nat. Hist. 6: 177. 1850. LECTOTYPE: Guadalupe, Texas, 1845, *F. Lindheimer 366.* = *C. occidentalis* Torr.

Desmodium wislizenii Engelm. ex Gray, Pl. Wrightiana 1: 53. 1852. HOLOTYPE: Cosihuiriachi, Mexico, 1846, *A. Wislizenus 183.* = *D. retinens* Schlecht.

Eysenhardtia spinosa Engelm. ex Gray, Boston J. Nat. Hist. 6: 174. 1850. ISOTYPE: Chihuahua, Mexico, 1846, *A. Wislizenus 133.*

Lespedeza leptostachya Engelm. in Gray, Proc. Amer. Acad. Arts 12: 57. 1877. LECTOTYPE: Iowa, 1871, *C. E. Bessey s.n.*

FAGACEAE

Quercus chrysolepis Liebm. var. *palmeri* Engelm., Trans. Acad. Sci. St. Louis 3: 393. 1877. HOLOTYPE: 80 mi. E of San Diego, California, 1875, *E. Palmer 30.* = *Q. palmeri* Engelm.

Quercus dumosa Nutt. var. *bullata* Engelm., Trans. Acad. Sci. St. Louis 3: 393. 1877. SYNTYPES: Santa Lucia Mts., California, *s.d., Brewer 473*; New Idria, California, *s.d., Brewer 776*; Pope Valley, California, 1863, *H. Bolander s.n.* = *Q. durata* Jeps.

Quercus falcata Michx. var. *subintegra* Engelm., Trans. Acad. Sci. St. Louis 3: 543. 1877. LECTOTYPE: South Carolina, 1875, *Mellichamp s.n.* = *Q. subintegra* Trel.

Quercus hypoleuca Engelm., Trans. Acad. Sci. St. Louis 3: 384. 1876. LECTOTYPE: Copper Mines, and Arizona, 1851–1852, *C. Wright 1869.*

Quercus lobata Nee var. *fruticosa* Engelm., Trans. Acad. Sci. St. Louis 3: 389. 1877. SYNTYPES: west of Shasta, California, 1862, *H. Brewer 1336*; near Tuolumne River, California, *Lemmon s.n.* = *Q. oerstediana* R. Br.

Quercus muehlenbergii Engelm., Trans. Acad. Sci. St. Louis 3: 391. 1877. TYPE MATERIAL: St. Louis, Missouri, Sept. 1838, *G. Engelmann s.n.* Annotated *Q. muhlenbergii* by Engelmann, but no annotation date. The only prepublication dated specimen.

Quercus tomentella Engelm., Trans. Acad. Sci. St. Louis 3: 393. 1877. HOLOTYPE: Guadalupe Island, California, *E. Palmer 89.*

Quercus undulata Torr. var. *jamesii* Engelm., Trans. Acad. Sci. St.Louis 3: 382. 1876. TYPE MATERIAL: fragment of "original species ex Hb Torrey," Rocky Mountains, *s.d., James s.n.*

FOUQUIERIACEAE

Fouquieria splendens Engelm. in Wisliz., Mem. Tour. No. Mex. 98. 1848. LECTOTYPE: south of Chihuahua, Mexico, 1847, *A. Wislizenus 261.*

FUMARIACEAE

Corydalis curvisiliqua Engelm. ex Gray., Pl. Wrightiana 2: 10. 1853. TYPE MATERIAL: Texas, Apr. 1848, *F. Lindheimer s.n.*; May 1851, *F. Lindheimer s.n.*

GENTIANACEAE

Erythraea nudicaulis Engelm. in Gray, Proc. Amer. Acad. Arts. 17: 222. 1882. HOLOTYPE: base of Santa Catalina Mountains, Arizona, *C. G. Pringle s.n.*

Geniostemon coulteri Engelm. & Gray, Proc. Amer. Acad. Arts 16: 104. 1881. TYPE MATERIAL: Mexico, *s.d.*, *Coulter, s.n.*, appears to be fragment of holotype from Gray's herbarium.

Geniostemon schafferi Engelm. & Gray, Proc. Amer. Acad. Arts 16: 104. 1881. TYPE MATERIAL: San Luis Potosí, Mexico, 1879, *Schaffer 80.*

Gentiana acuta Michx. var. *nana* Engelm., Trans. Acad. Sci. St. Louis 2: 214. 1862. HOLOTYPE: Colorado Territory, 1861, *C. C. Parry 309.* = *Gentianella amarella* (L.) Borner subsp. *acuta* (Michx.) J. M. Gillett.

Gentiana barbellata Engelm., Trans. Acad. Sci. St. Louis 2: 216. 1862. HOLOTYPE: Snowy Range, Colorado, 1862, *C. C. Parry s.n.* = *Gentianella barbellata* (Engelm.) J. M. Gillett.

Gentiana heterosepala Engelm., Trans. Acad. Sci. St. Louis 2: 215. 1862. HOLOTYPE: Uintah Mts., Utah, 1859, *H. Engelmann s.n.* = *Gentianella amarella* (L.) Borner.

Gentiana oregana Engelm. in Gray, Syn. Fl. N. Am. II. 1: 122. 1884. LECTOTYPE: Blue Mts., Oregon, 1874, *R. D. Nevius s.n.*

Gentiana parryi Engelm., Trans. Acad. Sci. St. Louis 2: 218. 1863. LECTOTYPE: Colorado Territory, 1861, *C. C. Parry 304.* Syntype: "Rocky Mountain Flora," 1862, *E. Hall & J. P. Harbour 470.*

Gentiana prostrata Haenke var. *americana* Engelm., Trans. Acad. Sci. St. Louis 2: 217. 1863. SYNTYPES: Rocky Mountains, 1862, *E. Hall & J. P. Harbour 475*; Snowy Range, *s.d.*, *C. C. Parry 306.*

Gentiana wislizenii Engelm., Trans. Acad. Sci. St. Louis 2: 215. 1863. HOLOTYPE: Llanos, Chihuahua, Mexico, 1846, *A. Wislizenus 206.* = *Gentianella wislizenii* (Engelm.) J. M. Gillett.

GERANIACEAE

Geranium fremontii Torr. ex Gray var. *parryi* Engelm. in Gray, Amer. J. Sci. II. 33: 405. 1862. LECTOTYPE: Clear Creek, Colorado, 1861, *C. C. Parry 113?*

Geranium gracile Engelm. in Gray, Mem. Amer. Acad. Arts. II. 4: 27. 1849. HOLOTYPE: Cosihuiriachi, Mexico, 1846, *A. Wislizenus 173* (2 sheets). = *G. atropurpureum* Heller.

Geranium pentagynum Engelm. in Wisliz., Mem. Tour. No. Mex. 90. 1848. HOLOTYPE: Wolf Creek, New Mexico, 1846, *A. Wislizenus 508* (2 sheets). = *G. richardsonii* Fisch. & Trautv.

HYDROPHYLLACEAE

Eutoca patuliflora Engelm. & Gray. Boston J. Nat. Hist. 5: 253. 1845. ISOTYPE: Texas, *s.d.*, *F. Lindheimer 280.* = *Phacelia patuliflora* (Engelm. & Gray) Gray.

Eutoca strictiflora Engelm. & Gray, Boston J. Nat. Hist. 5: 253. 1845. ISOTYPE: Texas, *s.d.*, *F. Lindheimer 279* (2 sheets). = *Phacelia strictiflora* (Engelm. & Gray) Gray.

ISOETACEAE

Isoetes bolanderi Engelm., Amer. Naturalist 8: 214. 1874. LECTOTYPE: Tuolumne River, California, 1866, *H. Bolander 5091.* Syntypes: Mary's Lake, California, 1870, *H. Bolander 5080*; Mono Trail, California, 1870, *H. Bolander 5093.*

Isoetes butleri Engelm. var. *immaculata* Engelm., Trans. Acad. Sci. St. Louis 4: 388. 1882. HOLOTYPE: near Nashville, Tennessee, 1880, *A. Gattinger 3812.* = *I. butleri* Engelm.

Isoetes cubana Engelm., Trans. Acad. Sci. St. Louis 4: 389.1882. HOLOTYPE: eastern Cuba, 1860, *C. Wright s.n.*

Isoetes echinospora Durieu var. *robusta* Engelm., Trans. Acad. Sci. St. Louis 4: 380. 1882. HOLOTYPE: Lake Champlain, New York?, 1879, *C. G. Pringle s.n.*

Isoetes engelmannii A. Braun var. *georgiana* Engelm., Trans. Acad. Sci. St. Louis 4: 385. 1882. HOLOTYPE: Georgia, 1873, *A. W. Chapman s.n.* = *I. engelmannii* A. Braun.

Isoetes flaccida Shuttlew. ex A. Braun var. *chap-*

manii Engelm., Trans. Acad. Sci. St. Louis 4: 386. 1882. HOLOTYPE: near Mariana, Florida, 1850, *Chapman s.n.* = *I. flaccida* Shuttlew.

Isoetes flaccida Shuttlew. ex A. Braun var. *rigida* Engelm., Trans. Acad. Sci. St. Louis 4: 386. 1882. HOLOTYPE: Lake Flint, Florida, 1878, *A. Garber s.n.* = *I. flaccida* Shuttlew.

Isoetes howellii Engelm., Trans. Acad. Sci. St. Louis 4: 385. 1882. HOLOTYPE: The Dalles, Oregon, *J. & T. J. Howell 1880.*

Isoetes lacustris L. var. *paupercula* Engelm., Trans. Acad. Sci. St. Louis 4: 377. 1882. LECTOTYPE: Middle Park, Colorado, 1881, *G. Engelmann s.n.* = *I. occidentalis* Hend.

Isoetes melanospora Engelm., Trans. Acad. Sci. St. Louis 3: 395. 1877.HOLOTYPE: Stone Mt., Georgia, 1869, *Canby s.n.* (2 sheets).

Isoetes nuda Engelm., Trans. Acad. Sci. St. Louis 4: 385. 1882. HOLOTYPE: The Dalles, Oregon, 1882, *T. Howell 26.* = *I. howellii* Engelm.

Isoetes pygmaea Engelm., Amer. Naturalist 8: 214. 1874. HOLOTYPE: Mono Pass, California, 1866, *H. Bolander 6025* (2 sheets). = *I. bolanderi* Engelm. var. *pygmaea* (Engelm.) Clute.

Isoetes riparia Engelm. in A. Braun, Flora (Regensb. Bot. Zeit.) 29: 178. 1846. HOLOTYPE: Philadelphia, Pennsylvania, 1844, *Zantziger s.n.*

Isoetes riparia Engelm. var. *canadensis* Engelm., Trans. Acad. Sci. St. Louis 4: 383. 1884. TYPE MATERIAL: Crow River, Canada, *s.d.*, *J. Macoun s.n.*

Isoetes saccharata Engelm. in Gray, Man. Bot. 5: 676. 1868. HOLOTYPE?: Salisbury, Maryland, 1866, *Canby s.n.*

JUGLANDACEAE

Juglans rupestris Engelm. in Torr., Bot. Sitgr. Rep. 171. 1853. TYPE MATERIAL: Texas, 1849, *F. Lindheimer 20 (1178)*.

JUNCACEAE

Juncus asper Engelm., Trans. Acad. Sci. St. Louis 2: 478. 1868. SYNTYPES: Quaker Bridge, New Jersey, 1864, 1865, 1866, *Smith s.n.*, 1866, 1867; *C. F. Parker s.n.* (2 sheets).

Juncus balticus Willd. var. *littoralis* Engelm., Trans. Acad. Sci. St. Louis 2: 442. LECTOTYPE & ISOLECTOTYPE: Ipswich, 1842, *Oakes s.n.* = *J. arcticus* Willd. subsp. *littoralis* Engelm.

Juncus balticus Willd. var. *montanus* Engelm., Trans. Acad. Sci. St. Louis 2: 442. LECTOTYPE & ISOLECTOTYPE: Rocky Mountains, 1862, *E. Hall & Harbour 567.* = *J. arcticus* Willd. subsp. *ater* (Rydb.) Hult.

Juncus bolanderi Engelm., Trans. Acad. Sci. St. Louis 2: 470. 1868. HOLOTYPE: Mission Dolore, California, 1865, *H. Bolander s.n.*

Juncus brachycarpus Engelm., Trans. Acad. Sci. St. Louis 2: 467. 1868. SYNTYPES: Charleston, South Carolina, *Beyrich s.n.*; Louisiana, no date, *J. Hale s.n.*; Detroit, Michigan, July 1867, *J. M. Bigelow s.n.*; Michigan, no date, *Folwell s.n.*

Juncus breweri Engelm., Trans. Acad. Sci. St. Louis 2: 440. 1866. HOLOTYPE: Monterey, California, May 1866, *W. H. Brewer 651.* Isotype: Monterey, California, May 1861, *W. H. Brewer 651.* = *J. arcticus* Willd. subsp. *mexicanus* (Willd.) Lint × subsp. *pacificus* (Engelm.) Lint.

Juncus canaliculatus Engelm., Bot. Gaz. 7: 6. 1882. HOLOTYPE: San Bernardino, California, 1881, *S. B. & W. F. Parish 1091.* = *J. macrophyllus* Coville.

Juncus chlorocephalus Engelm., Trans. Acad. Sci. St. Louis 2: 485. 1868. SYNTYPES: Sierras, California, 1866, *Hillebrand 2338* (2 sheets); *W. H. Brewer 1804* (2 sheets); *H. Bolander Cal. St. Surv. 6033.*

Juncus drummondii E. Mey. var. *humilus* Engelm., Trans. Acad. Sci. St. Louis 2: 445. 1868. HOLOTYPE: Mt. Shasta, California, 1862, *Brewer 1383.*

Juncus dubius Engelm., Trans. Acad. Sci. St. Louis 2: 459. 1868. SYNTYPE: Mariposa, California, *s.d.*, *H. Bolander Cal. St. Surv. 6032.*

Juncus hallii Engelm., Trans. Acad. Sci. St. Louis 2: 446. 1868. HOLOTYPE: Lake Ranch, Colorado, 1862, *E. Hall & J. P. Harbour 562.*

Juncus kelloggii Engelm., Trans. Acad. Sci. St. Louis 2: 494. 1868. HOLOTYPE: San Francisco, California, 1866, *A. Kellogg s.n.*

Juncus mertensianus Bong. var. *paniculatus* Engelm., Trans. Acad. Sci. St. Louis 2: 480. 1868. ISOTYPE: Rocky Mts., 1858, *Bourgeau s.n.*

Juncus obtusatus Engelm., Trans. Acad. Sci. St. Louis 2: 495. 1868. HOLOTYPE: Big Tree Grove, Mariposa, California, 1866, *H. Bolander Cal. St. Surv. 6028.*

Juncus oxymeris Engelm., Trans. Acad. Sci. St. Louis 2: 483. 1868. SYNTYPES: Big Tree Grove, Mariposa, California, 1866, *H. Bolander 95* (4 sheets).

Juncus parryi Engelm., Trans. Acad. Sci. St. Louis 2: 446. 1866. HOLOTYPE: Colorado, 1861, *C. C. Parry 360.*

Juncus phaeocephalus Engelm. var. *glomeratus*

Engelm., Trans. Acad. Sci. St. Louis 2: 484. 1868. SYNTYPES: San Francisco, California, 1866, *A. Kellogg 96* (6 sheets).

Juncus phaeocephalus Engelm. var. *gracilis* Engelm., Trans. Acad. Sci. St. Louis 2: 473. 1868. SYNTYPES: Sierra Nevadas, California, 1865, *H. Bolander Cal. St. Surv. 2339* (2 sheets), *H. Bolander 98* (6 sheets); 1865, *Brewer 1709.* = *J. mertensianus* Bong.

Juncus phaeocephalus Engelm. var. *paniculatus* Engelm., Trans. Acad. Sci. St. Louis 2: 484. 1868. SYNTYPES: Napa Valley, California, *s.d.*, *J. M. Bigelow s.n.*; San Francisco, California, *A. Kellogg 97* (4 sheets).

Juncus rugulosis Engelm. in Coult., Bot. Gaz. 6: 224: 1881. HOLOTYPE: San Bernardino Mountains, California, 9 Nov. 1880, *W. G. Wright s.n.*

Juncus smithii Engelm., Trans. Acad. Sci. St. Louis 2: 444. 1868. HOLOTYPE: Broad Mt., Pottsville, Pennsylvania, 1865, *C. E. Smith s.n.*

Juncus supiniformis Engelm., Trans. Acad. Sci. St. Louis 2: 461. 1868. HOLOTYPE: Mendocino, California, 1866, *H. Bolander Cal. St. Surv. 4767.*

Juncus triformis Engelm., Trans. Acad. Sci. St. Louis 2: 492. 1868. LECTOTYPE: De Long's Ranch, Yosemite Valley, California, 1866, *H. Bolander 30.*

Juncus triformis Engelm. var. *brachystylus* Engelm., Trans. Acad. Sci. St. Louis 2: 492. 1868. ISOLECTOTYPE: Ukiah, California, 1866, *H. Bolander 31* (3 sheets) & *Cal. St. Surv. 8457.* Syntype: Ukiah, California, 1866, *H. Bolander s.n.*

Juncus triformis Engelm. var. *stylosus* Engelm., Trans. Acad. Sci. St. Louis 2: 492. 1868. ISOLECTOTYPE: Yosemite Valley, California, 1866, *H. Bolander 30.* = *J. triformis* Engelm.

Juncus triformis Engelm. var. *uniflorus* Engelm., Trans. Acad. Sci. St. Louis 2: 493. 1868. SYNTYPES: Sierra Nevada, California, 1866, *Hillebrand Cal. St. Surv. 2333*; Long Valley, California, 1866, *H. Bolander 32 (Cal. St. Surv. 4691)* (2 sheets). = *J. hemiendytus* F. J. Herman.

Juncus vaseyi Engelm., Trans. Acad. Sci. St. Louis 2: 448. 1868. SYNTYPES: Saskatchewan, Canada, 1852 and 1858, *E. Bourgeau s.n.*; Colorado, 1862, *E. Hall s.n.*

LAMIACEAE

Brazoria scutellarioides Engelm. & Gray, Boston J. Nat. Hist. 5: 257. 1845. PARATYPES: on paths and slopes of the prairie, in heavy soil, Texas, *F. Lindheimer 286, 287.*

Monarda lindheimeri Engelm. & Gray, Boston J. Nat. Hist. 5: 228. 1845. SYNTYPE: Houston, Texas, 1843, *F. Lindheimer 151* (2 sheets).

Scutellaria cardiophylla Engelm. & Gray, Boston J. Nat. Hist. 5: 227. 1845. ISOTYPES: Texas, 1843, *F. Lindheimer 144* (2 sheets).

LINACEAE

Linum aristatum Engelm. in Wisliz., Mem. Tour. No. Mex. 101. 1848. HOLOTYPE: near Carizal, south of El Paso, Mexico, 1846, *A. Wislizenus 101.*

Linum greggii Engelm. ex Gray, Pl. Wrightiana 26. 1852. HOLOTYPE: San Antonio near Saltillo, Mexico, 31 Aug. 1848, *J. Gregg s.n.*

Linum rigidum Pursh var. *puberulum* Engelm. ex Gray, Pl. Wrightiana 25. 1852. ISOTYPE: New Mexico, 1847, *A. Fendler 85.* = *L. puberulum* (Engelm.) Heller.

Linum rupestre Engelm. in Gray, Boston J. Nat. Hist. 6: 232. 1850. ISOTYPE: New Braunfels, Texas, 1846, *F. Lindheimer 337.*

Linum rupestre Engelm. var. *cymulosum* Engelm. in Gray, Pl. Wrightiana 26. 1852. HOLOTYPE: battlefield of Buena Vista, Mexico, 1848, *J. Gregg s.n.*

LOASACEAE

Mentzelia chrysantha Engelm. ex Brandegee, Fl. S. W. Col. 237. 1878. HOLOTYPE: Cañon City, Colorado, 1874. *G. Engelmann s.n.*

LORANTHACEAE

Arceuthobium abietinum Engelm. in Gray, Proc. Amer. Acad. Arts 8: 401. 1872. TYPE MATERIAL: Oregon, 1871, *E. Hall 457 & 458* (2 sheets each); California, 1875, *J. Muir 7654.*

Arceuthobium campylopodium Engelm. in Gray, Boston J. Nat. Hist. 6: 214. 1845. ISOTYPE: Oregon, label says Rocky Mountains, ex herb Hooker, 1843, *C. A. Geyer 577* (2 sheets).

Arceuthobium campylopodium Engelm. var. *macrarthron* Engelm. in Gray, Boston J. Nat. Hist. 6: 214. 1845. SYNTYPES: Santa Fe, New Mexico, *A. Fendler 282* (2 sheets); California, 1848, *Douglas s.n.*; 1848, *C. A. Geyer s.n.*

Arceuthobium cryptopodum Engelm., in Gray, Boston J. Nat. Hist. 6: 214. 1850. HOLOTYPE: Santa Fe, New Mexico, 1847, *A. Fendler 283.* = *A. vaginata* (Willd.) Presl. subsp.

cryptopodum (Engelm.) Hawksworth & Wiens.

Arceuthobium divaricatum Engelm. in Rothr., Bot. Wheeler's Surv. 253. 1878. LECTOTYPE: Salt River Valley, Arizona, 1873, *Gilbert 116.* Syntype: Camp Apache, Arizona, 1874, *J. B. Girard s.n.*

Arceuthobium douglasii Engelm. in Rothr., Bot. Wheeler's Surv. 253. 1878. LECTOTYPE: Santa Fe River, New Mexico, 1874, *J. T. Rothrock 69.* Syntype: Camp Apache, Arizona, 1873, *G. K. Gilbert 109.*

Arceuthobium douglasii Engelm. var. *abietinum* Engelm. in Watson, Bot. Calif. 2: 106. 1880. LECTOTYPE: Sierra Valley, California, 1875, *Lemmon s.n.*. = *A. abietinum* Engelm.

Arceuthobium occidentale Engelm. in Rothr., Bot. Wheeler's Surv. 375. 1878. LECTOTYPE: Walker's Basin, California, 1875, *J. T. Rothrock 429.*

Arceuthobium robustum Engelm. in Gray, Mem. Amer. Acad. Arts. II. 4: 59. 1849. SYNTYPE: Camp Apache, Arizona, 1873, *G. Gilbert 108.* = *A. vaginatum* (Weins) Presl. subsp. *cryptopodum* (Engelm.) Hawksworth & Weins.

Arceuthobium verticilliflorum Engelm. in Watson, Bot. Calif. 2: 107. 1880. HOLOTYPE: Sierra Madre, Durango, Mexico, 1852, *Seeman 2138* (2 sheets).

Phoradendron flavescens Nutt. var. *macrophyllum* Engelm. in Rothr., Bot. Wheeler's Surv. 252. 1878. SYNTYPES: Gila River, Arizona, 1873, *Gilbert 104*; Camp Grant, 1874, *J. T. Rothrock 362.*

Phoradendron juniperinum Engelm. ex Gray, Mem. Amer. Acad. Arts. II. 4: 58. 1849. HOLOTYPE: Santa Fe, New Mexico, 1847, *A. Fendler 281.*

Phoradendron lanceolatum Engelm. ex Gray, Mem. Amer. Acad. Arts. II. 4: 59. 1849. HOLOTYPE: Rinconada, Mexico, 1847, *J. Gregg 255.*

Phoradendron orbiculatum Engelm. in Gray, Mem. Amer. Acad. Arts. II. 4: 59. 1849. LECTOTYPE: Little Rock, Arkansas, 1837, *G. Engelmann 707.* Syntype: same data but *G. Engelmann s.n.* = *P. flavescens* Nutt. var. *orbiculatum* Engelm.

LYTHRACEAE

Lythrum ovalifolium Engelm. ex Gray, Boston J. Nat. Hist. 6: 187. 1850. SYNTYPE: Pierdenales, Texas, 1845, *F. Lindheimer 450.*

MALVACEAE

Sida heterocarpa Engelm. ex Gray, Boston J. Nat. Hist. 6: 163. 1850. TYPE MATERIAL: Industry, Texas, 1844, *F. Lindheimer 189.* = *S. spinosa* L.

MARSILEACEAE

Marsilea macropoda Engelm. in A. Braun, Amer. J. Sci. II. 3: 56. 1847. HOLOTYPE: Matagorda Bay, Texas, 1845, *F. Lindheimer s.n.*

Marsilea tenuifolia Engelm. in A. Braun, Amer. J. Sci. II. 6: 89. 1848. HOLOTYPE: Guadalupe River, Texas, 1837, *F. Lindheimer s.n.*

MARTYNIACEAE

Martynia arenaria Engelm. in Wisliz., Mem. Tour. No. Mex. 100. 1848. HOLOTYPE: sandhills below El Paso, 1846, *A. Wislizenus 92.* = *Proboscidea altheaefolia* (Benth.) Dcne.

Martynia violacea Engelm. in Wisliz., Mem. Tour. No. Mex. 111. 1848. SYNTYPE: Lake Encinilla, north of Chihuahua, Mexico, 1846, *A. Wislizenus 145.* = *Proboscidea louisianica* (Mill.) Thell subsp. *fragrans* (Lindl.) Bretting.

NYMPHAEACEAE

Nuphar polysepalum Engelm. var. *pictum* Engelm., Trans. Acad. Sci. St. Louis 2: 282. 1866. LECTOTYPE: Colorado Territory, 1864, *C. C. Parry s.n.*

OLEACEAE

Menodora scoparia Engelm. ex Gray, Bot. Calif. 1: 471. 1876. SYNTYPES: Saltillo, Mexico, 1848, *J. Gregg 498 & 527.*

ONAGRACEAE

Gaura lindheimeri Engelm. & Gray, Boston J. Nat. History 5: 217. 1845. TYPE MATERIAL: prairie near Houston, Texas, 1843, *F. Lindheimer s.n.*

Gaura suffulta Engelm. in Gray, Boston J. Nat. Hist. 6: 190. 1850. ISOTYPE: New Braunfels, Texas, 1847, *F. Lindheimer 611* (4 sheets).

PAPAVERACEAE

Corydalis aurea Willd. var. *micrantha* Engelm. in Gray, Man. Bot. 5: 62. 1868. TYPE MATERIAL: "459" no additional collection information but label has complete description probably used in publication. = *C. micrantha* (Engelm.) Gray.

Corydalis crystallina Engelm. in Gray, Man. Bot. 5: 62. 1868. TYPE MATERIAL: Washington City, Arkansas, 1835, no collector.

Corydalis montana Engelm. in Gray, Man. Bot. 5: 62. 1868. TYPE MATERIAL: Santa Fe, New Mexico, 1847, *A. Fendler 17*. = *C. aurea* Willd.

Dicentra ochroleuca Engelm. in Coult., Bot. Gaz. 6: 233. 1881. HOLOTYPE: Santa Monica, California, 1880, *G. Engelmann s.n.* (2 sheets).

PASSIFLORACEAE

Passiflora affinis Engelm. ex Gray, Boston J. Nat. Hist. 6: 233. 1850. SYNTYPE: Texas, 1849, *F. Lindheimer 817*.

Passiflora tenuiloba Engelm. in Gray, Boston J. Nat. Hist. 6: 192. 1850. SYNTYPE: on the Liano, 1848 and 1849, *F. Lindheimer s.n.* (2 sheets).

PINACEAE

Abies grandis Lindl. var. *densiflora* Engelm., Trans. Acad. Sci. St. Louis 3: 599. 1878. TYPE MATERIAL: Mt. Hood, Oregon, 1871, *E. Hall s.n.*; British North America, 1862, *D. Lyall s.n.*; British Columbia, Canada, *s.d.*, *D. Lyall s.n.* = *A. amabilis* (Dougl.) Forbes.

Picea pungens Engelm., Gard. Chron. 11: 334. 1879. TYPE MATERIAL: upper Arkansas, Colorado, 1878, *M. E. Jones 364*; Lake County, Colorado, 1876, *G. Vasey s.n.* Both specimens prepublication date and annotated by Engelmann.

Pinus aristata Engelm., Trans. Acad. Sci. St. Louis 2: 205. 1863. TYPE MATERIAL: Rocky Mountains, 1862, *C. C. Parry s.n.*; Rocky Mountains, *s.d.*, *C. C. Parry s.n.* (2 sheets); the latter two specimens probably used for illustrations in publication.

Pinus arizonica Engelm. in Rothr., Bot. Wheeler's Surv. 260. 1878. HOLOTYPE: Santa Rita Mts., Arizona, 1874, *J. T. Rothrock 652*.

Pinus brachyptera Engelm. in Rothr., Bot. Wheeler's Surv. 89. 1878. LECTOTYPE: Rock Creek to Santa Fe, 1846, *A. Wislizenus 534* (2 sheets). = *P. ponderosa* Dougl. ex P. & C. Lawson.

Pinus chihuahuana Engelm. in Rothr., Bot. Wheeler's Surv. 103. 1878. HOLOTYPE: Cosihuiriachi, Mexico, 1846, *A. Wislizenus 232* (2 sheets).

Pinus edulis Engelm. in Rothr., Bot. Wheeler's Surv. 88. 1878. SYNTYPES: Cimarron to Santa Fe, 1846, *A. Wislizenus s.n.* & *535* (2 sheets); New Mexico, 1846, *J. Gregg s.n.*

Pinus elliottii Engelm., Trans. Acad. Sci. St. Louis 4: 186. 1880. SYNTYPES: South Carolina, 1871 (2 sheets), 1872, 1873, *Mellichamp s.n.* = *P. cubensis* Griseb.

Pinus flexilis James var. *macrocarpa* Engelm. in Rothr., Bot. Wheeler's Surv. 258. 1878. HOLOTYPE: San Francisco Mts., Arizona, 1871, *F. Bishoff s.n.*

Pinus flexilis James var. *reflexa* Engelm. in Rothr., Bot. Wheeler's Surv. 258. 1878. SYNTYPES: southern Arizona, *s.d.*, *J. T. Rothrock 654* & *1001*.

Pinus flexilis James var. *serrulata* Engelm. in Rothr., Bot. Wheeler's Surv. 258. 1878. HOLOTYPE: Mt. Graham, Arizona, 1874, *J. T. Rothrock 783*.

Pinus greggii Engelm. ex Parl. in DC., Prod. 16(2): 396. 1868. HOLOTYPE: Saltillo, Mexico, 1848, *J. Gregg 402*.

Pinus latisquama Engelm., Gard. Chron. 18: 712. 1882. HOLOTYPE: south of Saltillo, Mexico, 1880, *E. Palmer 1299*. = *P. pinaceana* Gord.

Pinus macrophylla Engelm. in Wisliz., Mem. Tour. No. Mex. 103. 1848. HOLOTYPE: Cosihuiriachi, Mexico, 1846, *A. Wislizenus 233* (2 sheets & 1 cone box). = *P. engelmannii* Carr.

Pinus osteosperma Engelm. in Wisliz., Mem. Tour. No. Mex. 89. 1848. LECTOTYPE: Buena Vista, Mexico, 1847, *J. Gregg 321* (2 sheets). = *P. cembroides* Zucc.

Pinus parryana Engelm., Amer. J. Sci. II. 34: 332.1862. HOLOTYPE: southeast of San Diego, California, in Mexico, 1850, *C. C. Parry s.n.* (2 sheets). = *P. quadrifolia* Parry.

Pinus strobiformis Engelm. in Wisliz., Mem. Tour. No. Mex. 102. 1848. LECTOTYPE: Cosihuiriachi, Mexico, 1846, *A. Wislizenus 231* (2 sheets & 1 cone box). Syntype: Cosihuiriachi, Mexico, 1846, *A. Wislizenus 155*. = *P. ayacahuite* Ehrenb. ex Schlecht.

Pinus wrightii Engelm., Trans. Acad. Sci. St. Louis 4: 185. 1880. SYNTYPES: eastern Cuba, 1860–1864, *C. Wright 3190* & *1462b* (1 sheet & 1 cone box); 1859, *C. Wright 1462 (a?)*.

Tsuga caroliniana Engelm. in Coult., Bot. Gaz. 6: 223. 1881. SYNTYPES: South Carolina, 1851, *L. R. Gibbs s.n.*, *A. H. Curtiss s.n.*; North Carolina, 1841, *A. Gray & Carey s.n.*

PLANTAGINACEAE

Plantago pusilla Nutt. var. *major* Engelm., Bot. Gaz. 8: 175. 1883. HOLOTYPE: Indian Territory, 1874, *G. D. Butler s.n.* = *P. elongata* Pursh.

POACEAE

Aristida basiramea Engelm. ex Vasey, Coult. Bot. Gaz. 9: 76. 1884. SYNTYPE: Minneapolis, Minnesota, 1883, *W. Upham s.n.*

Aristida ramosissima Engelm. ex Gray, Man. Bot. 5: 618. 1868. TYPE MATERIAL: east of Belleville, Illinois, Aug. 1845, *G. Engelmann s.n.*; St. Clair County, Illinois, Aug. 1858, *G. Engelmann s.n.*; southern Illinois, 1861, *G. Engelmann s.n.*

Monanthochloe littoralis Engelm., Trans. Acad. Sci. St. Louis 1: 436. 1859. SYNTYPES: Mantamoras, *s.d.*, *Berlandier 3227* (2 sheets); Texas, 1841, 1842, 1843, *F. Lindheimer s.n.* (5 sheets).

Spartina junciformis Engelm. & Gray, Boston J. Nat. Hist. 5: 238. 1845. SYNTYPE: Galveston, Texas, 1843, *F. Lindheimer 207* (3 sheets).

POLYGONACEAE

Eriogonum alpinum Engelm., Bot. Gaz. 7: 6. 1882. HOLOTYPE: Scotts Mt., California, 1880, *G. Engelmann s.n.*

Eriogonum atrorubens Engelm. in Wisliz., Mem. Tour. No. Mex. 108. 1848. HOLOTYPE & ISOTYPE: Cosihuiriachi, Mexico, 1846, *A. Wislizenus 172* (2 sheets).

Polygonum cristatum Engelm. & Gray, Boston J. Nat. Hist. 5: 259. 1845. HOLOTYPE: Texas, 1844, *F. Lindheimer 237 (exsiccatae no. 296)*, "n. sp." added by Engelm.

PORTULACACEAE

Lewisia brachycalyx Engelm. ex Gray, Proc. Amer. Acad. Arts 7: 400. 1868. SYNTYPES: Fort Whipple, Arizona, 1865, *E. Coues & E. Palmer 211* (2 sheets); Utah, 1859, *Brewer s.n.*

Portulaca lanceolata Engelm. in Gray, Boston J. Nat. Hist. 6: 154. 1850. SYNTYPE: Liano, Texas, 1848, *F. Lindheimer s.n.* = *P. umbraticola* H.B.K.

Portulaca retusa Engelm., Boston J. Nat. Hist. 6: 154. 1850. HOLOTYPE: "ex sem. texanis cult. St. Louis," from Llano in western Texas, Aug. 1849, *G. Engelmann s.n.*

Portulaca suffrutescens Engelm., Bot. Gaz. 6: 236. 1881. SYNTYPES: Copper Mines, 1851, *C. Wright 874*; Fort Whipple, Arizona, 1865, *E. Coues & E. Palmer 547*; Santa Rita Mts., Arizona, 1880, *G. Engelmann s.n.*

Talinum aurantiacum Engelm. in Gray, Boston J. Nat. Hist. 6: 153. 1850. SYNTYPES: on the Llano, Texas, 1848, *F. Lindheimer 579*; on the Sabinas, Texas, 1847, *F. Lindheimer s.n.*

Talinum calycium Engelm. in Wisliz., Mem. Tour. No. Mex. 88. 1848. HOLOTYPE: on the Cimarron, 1846, *A. Wislizenus 475* (2 sheets); one is annotated "n. sp." by Engelm.

Talinum sarmentosum Engelm. in Gray, Boston J. Nat. Hist. 6: 153. 1850. SYNTYPE: Texas, 1847, *F. Lindheimer 580.*

Talinum spathulatum Engelm. in Gray, Pl. Wrightiana 14. 1852. LECTOTYPE: western Texas to El Paso, Texas, 1849, *C. Wright 35.* = *T. paniculatum* (Jacq.) Gaertn.

POTAMOGETONACEAE

Potamogeton diversifolius Raf. var. *spicatus* Engelm., Amer. J. Sci. 46: 102. 1843. HOLOTYPE: Cosihuiriachi, Mexico, 1846–1847, *A. Wislizenus 159.*

RANUNCULACEAE

Ranunculus texensis Engelm. in Engelm. & Gray, Boston J. Nat. Hist. 5: 210. 1845. SYNTYPE: near Houston, Texas, 1843, *F. Lindheimer 1.* = *R. oblongifolius* Ell.

Ranunculus trachyspermus Engelm. in Engelm. & Gray, Boston J. Nat. Hist. 5: 211. 1845. SYNTYPE: Texas, 1843, *F. Lindheimer 2.* = *R. pusillus* Poir. var. *angustifolius* (Engelm.) L. Benson.

Ranunculus trachyspermus Engelm. var. *angustifolius* Engelm. in Engelm. & Gray, Boston J. Nat. Hist. 5: 211. 1845. SYNTYPE: Galveston Island, Texas, 1843, *F. Lindheimer 3.* = *R. pusillus* Poir. var. *angustifolius* (Engelm.) L. Benson.

Ranunculus trachyspermus Engelm. var. *lindheimeri* Engelm. in Engelm. & Gray, Boston J. Nat. Hist. 5: 211. 1845. SYNTYPE: Galveston, Texas, 1843, *F. Lindheimer s.n.*

Thalictrum fendleri Engelm. ex Gray, Mem. Amer. Acad. Arts. II. 4: 5. 1849. ISOTYPE: Santa Fe, New Mexico, 1847, *A. Fendler 13* (2 sheets).

ROSACEAE

Greggia rupestris Engelm. in Wisliz., Mem. Tour. No. Mex. 114. 1848. SYNTYPE: Cosihuiriachi, Mexico, 1846, *A. Wislizenus 228* (2 sheets); Saltillo, Mexico, *A. Wislizenus s.n.*; Buena Vista, Mexico, 1847, *A. Wislizenus 324*. = *Cowania mexicana* D. Don.

Prunus gracilis Engelm. & Gray, Boston J. Nat. Hist. 5: 243. 1845. ISOTYPES: west of the Brazos, Texas, March, 1844, *F. Lindheimer 237*; "Post Oak Plum . . . ," Texas, March, 1844, *F. Lindheimer s.n.*

Prunus minutiflora Engelm. in Gray, Boston J. Nat. Hist. 6: 185. 1850. LECTOTYPE: between San Antonio and New Braunfels, Texas, *s.d.*, *F. Lindheimer 388*.

Rosa minutifolia Engelm., Bull. Torrey Bot. Club 9: 97. 1882. HOLOTYPE: All Saint's Bay, California, 1882, *C. C. Parry & M. E. Jones s.n.*

Rosa spithamea A. Gray var. *subinermis* Engelm., Bot. Gaz. 6: 236. 1881. HOLOTYPE: Big Trees, Sierra Nevada, California, 1880, *G. Engelmann s.n.*

RUBIACEAE

Bouvardia glaberrima Engelm. in Wisliz., Mem. Tour. No. Mex. 107. 1848. LECTOTYPE: Cosihuiriachi, Mexico, 1846, *A. Wislizenus 161* (2 sheets).

SAXIFRAGACEAE

Fendlera rupicola A. Gray var. *lindheimeri* Engelm. & Gray in Gray, Pl. Wrightiana 1: 77. 1852. HOLOTYPE?: Texas, 1850, *F. Lindheimer 792* (2 sheets).

Heuchera sanguinea Engelm. in Wisliz., Mem. Tour. No. Mex. 107. 1848. HOLOTYPE: Llanos, 1846, *A. Wislizenus 210* (2 sheets).

Saxifraga debilis Engelm. ex Gray, Proc. Amer. Acad. Arts 15: 62. 1863. HOLOTYPE OR ISOTYPE: Colorado, 1861, *C. C. Parry 167*.

SCROPHULARIACEAE

Castilleja indivisia Engelm. in Engelm. & Gray, Boston J. Nat. Hist. 5: 47. 1845. SYNTYPE: from Houston to the Colorado, 1844 & 1846, *F. Lindheimer 284* (3 sheets).

Maurandya wislizenii Engelm. ex Gray in Torr., Bot. Mex. Bound. Surv. 111. 1859. LECTOTYPE: near Val Verde, New Mexico, 1846, *A. Wislizenus 45*.

Penstemon coccineus Engelm. in Wisliz., Mem. Tour. No. Mex. 107. 1848. HOLOTYPE: Llanos, 1846, *A. Wislizenus 207*. = *P. wislizenii* (Gray) Straw.

SPARGANIACEAE

Sparganium eurycarpum Engelm. in Gray, Man. Bot. 5: 481. 1868. TYPE MATERIAL: American Bottom, 13 Aug. 1860, *G. Engelmann s.n.* No specimens cited but collected prior to publication date.

Sparganium simplex Huds. var. *androcladum* Engelm. in Gray, Man. Bot. 5: 481. 1868. LECTOTYPE: near Boston, 1856, *G. Engelmann s.n.* Syntypes: American Bottom, near St. Louis, Missouri, 1860, *G. Engelmann s.n.*; St. Clair County, 1854, *G. Engelmann s.n.*; St. Louis, Missouri, *s.d.*, *G. Engelmann s.n.*, annotated "n. sp." by Engelm. = *S. androcladum* (Engelm.) Morong.

STYRACACEAE

Styrax platanifolia Engelm. ex Torr., Smithsonian Contrib. Knowl. 6: 4. 1854. SYNTYPE: Texas, 1851, *F. Lindheimer s.n.*

VALERIANACEAE

Fedia stenocarpa Engelm. ex Gray, Boston J. Nat. Hist. 6: 216. 1850. TYPE MATERIAL: New Braunfels, Texas, 1848, *F. Lindheimer 407*. = *Valerianella stenocarpa* (Engelm. ex Gray) Krok.

VITACEAE

Vitis arizonica Engelm., Amer. Naturalist 2: 321. 1869. SYNTYPES: Santa Cruz, Sonora, Mexico, *C. Wright 919*; New Mexico, *s.d.*, *C. Wright s.n.*; Sonora, Mexico, 1851, *G. Thurber 703*; Rio Verde, Arizona, 1865, *E. Coues & C. C. Parry 551 & 553*; southern Arizona, 1866, *C. C. Parry s.n.* = *V. monticola* Buckley subsp. *arizonica* (Engelm.) Rogers.

Vitis candicans Engelm. in Gray, Boston J. Nat. Hist. 6: 166. 1850. SYNTYPE: Texas, 1844, *F. Lindheimer s.n.*

ZYGOPHYLLACEAE

Guaiacum angustifolium Engelm. in Wisliz., Mem. Tour. No. Mex. 113. 1848. LECTOTYPE: about Parras and Saltillo, Mexico, 1847, *A. Wislizenus 293*. = *Porlieria angustifolia* A. Gray.

Larrea glutinosa Engelm. in Wisliz., Mem. Tour. No. Mex. 93. 1848. HOLOTYPE: Saltillo, Mexico, 1846, *J. Gregg 10*, annotated "n. sp." by Engelm. Syntype: Saltillo, Mexico, 1847, *J. Gregg 369*.

SYNOPSIS OF *DICHANTHELIUM* (POACEAE) IN FLORIDA[1]

Bruce F. Hansen and Richard P. Wunderlin[2]

ABSTRACT

Twenty-five taxa of Dichanthelium *are recognized for Florida, with synonymy and typification compiled. Keys to species and varieties and an index to names is provided. The new combinations* D. ensifolium *var.* breve, D. ensifolium *var.* unciphyllum, *and* D. portoricense *are proposed.*

Recent papers concerning *Dichanthelium* that have dealt with either the southeastern United States (Gould & Clark, 1978; Lelong, 1984, 1986) or with only a small part of the genus (Freckmann, 1981a) have been very influential in redefining the limits of the taxa. The present paper expands on the treatment of the Florida species in Wunderlin (1982) and Clewell (1985) in order to modernize the concepts and to rectify some errors. At the same time, it is an attempt to classify the Florida specimens better, recognizing that the taxa accepted here might well be inadequately separable in other geographic areas, which seems the rule for this genus. However, we feel that practicality alone would mandate such a classification for this very difficult genus to facilitate assignment of names to specimens. In *Dichanthelium,* reticulate evolution caused by hybridization and autogamy is extremely common (Spellenberg, 1975a, b; Lelong, 1984, 1986). Thus, no claim is made here that a "natural" classification has been constructed.

The merits of accepting the segregate genus *Dichanthelium* versus the inclusive *Panicum* will not be argued here except to point out that *Dichanthelium* is as "good" a grass genus as many others (e.g., *Brachiaria, Sacciolepis,* and many more in different tribes). We will not detail here which authors accept one or the other genus; those that wish to use *Panicum* will not be swayed by our arguments. Gould & Clark (1978) provided 24 characteristics separating *Dichanthelium* from *Panicum*; none of these alone separates the genera, but the total we believe defines *Dichanthelium* as a natural segregate from the large and variable *Panicum.* It is our belief that the acceptance of *Dichanthelium* provides a more consistent generic classification of the grasses of Florida.

The species and varietal concepts used are roughly those of Gould & Clark (1978) as modified by Lelong (1984, 1986). Because the synonymy is so extensive and in many cases confusing, all known synonyms are compiled and included in the hope that future workers will find it easier to follow the nomenclature. The types are listed where known, but it must be emphasized that little original research in typification is involved here; the citation of types is mostly from published material, principally Hitchcock & Chase (1910), Gould & Clark (1978), and Lelong (1984). It seems inevitable that several new combinations are necessary, this in a group already overburdened with surplus names.

The key fairly reflects the variation in *Dichanthelium* species, such that many taxa will key out in two or more places. When a character falls between an overlapping lead, either choice should lead to the correct species.

KEY TO THE FLORIDA SPECIES OF *DICHANTHELIUM*

1a. Leaves at base of plant numerous, relatively long and soft, similar to and only slightly shorter, if at all, than the soft, yellowish green lower culm blades; plants branching only at base; blades mostly 4–10 mm wide.

---

[1] *The authors wish to thank Gerrit Davidse of the Missouri Botanical Garden for carefully reviewing the manuscript and for many helpful comments. Thanks are also due to Dan Nicolson of the Smithsonian Institution for help with a knotty nomenclatural problem, and to Jimmy Massey of North Carolina State University for help in locating certain W. W. Ashe collections.*

ANN. MISSOURI BOT. GARD. 75: 1637–1657. 1988.

2a. Sheaths retrorsely pilose; uppermost culm blade at least ¾ as long as those of basal tuft .... *D. laxiflorum*
2b. Sheaths glabrous or ascending pilose; uppermost culm blade less than ¾ as long as those of basal tuft .... *D. strigosum*
1b. Leaves at base of plant typically forming a basal rosette of short, relatively broad blades, these usually conspicuously shorter than the culm blades; plants normally branching above the base, especially in the autumnal phase; blades 3–25 mm wide or wider.
3a. Spikelets 0.8–3.2 mm long.
4a. Spikelets 0.8–2 mm long.
5a. Ligule hairs, at least some, 2–5 mm long .... *D. acuminatum*
5b. Ligule hairs under 1.5 mm long or absent.
6a. Lower culm internodes (and usually sheaths) pubescent, puberulent, strigose, or villous.
7a. Blades of midculm leaves mostly 2–5 mm wide; plants usually at least 10 cm tall .... *D. aciculare*
7b. Blades of midculm leaves less than 2 mm wide; plants less than 10 cm tall .... *D. ensifolium* (var. *breve*)
6b. Lower culm internodes (and usually sheaths) glabrous.
8a. Blades of midculm leaves (vernal phase) 5–15 cm long, mostly 2–5 mm wide .... *D. aciculare*
8b. Blades of midculm leaves less than 6 cm long, or if longer, then wider than 6 mm.
9a. Bases of lower culm leaves cordate or subcordate; blades 7–30 mm wide.
10a. Spikelets 1–1.1 mm long .... *D. erectifolium*
10b. Spikelets 1.4–2.2 mm long .... *D. sphaerocarpon*
9b. Bases of lower culm leaves other than cordate or subcordate; blades usually less than 7 mm wide.
11a. Spikelets 1.6–2.5 mm long; plants usually diffuse .... *D. dichotomum*
11b. Spikelets 0.8–1.5 mm long; plants usually cushion-forming .... *D. ensifolium*
4b. Spikelets 2.1–3.2 mm long.
12a. Blades of primary culms, at least some, (10–)13–25 mm wide.
13a. Culm nodes conspicuously bearded, the lower internodes with long, spreading hairs .... *D. scoparium*
13b. Culm nodes glabrous or slightly hairy, the internodes typically glabrous.
14a. Ligule a fringed or entire membrane.
15a. Plants less than 75 cm tall; leaf bases cordate .... *D. commutatum*
15b. Plants mostly more than 75 cm tall; leaf bases rounded .... *D. scabriusculum*
14b. Ligule a ring of hairs or absent.
16a. Spikelets 1.4–2.2 mm long, broadly elliptic to suborbicular .... *D. sphaerocarpon*
16b. Spikelets 2.4–3.5 mm long, narrowly ovate or elliptic .... *D. clandestinum*
12b. Blades of primary culms up to 12 mm wide.
17a. Leaf bases cordate or subcordate.
18a. Spikelets 1.4–2.2 mm long, broadly elliptic to ovate .... *D. sphaerocarpon*
18b. Spikelets 2.4–3.2 mm long, elliptic to narrowly ovate .... *D. commutatum*
17b. Leaf bases other than cordate or subcordate.
19a. Ligule hairs, at least some, 2–5 mm long.
20a. Nerves of the upper glume and lemma of the lower floret broad, distinct; sheaths glabrous or pubescent with short hairs .... *D. oligosanthes*
20b. Nerves of the upper glume and lemma of the lower floret narrow, relatively indistinct; sheaths spreading pubescent with long hairs.
21a. Spikelets 2.2–3.1 mm long; ligules usually with a distinct ring of short hairs in front of long hairs .... *D. ovale*
21b. Spikelets 1.4–2 mm long; ligules lacking a distinct ring of shorter hairs .... *D. acuminatum*
19b. Ligule hairs less than 2 mm long.
22a. Culm nodes, at least lower ones, conspicuously bearded.
23a. Glabrous-glandular band present just below the nodes; leaves usually velvety-pubescent below .... *D. scoparium*
23b. Glabrous-glandular band not present; leaves glabrous or variously pubescent below, not velvety.
24a. Culm internodes, at least lower ones, strigose or villous; blades pubescent below .... *D. ovale*
24b. Culm internodes glabrous; blade surfaces glabrous .... *D. dichotomum*
22b. Culm nodes not bearded, lower ones sometimes sparsely hairy or puberulent.
25a. Ligule membranous; plants typically 75–150 cm tall .... *D. scabriusculum*
25b. Ligule a ring of hairs or absent; plants mostly less than 70 cm tall.

26a. Blades of midculm leaves (vernal phase) linear and stiff, often becoming involute, mostly 2–5 mm wide, 6–15 cm long .... *D. aciculare*
26b. Blades of midculm leaves lanceolate, usually soft, remaining flattened, mostly more than 5 mm wide when 8 cm long or longer.
  27a. Upper glume and lemma of the lower floret with broad, rounded nerves; spikelets rounded at the apex .... *D. oligosanthes*
  27b. Upper glume and lemma of the lower floret with narrow, faint or relatively indistinct nerves; spikelets usually pointed at the apex.
    28a. Lower culm internodes pubescent .... *D. portoricense*
    28b. Lower culm internodes glabrous .... *D. dichotomum*
3b. Spikelets 3.3–5.2 mm long.
  29a. Blades of at least some culm leaves 13–35 mm wide.
    30a. Spikelets broadly elliptic to obovate, usually with broad, heavy nerves .... *D. oligosanthes*
    30b. Spikelets narrowly elliptic to obovate, not strongly nerved.
      31a. Culm nodes glabrous or slightly pubescent; spikelets 3.3–3.8 mm long .... *D. clandestinum*
      31b. Culm nodes bearded; spikelets 3.8–5.2 mm long.
        32a. Ligules 2.5–4 mm long; leaf blades usually puberulent-tomentose on one or both sufaces .... *D. ravenelii*
        32b. Ligules 1.5 mm long; leaf blades glabrous to puberulent .... *D. boscii*
  29b. Blades of culm leaves up to 12 mm wide.
    33a. Midculm blades narrow, stiffly ascending, often becoming involute, mostly 6–15 cm long, less than 5 mm wide .... *D. aciculare*
    33b. Midculm blades broader, spreading, 3–8 cm long, 3–8 mm wide .... *D. portoricense*

Dichanthelium aciculare (Desvaux ex Poiret) Gould & Clark, Ann. Missouri Bot. Gard. 65: 1116. 1978. *Panicum aciculare* Desvaux ex Poiret in Lamarck, Encycl. Suppl. 4: 274. July 1816. TYPE: United States. *Desvaux Herb. s.n.* (holotype, P; isotype, US, fragm.). Although the protologue gives the locality as "Habitat in india orientale," Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 166. 1910) stated that the type collection "is without doubt from the southeastern United States."

Panicum angustifolium Elliott, Sketch Bot. S. Carolina 1: 129. Dec 1816. *Panicum nitidum* Lamarck var. *angustifolium* (Elliott) A. Gray, N. Amer. Gram. 2: 112. 1835. *Chasea angustifolia* (Elliott) Nieuwland, Amer. Midl. Naturalist 2: 64. 1911. *Dichanthelium angustifolium* (Elliott) Gould, Brittonia 26: 59. 1974. TYPE: United States. South Carolina: *Elliott s.n.* (holotype, CHARL; isotype, US?).

Panicum setaceum Muhlenberg, Descr. Gram. 99. 1817. TYPE: United States. Georgia: *Muhlenberg Herb. s.n.* (lectotype, PH-M). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 166. 1910).

Panicum subuniflorum Bosc ex Sprengel, Syst. Veg. 1: 312. 1825. TYPE: United States. "Carolina": *Bosc s.n.* (lectotype, B-W; isotype, G). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 166. 1910).

Panicum curtisii Steudel, Syn. Pl. Glumac. 1: 66. 1853. TYPE: United States. South Carolina: *Curtis s.n.* (holotype, P).

Panicum neuranthum Grisebach, Cat. Pl. Cub. 232. 1866. TYPE: Cuba. Oriente: 1860, *Wright 3453* (lectotype, GOET). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 175. 1910).

Panicum neuranthum Grisebach var. *ramosum* Grisebach, Cat. Pl. Cub. 232. 1866. *Panicum fusiforme* A. Hitchcock, Contr. U.S. Natl. Herb. 12: 222. 1909. TYPE: Cuba. 1863, *Wright 3454* (holotype, GOET).

Panicum nemopanthum Ashe, J. Elisha Mitchell Sci. Soc. 15: 42. 1898. TYPE: United States. North Carolina: Wake Co., Penitentiary Woods, Raleigh, Apr. 1895, *Ashe s.n.* (lectotype, US). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 177. 1910).

Panicum arenicola Ashe, J. Elisha Mitchell Sci. Soc. 15: 56. 1898. TYPE: United States. North Carolina: Orange Co., Chapel Hill, June 1898, *Ashe s.n.* (lectotype, US). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 166. 1910).

Panicum ovinum Lamson-Scribner & J. G. Smith, U.S.D.A. Div. Agrost. Circ. 16: 3. 1899. *Panicum aciculare* Desvaux ex Poiret var. *ovinum* (Lamson-Scribner & J. G. Smith) Beetle, Phytologia 48: 192. 1981. TYPE: United States. Texas: Waller Co., 25 May 1898, *Thurow s.n.* (holotype, US).

Panicum arenicoloides Ashe, J. Elisha Mitchell Sci. Soc. 16: 89. Feb. 1900. *Panicum aciculare* Desvaux ex Poiret var. *arenicoloides* (Ashe) Beetle, Phytologia 48: 192. 1981. TYPE: United States. North Carolina: New Hanover Co., near Wilmington, 7 June 1899, *Ashe s.n.* (holotype, NCU?; isotype, US, fragm.). Specimen at NCU not located.

Panicum filirameum Ashe, J. Elisha Mitchell Sci. Soc. 16: 88. Feb. 1900. TYPE: United States. North Carolina: New Hanover Co., June 1899, *Ashe s.n.* (holotype, NCU; isotype, US).

Panicum orthophyllum Ashe, J. Elisha Mitchell Sci. Soc.

16: 90. Feb. 1900. TYPE: United States. North Carolina: New Hanover Co., June 1899, *Ashe s.n.* (holotype, NCU?; isotype, US, fragm.). Specimen at NCU not located.

Panicum delawarense Ashe, North Carolina Agric. Exp. Sta. Bull. 175: 116. Aug 1900. TYPE: United States. Delaware: Newcastle Co., near Centerville, 6 July 1878, *Commons s.n.* (holotype, NCU).

Panicum pinetorum Swallen, Proc. Biol. Soc. Wash. 55: 93. July 1942. TYPE: United States. Florida: Lee Co., near Bonita Springs, 14 Oct. 1940, *Silveus 6604* (holotype, NA).

Panicum bennettense W. Brown, Bull. Torrey Bot. Club 69: 539, f. 1. Oct. 1942. TYPE: United States. North Carolina: Durham Co., Bennett Memorial, 5 mi. W of Durham, *Brown 2492* (holotype, DUKE).

The vernal phase is easily recognized by the long, narrow, rather stiff upright leaves. In the autumnal phase, *D. aciculare* can be confused with several other species, making determinations very difficult.

This species usually occurs in drier sites throughout Florida.

Dichanthelium acuminatum (Swartz) Gould & Clark, Ann. Missouri Bot. Gard. 65: 1123. 1978. *Panicum acuminatum* Swartz, Prodr. 23. 1788. TYPE: Jamaica: *Swartz s.n.* (holotype, S; isotype, US, fragm.).

As treated here, specimens with long ligule hairs define the *Dichanthelium acuminatum* complex, which consists of three species characterized by spikelet length: *D. leucothrix* (0.8–1.2 mm), *D. acuminatum* (1.4–2 mm), and *D. ovale* (2.2–3 mm). *Dichanthelium ovale* was separated from *D. acuminatum* by Gould & Clark (1978) by its supposedly doubled ligule, which forced specimens with midsized spikelets into *D. ovale.* While it can at times be quite pronounced, this character is often difficult to see and actually becomes undetectable on many specimens. When segregated by spikelet length, however, formerly confusing taxa such as *D. ovale* var. *addisonii* (Gould & Clark, 1978) and *D. ovale* vars. *villosum* and *pseudopubescens* (Lelong, 1984, 1986) fall readily into *D. acuminatum.*

Within *D. acuminatum,* many of the pubescence and habit phases have received varietal or specific status in the past. Lelong (1984, 1986) recognized six varieties. His varieties *acuminatum,* "*unciphyllum,*" and *columbianum* rely on whether the culm and sheath pubescence is appressed or spreading or both; this completely intergrades in a large suite of specimens. His variety *fasciculatum* is based on larger leaves, again a completely intergrading character. On the other hand, in the glabrous varieties *lindheimeri* and *densiflorum*, the lack of pubescence seems to be correlated with smaller spikelet size and generally robust habit for the former, and with an elongate inflorescence for the latter. Therefore, we are recognizing only three varieties in Florida:

1a. Culms and sheaths pubescent .... var. *acuminatum*
1b. Culms and sheaths glabrous or nearly so.
  2a. Panicle narrow, commonly 8–12 cm long; leaves dark green .... var. *densiflorum*
  2b. Panicle broad, 5–8 cm long; leaves yellow green .... var. *lindheimeri*

Dichanthelium acuminatum var. acuminatum

Panicum lanuginosum Elliott, Sketch Bot. S. Carolina 1: 123. 1816. *Dichanthelium lanuginosum* (Elliott) Gould, Brittonia 20: 60. 1974. TYPE: United States. Georgia: *Baldwin s.n.* (holotype, CHARL; isotype, US, fragm.).

Panicum dichotomum Linnaeus var. *fasciculatum* Torrey, Fl. N. Middle United States 145. 1824. *Panicum huachucae* Ashe var. *fasciculatum* (Torrey) F. Hubbard, Rhodora 14: 171. 1912. *Panicum lindheimeri* Nash var. *fasciculatum* (Torrey) Fernald, Rhodora 23: 228. 1922 ("1921"). *Panicum lanuginosum* Elliott var. *fasciculatum* (Torrey) Fernald, Rhodora 36: 77. 1934. *Dichanthelium lanuginosum* (Elliott) Gould var. *fasciculatum* (Torrey) Spellenberg, Madroño 23: 145. 1975. *Dichanthelium acuminatum* (Swartz) Gould & Clark var. *fasciculatum* (Torrey) Freckmann, Phytologia 48: 108. 1981. *Panicum acuminatum* Swartz var. *fasciculatum* (Torrey) Lelong, Brittonia 36: 169. 1984. TYPE: United States. New Jersey: *Torrey s.n.* (holotype, NY).

Panicum nitidum Lamarck var. *ciliatum* Torrey, Fl. N. Middle United States 146. 1824. TYPE: United States. New Jersey: *Torrey s.n.* (holotype, NY; isotype, US, fragm.).

Panicum nitidum Lamarck var. *pilosum* Torrey, Fl. N. Middle United States 146. 1824. TYPE: United States. New York: *Torrey s.n.* (holotype, NY; isotype, US, fragm.).

Panicum nitidum Lamarck var. *villosum* A. Gray, N. Amer. Gram. 2: 111. 1835. *Dichanthelium acuminatum* (Swartz) Gould & Clark var. *villosum* (A. Gray) Gould & Clark, Ann. Missouri Bot. Gard. 65: 1124. 1978. *Panicum acuminatum* Swartz var. *villosum* (A. Gray) Beetle, Phytologia 48: 192. 1981. *Panicum ovale* Elliott var. *villosum* (A. Gray) Lelong, Brittonia 36: 272. 1984. TYPE: United States. New York: Ontario Co., *Sartwell? s.n.* (holotype, GH?).

Panicum dichotomum Linnaeus var. *villosum* Vasey, U.S.D.A. Div. Agrost. Bull. 8: 31. 1889. TYPE: United States. District of Columbia: near Pierce's Mill, Rock Creek, 1 July 1883, *Vasey s.n.* (lectotype, US). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 233. 1910).

Panicum villosissimum Nash, Bull. Torrey Bot. Club 23: 149. 1896. *Dichanthelium lanuginosum* (Elliott) Gould var. *villosissimum* (Nash) Gould, Brittonia 26: 60. 1974. *Dichanthelium villosissimum* (Nash) Freckmann, Phytologia 39: 270. 1978. TYPE: United

States. Georgia: Bibb Co., Ocmulgee River swamp below Macon, 18–24 May 1895, *Small s.n.* (holotype, NY; isotypes, NY, US).

Panicum atlanticum Nash, Bull. Torrey Bot. Club 24: 346. 1897. TYPE: United States. New York: Bronx, New York Botanical Garden, 24 June 1897, *Nash s.n.* (holotype, NY; isotypes, NY, US).

Panicum commonsianum Ashe, J. Elisha Mitchell Sci. Soc. 15: 55. Feb. 1898. *Panicum columbianum* Lamson-Scribner var. *commonsianum* (Ashe) Dore in McNeill & Dore, Naturaliste Canad. 103: 562. 1976. *Dichanthelium commonsianum* (Ashe) Freckmann, Phytologia 39: 271. 1978. TYPE: United States. New Jersey: Cape May Co., Cape May, June 1898, *Commons 341* (holotype, NCU; isotypes, NY, US).

Panicum filiculme Ashe, J. Elisha Mitchell Sci. Soc. 15: 59. Feb. 1898, non Hackel 1895. TYPE: United States. Georgia: DeKalb Co., Stone Mountain, Aug. 1895, *Ashe s.n.* (lectotype, US). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 210. 1910).

Panicum haemacarpon Ashe, J. Elisha Mitchell Sci. Soc. 15: 55. Feb. 1898. TYPE: United States. District of Columbia: 1897, *Kearney s.n.* (lectotype, NCU; isolectotypes, NY, US). Lectotypified by Hichcock and Chase (Contr. U.S. Natl. Herb. 15: 233. 1910). Although Lelong (1984) cited NY as the location of the lectotype, Hitchcock & Chase (1910) clearly stated that the type is in Ashe's herbarium, which is now at NCU.

Panicum huachucae Ashe, J. Elisha Mitchell Sci. Soc. 15: 51. Feb. 1898. *Panicum lanuginosum* Elliott var. *huachucae* (Ashe) A. Hitchcock, Rhodora 8: 208. 1906. TYPE: United States. Arizona: Huachuca Mountains, 1882, *Lemmon s.n.* (lectotype, US). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 215. 1910).

Panicum meridionale Ashe, J. Elisha Mitchell Sci. Soc. 15: 59. Feb. 1898. *Panicum unciphyllum* Trinius var. *meridionale* (Ashe) Lamson-Scribner & Merrill, Rhodora 3: 123. 1901. *Panicum lindheimeri* Nash subvar. *meridionale* (Ashe) Farwell, Amer. Midl. Naturalist 11: 45. 1928. *Panicum lanuginosum* Elliott subvar. *meridionale* (Ashe) Farwell, Pap. Michigan Acad. Sci. 26: 5. 1941. *Dichanthelium meridionale* (Ashe) Freckmann, Phytologia 39: 270. 1978. TYPE: United States. North Carolina: Burke Co., Jonas Ridge, June 1893, *Ashe s.n.* (lectotype, US). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 210. 1910).

Panicum microphyllum Ashe, J. Elisha Mitchell Sci. Soc. 15: 61. Feb. 1898. TYPE: United States. North Carolina: Orange Co., Chapel Hill, June 1898, *Ashe s.n.* (holotype, not located). Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 210. 1910) relegated this name to the synonymy of *Panicum meridionale* based on the description only.

Panicum scoparioides Ashe, J. Elisha Mitchell Sci. Soc. 15: 53. Feb. 1898. *Panicum villosissimum* Nash var. *scoparioides* (Ashe) Fernald, Rhodora 36: 79. 1934. TYPE: United States. Delaware: Newcastle Co., Centreville, 25 June 1873, *Commons 283* (lectotype, US; isotype, NY). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 238. 1910).

Panicum tennesseense Ashe, J. Elisha Mitchell Sci. Soc. 15: 52. Feb. 1898. *Panicum lindheimeri* Nash var. *tennesseense* (Ashe) Farwell, Amer. Midl. Naturalist 11: 45. 1928. TYPE: United States. Tennessee: La Vergne Co., 7 Aug. 1897, *Biltmore Herb. 7087* (holotype, US).

Panicum addisonii Nash, Bull. Torrey Bot. Club 25: 83. 12 Feb. 1898. *Panicum commonsianum* Ashe subsp. *addisonii* (Nash) W. Stone, New Jersey State Mus. Annual Rep. 1910: 205. 1911. *Panicum commonsianum* Ashe var. *addisonii* (Nash) R. Pohl, Amer. Midl. Naturalist 38: 582. 1947. *Dichanthelium ovale* (Elliott) Gould & Clark var. *addisonii* (Nash) Gould & Clark, Ann. Missouri Bot. Gard. 65: 1115. 1978. TYPE: United States. New Jersey: Cape May Co., Wildwood, 30–31 May 1897, *Bicknell s.n.* (holotype, NY; isotype, US, fragm.).

Panicum implicatum Lamson-Scribner in Britton & Brown, Ill. Fl. N. U.S. 3: 498. 20 June 1898. *Panicum unciphyllum* Trinius var. *implicatum* (Lamson-Scribner) Lamson-Scribner & Merrill, Rhodora 3: 123. 1901. *Panicum lindheimeri* Nash var. *implicatum* (Lamson-Scribner) Fernald, Rhodora 23: 228. 1922 ("1921"). *Panicum lanuginosum* Elliott var. *implicatum* (Lamson-Scribner) Fernald, Rhodora 36: 77. 1934. *Dichanthelium acuminatum* (Swartz) Gould & Clark var. *implicatum* (Lamson-Scribner) Gould & Clark, Ann. Missouri Bot. Gard. 65: 1126. 1978. *Panicum acuminatum* Swartz var. *implicatum* (Lamson-Scribner) Beetle, Phytologia 48: 192. 1981. TYPE: United States. Maine: Cumberland Co., Cape Elizabeth, 26–27 July 1895, *Lamson-Scribner s.n.* (holotype, US; isotype, NY).

Panicum thurowii Lamson-Scribner & J. G. Smith, U.S.D.A. Div. Agrost. Circ. 16: 5. 1 July 1899. *Dichanthelium acuminatum* (Swartz) Gould & Clark var. *thurowii* (Lamson-Scribner & J. G. Smith) Gould & Clark, Ann. Missouri Bot. Gard. 65: 1125. 1978. TYPE: United States. Texas: Waller Co., 5 June 1898, *Thurow 9* (holotype, US).

Panicum ciliosum Nash, Bull. Torrey Bot. Club 26: 568. Nov. 1899. TYPE: United States. Mississippi: Harrison Co., Biloxi, 1 Sept. 1898, *Tracy 4580* (holotype, NY; isotypes, NCU, US).

Panicum pseudopubescens Nash, Bull. Torrey Bot. Club 26: 577. Nov. 1899. *Panicum villosissimum* Nash var. *pseudopubescens* (Nash) Fernald, Rhodora 36: 79. 1934. *Panicum ovale* Elliott var. *pseudopubescens* (Nash) Lelong, Brittonia 36: 271. 1984. TYPE: United States. Alabama: Lee Co., Auburn, 7 May 1898, *Earle & Baker 1537* (holotype, NY; isotype, US).

Panicum occidentale Lamson-Scribner, Annual Rep. Missouri Bot. Gard. 10: 48. 1899. TYPE: Canada. British Columbia: Vancouver Island, "Hab. in Nootka-Sund," *Haenke s.n.* (holotype, MO; isotypes, PR, US, fragm.). The choice of the PR specimen as lectotype by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 228. 1910) is invalid; Lamson-Scribner worked from the specimen at MO and never saw the PR material.

Panicum orangense Ashe, J. Elisha Mitchell Sci. Soc. 15: 113. 1899. TYPE: United States. North Carolina: Orange Co., Chapel Hill, 29 June 1898, *Ashe s.n.* (lectotype, US). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 220. 1910).

Panicum albemarlense Ashe, J. Elisha Mitchell Sci. Soc. 16: 84. Feb. 1900. *Panicum meridionale* Ashe var. *albemarlense* (Ashe) Fernald, Rhodora 36: 76. 1934. TYPE: United States. North Carolina: Beauford or

Hyde Co., near Scranton, 26 May 1899, *Ashe s.n.* (lectotype, US). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 212. 1910).

Panicum subvillosum Ashe, J. Elisha Mitchell Sci. Soc. 16: 86. Feb. 1900. TYPE: United States. Minnesota: Carlton Co., Carlton, Aug., *Ashe s.n.* (holotype, NCU).

Panicum wilmingtonense Ashe, J. Elisha Mitchell Sci. Soc. 16: 86. Feb. 1900. TYPE: United States. North Carolina: New Hanover Co., near Wilmington, 17 May 1899, *Ashe s.n.* (holotype, NCU; isotype, US).

Panicum alabamense Ashe, North Carolina Agric. Exp. Sta. Bull. 164: 116. Aug. 1900, non Trinius 1854. TYPE: United States. Alabama: Lee Co., Auburn, 7 May 1898, *Alabama Biol. Surv. 1530* (holotype, NCU; isotypes, NY, US).

Panicum auburne Ashe, North Carolina Agric. Exp. Sta. Bull. 175: 115. Aug. 1900. TYPE: United States. Alabama: Lee Co., Auburn, 7 May 1898, *Earle & Baker 1527* (holotype, NCU; isotype, US).

Panicum unciphyllum Trinius forma *pilosum* Lamson-Scribner & Merrill, Rhodora 3: 124. 20 May 1901. TYPE: United States. Maine: Penobscot Co., Orono, 7 July 1891, *Fernald 501* (holotype, GH).

Panicum unciphyllum Trinius forma *prostratum* Lamson-Scribner & Merrill, Rhodora 3: 124. 20 May 1901. *Panicum languidum* A. Hitchcock & Chase, Contr. U.S. Natl. Herb. 15: 232. 1910. TYPE: United States. Maine: York Co., South Berwick, 26 Sep. 1897, *Fernald s.n.* (holotype, GH).

Panicum xanthospermum Lamson-Scribner & C. Mohr, in Mohr, Contr. U.S. Natl. Herb. 6: 348. 31 July 1901. TYPE: United States. Alabama: Butler Co., Greenville, 8 May 1898, *Mohr s.n.* (holotype, US).

Panicum comophyllum Nash, Bull. Torrey Bot. Club 30: 380. 10 July 1903. TYPE: Puerto Rico: Santurce, 9 Jan. 1899, *Heller & Heller 12* (holotype, NY).

Panicum chrysopsidifolium Nash in Small, Fl. S.E. U.S. 100, 1327. 22 July 1903. TYPE: United States. Florida: Leon Co., Lake Jackson, 12 May 1886, *Curtiss D* (holotype, NY).

Panicum lanuginosum Elliott var. *siccanum* A. Hitchcock & Chase, Rhodora 8: 207, 1906. TYPE: United States. Illinois: LaSalle Co., Starved Rock, 1 July 1901, *Chase 1602* (holotype, US).

Panicum oricola A. Hitchcock & Chase, Rhodora 8: 208. 1906. *Panicum columbianum* Lamson-Scribner var. *oricola* (A. Hitchcock & Chase) Fernald, Rhodora 36: 79. 1934. TYPE: United States. Delaware: Sussex Co., Lewes, 18 June 1905, *Hitchcock 47* (holotype, US; isotypes, MO, NY).

Panicum praecocius A. Hitchcock & Chase, Rhodora 8: 206. 1906. *Panicum lanuginosum* Elliott var. *praecocius* (A. Hitchcock & Chase) Dore in McNeill & Dore, Naturaliste Canad. 103: 576. 1976. *Dichanthelium villosissimum* (Nash) Freckmann var. *praecocius* (A. Hitchcock & Chase) Freckmann, Phytologia 39: 270. 1978. TYPE: United States. Illinois: Stark Co., near Wady Petra, 30 June 1900, *Chase 649* (holotype, US).

Panicum unciphyllum Trinius var. *thinium* A. Hitchcock & Chase, Rhodora 8: 209. 1906. *Panicum columbianum* Lamson-Scribner var. *thinium* (A. Hitchcock & Chase) A. Hitchcock & Chase in Robinson, Rhodora 10: 64. 1908. *Panicum heterophyllum* Bosc ex C. Nees von Esenbeck var. *thinium* (A. Hitchcock & Chase) F. Hubbard, Rhodora 14: 172. 1912. *Dichanthelium sabulorum* (Lamarck) Gould & Clark var. *thinium* (A. Hitchcock & Chase) Gould & Clark, Ann. Missouri Bot. Gard. 65: 1113. 1978. TYPE: United States. New Jersey: Ocean Co., Toms River, 28 July 1906, *Chase 3577* (holotype, US).

Panicum oweniae Bicknell, Bull. Torrey Bot. Club 35: 185. 29 Apr. 1908. TYPE: United States. Massachusetts: Nantucket Co., W of Nantucket, 20 Sep. 1907, *Bicknell s.n.* (holotype, NY; isotypes, NY, US).

Panicum huachucae Ashe var. *silvicola* A. Hitchcock & Chase in Robinson, Rhodora 10: 64. 16 May 1908. TYPE: United States. District of Columbia: 28 June 1904, *Chase 2400* (holotype, US).

Panicum olivaceum A. Hitchcock & Chase, Contr. U.S. Natl. Herb. 15: 225. 1910. TYPE: Guatemala. Alta Verapaz: Coban, Feb. 1888, *Türckheim 428* (holotype, US).

Panicum pacificum A. Hitchcock & Chase, Contr. U.S. Natl. Herb. 15: 229. 1910. TYPE: United States. California: Shasta Co., Castle Crag, ¼ mi. E of hotel, 3 Aug. 1908, *Hitchcock 3070* (holotype, US).

Panicum lindheimeri Nash var. *septentrionale* Fernald, Rhodora 23: 227. 1922 ("1921"). *Panicum lanuginosum* Elliott var. *septentrionale* (Fernald) Fernald, Rhodora 36: 77. 1934. TYPE: Canada. New Brunswick: St. John River, Woodstock, 14 July 1916, *Fernald & Long 12527* (holotype, GH).

Panicum deamii A. Hitchcock & Chase in Deam, Indiana Conserv. Dept. Publ. 82: 284, pl. 75(18). 1929. TYPE: United States. Indiana: Lake Co., ¼ mi. S of Pine, 21 June 1926, *Deam 43287* (holotype, US).

Panicum mundum Fernald, Rhodora 38: 392, pl. 443(1–5). 1936. TYPE: United States. Virginia: Sussex Co., 4 mi. NW of Homeville, 25 Aug. 1936, *Fernald & Long 6499* (holotype, GH; isotypes, MO, NY, US).

Panicum brodiei H. Saint John, Fl. S.-e. Washington 51. 1937. TYPE: United States. Washington: Whitman Co., Wawai, Snake River, June 1893, *Brodie s.n.* (holotype, WS).

Panicum lassenianum Schmoll, Madroño 5: 95. 1939. TYPE: United States. California: Plumas Co., Devil's Kitchen, Hot Spring Valley, *Jepson 4082* (holotype, US).

Panicum glutinoscabrum Fernald, Rhodora 49: 122. 1947. TYPE: United States. Virginia: Nansemond Co., ca. ½ mi. W of Kilby, 8–12 Sep. 1946, *Fernald et al. 15186* (holotype, GH; isotype, PH).

This taxon is common in north Florida south to the central peninsula, occurring primarily in pine flatwoods.

Dichanthelium acuminatum (Swartz) Gould & Clark var. **densiflorum** (Rand & Redfield) Gould & Clark, Ann. Missouri Bot. Gard. 65: 1127. 1978. *Panicum nitidum* Lamarck var. *densiflorum* Rand & Redfield, Fl. Mt. Desert 174. 1894. *Panicum acuminatum* Swartz var. *densiflorum* (Rand & Redfield) Lelong, Brittonia 36: 270. 1984. TYPE: United States. Maine: Hancock Co., Mt. Desert, Ripples Pond, 28 July 1892, *Rand s.n.* (holotype, GH).

Panicum spretum Schultes, Mant. 2: 248. 1824. *Dichanthelium spretum* (Schultes) Freckmann, Phytologia 48: 102. 1981. TYPE: United States: "N. Anglica," *Muhlenberg Herb. Panicum no. 37* (holotype, PH).

Panicum eatonii Nash, Bull. Torrey Bot. Club 25: 84. 1898. TYPE: United States. New Hampshire: Rockingham Co., Seabrook, 1897, *Eaton s.n.* (holotype, NY; isotype, US).

Panicum octonodum J. G. Smith, U.S.D.A. Div. Agrost. Bull. 17: 73. 1899. *Panicum nitidum* Lamarck var. *octonodum* (J. G. Smith) Lamson-Scribner & Merrill, U.S.D.A. Div. Agrost. Bull. 24: 34. 1901. TYPE: United States. Texas: Waller Co., 5 May 1898, *Thurow 6* (holotype, US).

Panicum paucipilum Nash, Bull. Torrey Bot. Club 26: 573. Nov. 1899. TYPE: United States. New Jersey: Cape May Co., Wildwood, 30–31 May 1897, *Bicknell s.n.* (holotype, NY; isotypes, NY, US).

This weak variety is apparently rather uncommon in Florida, found only along the northern edge of the state.

Dichanthelium acuminatum var. **lindheimeri** (Nash) Gould & Clark, Ann. Missouri Bot. Gard. 65: 1127. 1978. *Panicum lindheimeri* Nash, Bull. Torrey Bot. Club 24: 196. 1897. *Panicum lindheimeri* Nash var. *typicum* Fernald, Rhodora 23: 227. 1922 ("1921"), nom. inadmiss. *Panicum lanuginosum* Elliott var. *lindheimeri* (Nash) Fernald, Rhodora 36: 77. 1934. *Dichanthelium lindheimeri* (Nash) Gould, Brittonia 26: 60. 1974. *Dichanthelium lanuginosum* (Elliott) Gould var. *lindheimeri* (Nash) Freckmann, Phytologia 39: 270. 1978. *Panicum acuminatum* Swartz var. *lindheimeri* (Nash) Beetle, Phytologia 48: 193. 1981. TYPE: United States. Texas: Comal Co., banks of the Guadelupe River, Near New Braunfels, 1846, *Lindheimer 565* (holotype, NY; isotypes, MO, NY).

Panicum funstonii Lamson-Scribner & Merrill, U.S.D.A. Div. Agrost. Circ. 35: 4. 1901. TYPE: United States. California: Tulare Co., bank of Kaweah River at Three Rivers, 26 July 1891, *Coville & Funston 1286* (holotype, US).

In Florida, this variety is confined to the northern counties. Variety *lindheimeri* represents the more glabrous extremes of *D. acuminatum*.

Dichanthelium boscii (Poiret) Gould & Clark, Ann. Missouri Bot. Gard. 65: 1101. 1978. *Panicum boscii* Poiret in Lamarck, Encycl. Suppl. 4: 278. 1816. TYPE: United States: *Bosc s.n.* (lectotype, P; isotype, US, fragm.). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 317. 1910).

Panicum waltheri Poiret in Lamarck, Encycl. Suppl. 4: 282. 1816. *Panicum porterianum* Nash, Bull. Torrey Bot. Club 22: 420. 1895, nom. illegit. TYPE: United States: "in pratis sylvestris Virginiae Carolinae," *Michaux s.n.* (lectotype, P). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 317. 1910). The application of *Panicum porterianum* can be quite confusing. Nash based his new name on three entities, namely "*Panicum latifolium* Walt. Fl. Car. 73. 1788. Not Linnaeus, 1753. *Panicum Walteri* [*waltheri*] Poir. in Lam. Encycl. Suppl. 4: 282. 1816. Not Pursh, 1814. *Panicum latifolium* var. *molle* Vasey, Bull. Bot. Div., U.S. Dept. Agric. 8: 33 [error for 34]. 1889." If, as interpreted here, *Panicum waltheri* Poir. is not a later homonym of *P. walteri* Pursh 1814, *P. waltheri* Poir. is a valid earlier name cited under *P. porterianum*, which makes the latter name illegitimate and automatically typified by the type of *P. waltheri* Poir. If, on the other hand, *P. waltheri* Poir. is considered a typographic error for *walteri*, and is therefore a later homonym of *P. walteri* Pursh, the lectotype of *P. porterianum* may be chosen from any of the entities cited by Nash. This was effectively done by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 317. 1910), who cited *P. porterianum* as a nomen novum for *P. walt*[*h*]*eri* Poir. Therefore, whether *P. waltheri* Poir. is judged to be valid or not, *P. porterianum* is always disposed as its homotypic synonym.

Panicum latifolium Linnaeus var. *australe* Vasey, U.S.D.A. Div. Agrost. Bull. 8: 34. 1889. TYPE: United States. Alabama: Clark Co., Thomasville, 16 Apr. 1888, *Mohr s.n.* (holotype, US).

Panicum latifolium Linnaeus var. *molle* Vasey, U.S.D.A. Div. Agrost. Bull. 8: 34. 1889. *Panicum waltheri* Poiret var. *molle* (Vasey) Porter, Bull. Torrey Bot. Club 20: 194. 1893. *Panicum boscii* Poiret var. *molle* (Vasey) A. Hitchcock & Chase in Robinson, Rhodora 10: 64. 1908. *Panicum pubifolium* Nash, Bull. Torrey Bot. Club 26: 577. 1899. TYPE: United States. District of Columbia: *Ward s.n.* (holotype, US).

This species is rather uncommon in Florida, occurring in the panhandle and south to Levy County.

Dichanthelium clandestinum (Linnaeus) Gould, Brittonia 26: 59. 1974. *Panicum clandestinum* Linnaeus, Sp. Pl. 58. 1753. *Milium clandestinum* (Linnaeus) Moench, Methodus 204. 1794. *Panicum latifolium* Linnaeus var. *clandestinum* (Linnaeus) Pursh, Fl. Amer. Sept. 1: 68. 1814. *Chasea clandestina* (Linnaeus) Nieuwland, Amer. Midl. Naturalist 2: 64. 1911. TYPE: United States. Pennsylvania: *Kalm s.n.* (lectotype, LINN 80.57). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 312. 1910).

Panicum pedunculatum Torrey, Fl. N. Middle United States 141. 1824. *Panicum clandestinum* Linnaeus var. *pedunculatum* (Torrey) Torrey, Fl. New York

2: 426. 1841. TYPE: United States. New York: "On the island of New-York," Aug., *Torrey s.n.* (holotype, NY; isotype, US, fragm.).

Panicum decoloratum Nash, Bull. Torrey Bot. Club 26: 570. 1899. TYPE: United States. Pennsylvania: Bucks Co., Tullytown, 30 May 1899, *Bicknell s.n.* (holotype, NY; isotype, US).

An uncommon species in Florida, found only in the western panhandle. It occurs in moist to wet sandy soil in woods.

Dichanthelium commutatum (Schultes) Gould, Brittonia 26: 59. 1974. *Panicum nervosum* Muhlenberg ex Elliott, Sketch Bot. S. Carolina 1: 122. 1816, non Lamarck 1797. *Panicum commutatum* Schultes, Mant. 2: 242. 1824. *Panicum polyneuron* Steudel, Syn. Pl. Glumac. 1: 91. 1854, nom. illegit. TYPE: United States. "Car. et Geor.," *Elliott Herb. s.n.* (lectotype, CHARL). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 303. 1910).

Panicum nitidum Lamarck var. *majus* Pursh, Fl. Amer. Sept. 1: 67. 1814. TYPE: United States: *Pursh s.n.* (lectotype, K). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 303. 1910).

Panicum umbrosum LeConte ex Torrey, Cat. Pl. New York 91. 1819, non Retzius 1786. TYPE: United States. New York: Essex Co., Bloomingdale, *LeConte s.n.* (lectotype, NY). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 301. 1910).

Panicum enslinii Trinius, Gram. Panic. 230. 1826. TYPE: United States. "Am. bor.," *Enslin s.n.* (lectotype, LE). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 304. 1910).

Panicum leiophyllum Fournier, Mexic. Pl. 2: 20: 1886, non C. Nees von Esenbeck 1829. TYPE: Mexico. Veracruz: "in valle Cordovensi," Jan., *Bourgeau s.n.* (holotype, P).

Panicum commutatum Schultes var. *minor* Vasey, U.S.D.A. Div. Agrost. Bull. 8: 34. 1889, as "minorus." *Panicum ashei* G. Pearson ex Ashe, J. Elisha Mitchell Sci. Soc. 15: 35. 1898. *Panicum commutatum* Schultes var. *ashei* (G. Pearson ex Ashe) Fernald, Rhodora 36: 83. 1934. TYPE: United States. South Carolina: Aiken Co., Aiken, 1867, *Ravenel s.n.* (lectotype, NY). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 304. 1910). *Panicum ashei* is a new name for Vasey's variety and should be treated as a homotypic synonym, not retypified with another element as did Hitchcock & Chase (1910).

Panicum joorii Vasey, U.S.D.A. Div. Agrost. Bull. 8: 31. 1889. TYPE: United States. Louisiana: East Baton Rouge Par., near Baton Rouge, 1 Oct. 1885, *Joor 39* (holotype, US).

Panicum commutatum Schultes var. *latifolium* Lamson-Scribner in Kearney, Bull. Torrey Bot. Club 20: 476. 1893. TYPE: United States. Kentucky: Harlan Co., Pine Mountain, Aug. 1893, *Kearney 299* [?] (lectotype, US). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 304. 1910). The lectotype is a sheet without data; collection data come from the protologue.

Panicum manatense Nash, Bull. Torrey Bot. Club 24: 42. 1897. TYPE: United States. Florida: Manatee Co., NE of Palmetto, 21 Aug. 1895, *Nash 2428a* (holotype, NY).

Panicum equilaterale Lamson-Scribner, U.S.D.A. Div. Agrost. Bull. 11: 42, pl. 2. 30 July 1898. TYPE: United States. Florida: Lake Co., Eustis, Aug. 1894, *Nash 1674* (lectotype, US). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 310. 1910).

Panicum commelinifolium Ashe, J. Elisha Mitchell Sci. Soc. 15: 29. 1898, non Rudge 1805. *Panicum curranii* Ashe, J. Elisha Mitchell Sci. Soc. 15: 113. 1899. TYPE: United States. Georgia: DeKalb Co., near Stone Mountain, 1–6 Aug. 1895, *Small s.n.* (lectotype, US). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 304. 1910).

Panicum epilifolium Nash, Bull. Torrey Bot. Club 26: 571. 1899. TYPE: United States. Florida: Lake Co., Eustis, 12–31 Mar. 1894, *Nash 45* (lectotype, NY). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 310. 1910).

Panicum subsimplex Ashe, North Carolina Agric. Exp. Sta. Bull. 175: 115. 1900. TYPE: United States. Delaware: Newcastle Co., near Wilmington, 16 Aug. 1897, *Commons s.n.* (holotype, NCU).

Panicum mutabile Lamson-Scribner & J. G. Smith ex Nash in Small, Fl. S.E. U.S. 103, 1327. 1903. TYPE: United States. Mississippi: Harrison Co., Biloxi, 1896, *Tracy 3074* (holotype, NY).

Panicum hintonii Swallen, Contr. U.S. Natl. Herb. 29: 419. 1950. TYPE: Mexico. México: Bejucos, Temascaltepec, 8 Nov. 1932, *Hinton 2527* (holotype, US).

Dichanthelium commutatum is very common throughout Florida. It is found primarily in moist, shaded areas.

Dichanthelium dichotomum (Linnaeus) Gould, Brittonia 26: 59. 1974. *Panicum dichotomum* Linnaeus, Sp. Pl. 58. 1753. TYPE: United States. Virginia: "Habitat in Virginia," *Clayton 458* (lectotype, BM; isotype, US, fragm.). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 190. 1910). Lelong (1984) erred by citing the lectotype at LINN.

Panicum nitidum Lamarck, Tabl. Encycl. 1: 172. 1791. *Panicum dichotomum* Linnaeus var. *nitidum* (Lamarck) Wood, Class-Book Bot., ed. 1861. 786. 1861. TYPE: United States. "E. Carolina," *Fraser s.n.* (holotype, P-LA).

Panicum nodiflorum Lamarck, Encycl. 4: 744. 1798. *Panicum dichotomum* Linnaeus var. *nodiflorum* (Lamarck) Grisebach, Cat. Pl. Cub. 234. 1866. TYPE: United States. "Caroline," *Fraser s.n.* (holotype, P-LA; isotype, US, fragm.).

Panicum barbulatum Michaux, Fl. Bor.-Amer. 1: 49. 1803. *Panicum dichotomum* Linnaeus var. *barbulatum* (Michaux) Alph. Wood, Class-Book Bot., ed. 1861. 786. 1861. *Panicum pubescens* Lamarck var. *barbulatum* (Michaux) Britton, Cat. Pl. New Jersey 280. 1889. *Panicum nitidum* Lamarck var. *barbulatum* (Michaux) Chapman, Fl. South. U.S., ed. 3. 586. 1897. TYPE: Canada: "Hab. in Canada P. capillari affine. Ad ripas amnis: *Riviere* a Jacques Cartier dicti legi," *Michaux s.n.* (lectotype, P-M; isotype, US, fragm.). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 193. 1910).

Panicum microcarpon Muhlenberg ex Elliott, Sketch Bot. S. Carolina 1: 127. 1816. TYPE: United States. Georgia: *Baldwin s.n.* (lectotype, CHARL). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 181. 1910).

Panicum angustifolium LeConte ex Torrey, Cat. Pl. New York 91. 1818, non Elliott 1816. TYPE: unknown.

Panicum tremulum Sprengel, Neue Entd. 2: 103. 1821. TYPE: United States: *Muhlenberg Herb. s.n.* (lectotype, B [destroyed]; isotype, US, fragm.). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 190. 1910).

Panicum nitidum Lamarck var. *barbatum* Torrey, Fl. N. Middle United States 146. 1824. TYPE: unknown.

Panicum nitidum Lamarck var. *ramulosum* Torrey, Fl. N. Middle United States 146. 1824. *Panicum dichotomum* Linnaeus var. *ramulosum* (Torrey) Lelong, Brittonia 36: 265. 1984. TYPE: United States. New Jersey: near Quaker Bridge, June 1818, *Torrey s.n.* (holotype, NY).

Panicum dumus Desvaux, Opusc. Sci. Phys. Nat. 88. 1831. TYPE: United States? "America calidiori," *Desvaux Herb. s.n.* (holotype, P).

Panicum dichotomum Linnaeus var. *divaricatum* Vasey, U.S.D.A. Div. Agrost. Bull. 8: 30. 1889. TYPE: United States. Mississippi: Scott Co., Lake, *Tracy 127* (lectotype, US). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 191. 1910).

Panicum dichotomum Linnaeus var. *viride* Vasey, U.S.D.A. Div. Agrost. Bull. 8: 30. 1889. *Panicum nitidum* Lamarck var. *viride* (Vasey) Britton, Trans. New York Acad. Sci. 9: 14. 1889. *Panicum ramulosum* Michaux var. *viride* (Vasey) Porter, Bull. Torrey Bot. Club 20: 194. 1893. TYPE: United States. District of Columbia: Woodley Park, 1881, *Ward s.n.* (lectotype, US). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 191. 1910).

Panicum nudicaule Vasey, U.S.D.A. Div. Agrost. Bull. 8: 31. 1889. TYPE: United States. Florida: Santa Rosa Co., May 1886, *Curtiss 3583* (lectotype, US; isotypes, NY, TAES). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 179, 1910).

Panicum dichotomum Linnaeus var. *commune* S. Watson & Coulter in A. Gray, Manual, ed. 6. 633. 1890. TYPE: unknown.

Panicum sphagnicola Nash, Bull. Torrey Bot. Club 22: 422. 1895. TYPE: United States. Florida: Columbia Co., Lake City, 29–31 Aug. 1895, *Nash 2500* (lectotype, NY; isotypes, NY). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 199. 1910).

Panicum annulum Ashe, J. Elisha Mitchell Sci. Soc. 15: 58. 1898. *Panicum bogueanum* Ashe, J. Elisha Mitchell Sci. Soc. 16: 85. 1900, nom. illegit. TYPE: United States. District of Columbia: 1882, *Ward s.n.* (lectotype, US). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 185. 1910).

Panicum lucidum Ashe, J. Elisha Mitchell Sci. Soc. 15: 47. 1898. *Panicum dichotomum* Linnaeus var. *lucidum* (Ashe) Lelong, Brittonia 36: 265. 1984. TYPE: United States. North Carolina: Dare Co., swamps bordering Lake Mattamuskeet, June 1898, *Ashe s.n.* (lectotype, US). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 198. 1910).

Panicum maculatum Ashe, J. Elisha Mitchell Sci. Soc. 15: 44. 1898, non Aublet 1775. *Panicum yadkinense* Ashe, J. Elisha Mitchell Sci. Soc. 16: 85. 1900. *Panicum dichotomum* Linnaeus var. *yadkinense* (Ashe) Lelong, Brittonia 36: 266. 1984. TYPE: United States. North Carolina: Wake Co., Raleigh, May 1895, *Ashe s.n.* (lectotype, US). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 195. 1910).

Panicum mattamuskeetense Ashe, J. Elisha Mitchell Sci. Soc. 15: 45. 1898. *Panicum dichotomum* Linnaeus var. *mattamuskeetense* (Ashe) Lelong, Brittonia 36: 265. 1984. TYPE: United States. North Carolina: Hyde Co., Lake Mattamuskeet, 10 June–6 July 1898, *Ashe s.n.* (lectotype, US; isotype, NY). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 186. 1910).

Panicum roanokense Ashe, J. Elisha Mitchell Sci. Soc. 15: 44. 1898. *Panicum dichotomum* Linnaeus var. *roanokense* (Ashe) Lelong, Brittonia 36: 265. 1984. TYPE: United States. North Carolina: Dare Co., Roanoke Island, June 1898, *Ashe s.n.* (lectotype, US). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 196. 1910).

Panicum clutei Nash, Bull. Torrey Bot. Club 26: 569. 1899. *Panicum mattamuskeetense* Ashe var. *clutei* (Nash) Fernald, Rhodora 39: 386. 1937. TYPE: United States. New Jersey: Tuckerton to Atsion, 3–6 July 1899, *Clute s.n.* (holotype, NY).

Panicum curtivaginum Ashe, J. Elisha Mitchell Sci. Soc. 16: 85. 1900. TYPE: United States. Mississippi: Jackson Co., Petit Bois Island, 8 May 1898, *Tracy 4584* (lectotype, NCU?; isotype, US). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 196. 1910). Specimen at NCU not located.

Panicum taxodiorum Ashe, J. Elisha Mitchell Sci. Soc. 16: 91. 1900. TYPE: United States. Louisiana: Calcasieu Par., Lake Charles, Sep. 1898, *Mackenzie 460* (lectotype, NCU; isotype, NY). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 198. 1910). Both Lelong (1984) and Gould & Clark (1978) cited the "holotype" as residing at NY. Hitchcock & Chase, by contrast, stated that the type was in Ashe's herbarium, which is now at NCU.

Panicum multirameum Lamson-Scribner, U.S.D.A. Div. Agrost. Circ. 19: 2. 1900. TYPE: Mexico. Veacruz: Near Jalapa, 1889, *Pringle 7882* (lectotype, US; isotype, MO). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 185. 1910).

Panicum subbarbulatum Lamson-Scribner & Merrill, U.S.D.A. Div. Agrost. Circ. 29: 9. 1901. TYPE: United States: *Elliott Herb. s.n.* (holotype, CHARL).

Panicum gravius A. Hitchcock & Chase, Rhodora 8: 205. 1906. TYPE: United States. Delaware: Newcastle Co., on the old Commons farm, between Centreville and Mt. Cuba, 30 July 1906, *Chase 3620* (holotype, US).

Panicum caerulescens Hackel ex A. Hitchcock, Contr. U.S. Natl. Herb. 12: 219. 1909. TYPE: United States.

Florida: Dade Co., Miami, 3 Apr. 1906, *Hitchcock 706* (holotype, US; isotype, NY).

Panicum lucidum Ashe var. *opacum* Fernald, Rhodora 39: 386. 1937. TYPE: United States. Virginia: Prince George Co., N of Gary Church, 25 Aug. 1936, *Fernald & Long 6484* (holotype, GH; isotypes, MO, NY, PH, US).

Gould & Clark (1978) included the generally cushion-forming plants with small spikelets as varieties of *D. dichotomum.* We agree with Lelong (1984, 1986) that these should be separated from *D. dichotomum,* but instead of two species each with two varieties, as one species with three varieties: *D. ensifolium* vars. *ensifolium, unciphyllum,* and *breve.* This leaves *D. dichotomum* consisting of the larger, more diffuse plants with spikelets longer than 1.5 mm. Lelong (1984, 1986) recognized seven varieties of *P. dichotomum* in this group, based on leaf size and pubescence forms. The Florida material shows too much overlap in these characters for satisfactory separation.

This species is common throughout Florida, occurring in both dry and moist habitats.

Dichanthelium ensifolium (Baldwin ex Elliott) Gould, Brittonia 26: 59. 1974. *Panicum ensifolium* Baldwin ex Elliott, Sketch Bot. S. Carolina 1: 126. 1816. *Panicum nitidum* Lamarck var. *ensifolium* (Baldwin ex Elliott) Vasey, U.S.D.A. Div. Agrost. Bull. 8: 29. 1889. *Dichanthelium dichotomum* (Linnaeus) Gould var. *ensifolium* (Baldwin ex Elliott) Gould & Clark, Ann. Missouri Bot. Gard. 65: 1119. 1978. TYPE: United States. Georgia: *Baldwin s.n.* (holotype, CHARL; isotypes, PH, US, fragm.).

We recognize three varieties of *Dichanthelium ensifolium* in Florida:

1a. Lower internodes strigose; leaves less than 2 mm wide .... var. *breve*
1b. Lower internodes glabrous to slightly puberulent; most leaves wider than 2 mm.
    2a. Spikelets pubescent; leaves often with white margins .... var. *unciphyllum*
    2b. Spikelets glabrous to sparingly pubescent; leaves without white margins ... var. *ensifolium*

Dichanthelium ensifolium (Baldwin ex Elliott) Gould var. **ensifolium**

Panicum chamaelonche Trinius, Gram. Panic. 242. 1826. TYPE: United States. "Am. bor.," *Enslin s.n.* (holotype, LE; isotype, US, fragm.).

Panicum nitidum Lamarck var. *minus* Vasey, Contr. U.S. Natl. Herb. 3: 30. 1892. TYPE: United States. Florida: St. Johns Co., St. Augustine, Apr. 1869, *Canby s.n.* (lectotype, US). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 268. 1910).

Panicum baldwinii Nuttall ex Chapman, Fl. South. U.S., ed. 3. 586. 1897. TYPE: United States. Florida: *Baldwin s.n.* (lectotype, PH). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 168. 1910).

Panicum brittonii Nash, Bull. Torrey Bot. Club 24: 194. 1897. TYPE: United States. New Jersey: Ocean Co., Forked River, 29 May–2 June 1896, *Britton s.n.* (holotype, NY).

Panicum glabrifolium Nash, Bull. Torrey Bot. Club 24: 196. 1897. *Dichanthelium dichotomum* (Linnaeus) Gould var. *glabrifolium* (Nash) Gould & Clark, Ann. Missouri Bot. Gard. 65: 1120. 1978. TYPE: United States. Florida: Hillsborough Co., Tampa, 20 Aug. 1895, *Nash 2415a* (holotype, NY).

Panicum cuthbertii Ashe, J. Elisha Mitchell Sci. Soc. 15: 48. 1898. TYPE: United States. South Carolina: Beaufort Co., St. Helena Island, 1887, *Cuthbert s.n.* (holotype, NCU; isotype, US, fragm.).

Panicum glabrissimum Ashe, J. Elisha Mitchell Sci. Soc. 15: 62. 1898. *Panicum shallotte* Ashe, J. Elisha Mitchell Sci. Soc. 16: 84. 1900, nom. illegit. TYPE: United States. North Carolina: Dare Co., Manteo, June 1898, *Ashe s.n.* (lectotype, US; isotype, NY, US). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 265. 1910).

Panicum curtifolium Nash, Bull. Torrey Bot. Club 26: 569. 1899. *Panicum ensifolium* Baldwin ex Elliott var. *curtifolium* (Nash) Lelong, Brittonia 36: 266. 1984. TYPE: United States. Mississippi: Jackson Co., Ocean Springs, 2 May 1898, *Nash 4598* (holotype, NY; isotype, US).

Panicum earlei Nash, Bull. Torrey Bot. Club 26: 571. 1899. TYPE: United States. Alabama: Lee Co., Auburn, 7 May 1898, *Earle & Baker 1532* (holotype, NY; isotype, US).

Panicum flavovirens Nash, Bull. Torrey Bot. Club 26: 572. 1899. TYPE: United States. Florida: Lake Co., "along the edge of road leading to the ford near the J.T. & K.W. R.R. bridge across the Wekiva river," near Eustis, 26–30 June 1895, *Nash 2061* (holotype, NY).

Panicum austromontanum Ashe, J. Elisha Mitchell Sci. Soc. 16: 85. 1900. TYPE: United States. Alabama: Jackson Co., Sand Mountain, June 1899, *Ashe s.n.* (lectotype, US). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 267. 1910).

Panicum parvipaniculatum Ashe, J. Elisha Mitchell Sci. Soc. 16: 87. 1900. TYPE: United States. North Carolina: Onslow Co., 10–18 mi. E of Jacksonville, 20 May 1899, *Ashe s.n.* (lectotype, NCU; isotype, US). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 265. 1910).

Panicum vernale A. Hitchcock & Chase, Contr. U.S. Natl. Herb. 15: 266. 1910. TYPE: United States. Florida: Columbia Co., Lake City, 16 Apr. 1906, *Hitchcock 1020* (holotype, US; isotype, ISC).

This variety is very common throughout Florida, occurring in seeps, bogs, and wet pinelands.

Dichanthelium ensifolium (Baldwin ex Elliott) Gould var. **breve** (A. Hitchcock & Chase) B. F. Hansen & Wunderlin, comb. nov. BASIONYM: *Panicum breve* A. Hitchcock & Chase, Contr. U.S. Natl. Herb. 15: 271. 1910. *Dichan-*

thelium dichotomum (Linnaeus) Gould var. *breve* (A. Hitchcock & Chase) Gould & Clark, Ann. Missouri Bot. Gard. 65: 1120. 1978. *Panicum chamaelonche* Trinius var. *breve* (A. Hitchcock & Chase) Lelong, Brittonia 36: 267. 1984. TYPE: United States. Florida: Martin Co., "Jensen," 5 Apr. 1906, *Hitchcock 734* (holotype, US).

This variety is endemic to the white sand scrub vegetation of central Florida.

Dichanthelium ensifolium (Baldwin ex Elliott) Gould var. **unciphyllum** (Trinius) B. F. Hansen & Wunderlin, comb. nov. BASIONYM: *Panicum unciphyllum* Trinius, Gram. Panic. 242. 1826; and the autonym created by *P. unciphyllum* Trinius var. *implicatum* (Lamson-Scribner) Lamson-Scribner & Merrill 1901. *Panicum acuminatum* Swartz var. *unciphyllum* (Trinius) Lelong, Brittonia 36: 269. 1984. TYPE: North America, without data (lectotype, LE). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 259. 1910). For comments concerning the mistypification by Lelong (1984), see under *D. acuminatum* var. *implicatum*.

Panicum tenue Muhlenberg, Descr. Gram. 118. 1817. *Panicum liton* Schultes, Mant. 2: 250. 1824, nom. illegit. *Panicum macrum* Kunth, Révis. Gramin. 1: 40. 1829, nom. illegit. *Dichanthelium dichotomum* (Linnaeus) Gould var. *tenue* (Muhlenberg) Gould & Clark, Ann. Missouri Bot. Gard. 65: 1119. 1978. TYPE: United States: *Muhlenberg Herb. 192* (lectotype, PH-M; isotype, US, fragm.). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 259. 1910).

Panicum albomarginatum Nash, Bull. Torrey Bot. Club 24: 40. 1897. TYPE: United States. Florida: Lake Co., near Eustis, June 1894, *Nash 925* (holotype, NY; isotypes, MO, NY, US).

Panicum trifolium Nash, Bull. Torrey Bot. Club 26: 580. 1899. TYPE: United States. Georgia: Bibb Co., Ocmulgee River Swamp below Macon, 18–24 May 1895, *Small s.n.* (holotype, NY; isotype, US).

Panicum gracilicaule Nash in Small, Fl. S.E. U.S. 98, 1327. 1903, non Rendle 1899. *Panicum concinnius* A. Hitchcock & Chase, Contr. U.S. Natl. Herb. 15: 263. 1910. TYPE: United States. Alabama: Jackson Co., Sand Mountain, 1900, *Harbison 2415* (holotype, NY).

Lelong (1984, 1986) applied the epithet *unciphyllum* to a variety of *D. acuminatum*. While *unciphyllum* is certainly the earliest epithet for Lelong's variety, there is a good deal of doubt that it belongs with *D. acuminatum*. Hitchcock & Chase (1910) lectotypified *Panicum unciphyllum* with material now at LE. The LE material apparently has two collections on one sheet. According to Hitchcock & Chase, the collection chosen as lectotype is conspecific with *Panicum tenue*, while the other collection (by Enslin) matches *Panicum columbianum*, neither of which belongs in *D. acuminatum*. Without having seen the specimen, Lelong (1984) cited as holotype (not lectotype) of *Panicum unciphyllum* the Enslin collection at LE, this without explanation of the rejection of the earlier Hitchcock & Chase lectotypification. Without such explanation and barring further discoveries concerning the type, the lectotypification of Hitchcock & Chase must be followed. Therefore, *Panicum unciphyllum* is once again considered conspecific with *Panicum tenue*, which in turn is placed in *Dichanthelium ensifolium*. It is unfortunate that *unciphyllum* also turns out to be the earliest varietal epithet for what has been called *Panicum tenue*, this adding to the confusion.

This variety often approaches *D. dichotomum* in general aspect but is better classified with *D. ensifolium* on the basis of spikelet size. It is common throughout Florida, occurring in wet pinelands and woods.

Dichanthelium erectifolium (Nash) Gould & Clark, Ann. Missouri Bot. Gard. 65: 1105. 1978. *Panicum sphaerocarpon* Elliott var. *floridanum* Vasey, U.S.D.A. Div. Agrost. Bull. 8: 33. 1889. *Panicum erectifolium* Nash, Bull. Torrey Bot. Club 23: 148. 1896. *Panicum floridanum* (Vasey) Chapman, Fl. South. U.S., ed. 3. 585. 1897, non Trinius 1835. TYPE: United States. Florida: "Moist pine barrens, Mosquito Inlet," May 1879, *Curtiss 3599* (lectotype, US; isotype, MO). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 256. 1910).

This species is closely related to *D. sphaerocarpon* but readily separable on the basis of spikelet size. It is quite common throughout most of Florida, except for southern Florida and the Keys, in moist flatwoods and meadows.

Dichanthelium laxiflorum (Lamarck) Gould, Brittonia 26: 60. 1974. *Panicum laxiflorum* Lamarck, Encycl. 4: 748. 1798. *Panicum dichotomum* Linnaeus var. *laxiflorum* (Lamarck) Beal, Grasses N. Amer. 2: 139. 1896. TYPE: United States?: *Lamarck Herb. s.n.* (holotype, P-L).

Panicum xalapense Kunth, in Humboldt, Bonpland & Kunth, Nov. Gen. Sp. 1: 103. 1816. TYPE: Mexico. Veracruz: near Jalapa, *Humboldt & Bonpland s.n.* (holotype, P).

Panicum ruprechtii Fournier, Mexic. Pl. 2: 21. 1886, non Fenzl 1854. TYPE: Mexico. Veracruz: Jalapa, *Galeotti 5733* (holotype, BR).

Panicum pyriforme Nash, Bull. Torrey Bot. Club 26: 579. 1899. TYPE: United States. Florida: Lake Co., Orange Bend, 12–31 Mar. 1894, *Nash 239* (holotype, NY; isotypes, MO, NY, US).

Panicum xalapense Kunth var. *strictirameum* A. Hitchcock & Chase, Contr. U.S. Natl. Herb. 15: 161. 1910. *Panicum laxiflorum* Lamarck var. *strictirameum* (A. Hitchcock & Chase) Fernald, Rhodora 36: 75. 1934. TYPE: United States. Mississippi: Hinds Co., Jackson, 28 Apr. 1906, *Hitchcock 1311* (holotypes, US).

Dichanthelium laxiflorum is common throughout Florida except for Dade and Monroe counties. It is usually found in moist woods.

Dichanthelium leucothrix (Nash) Freckmann, Phytologia 58: 101. 1981. *Panicum leucothrix* Nash, Bull. Torrey Bot. Club 24: 41. 1897. *Panicum acuminatum* Swartz var. *leucothrix* (Nash) Lelong, Brittonia 36: 271. 1984. TYPE: United States. Florida: Lake Co., near Eustis, July 1894, *Nash 1338* (holotype, NY; isotypes, NCU, NY, TAES, US).

Panicum strictum Bosc ex Roemer & Schultes, Syst. Veg. 2: 447. 1817, non R. Brown 1810. TYPE: United States. "Carolina," *Bosc s.n.* (lectotype, M; isotype, B-W). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 207. 1910).

Panicum minutulum Desvaux, Opusc. Sci. Phys. Nat. 87. 1831, non Gaudichaud-Beaupré 1826. TYPE: United States?: *Desvaux Herb. s.n.* (holotype, P).

Panicum parvispiculum Nash, Bull. Torrey Bot. Club 24: 347. 1897. TYPE: United States. Georgia: McIntosh Co., Darien Junction, 25–27 June 1895, *Small s.n.* (holotype, NY; isotype, US, fragm.).

Panicum wrightianum Lamson-Scribner, U.S.D.A. Div. Agrost. Bull. 11: 44, f. 4. 1898. *Dichanthelium acuminatum* (Swartz) Gould & Clark var. *wrightianum* (Lamson-Scribner) Gould & Clark, Ann. Missouri Bot. Gard. 65: 1126. 1978. *Dichanthelium wrightianum* (Lamson-Scribner) Freckmann, Phytologia 48: 101. 1981. TYPE: Cuba: *Wright 3463* (holotype, US).

Panicum longiligulatum Nash, Bull. Torrey Bot. Club 26: 574. 1899. *Dichanthelium acuminatum* (Swartz) Gould & Clark var. *longiligulatum* (Nash) Gould & Clark, Ann. Missouri Bot. Gard. 65: 1127. 1978. *Dichanthelium longiligulatum* (Nash) Freckmann, Phytologia 48: 102. 1981. *Panicum acuminatum* Swartz var. *longiligulatum* (Nash) Lelong, Brittonia 36: 270. 1984. TYPE: United States. Florida: Franklin Co., Apalachicola, 1892, *Vasey s.n.* (holotype, NY).

Dichanthelium leucothrix is the small-fruited member of the *D. acuminatum* complex. Robust, glabrous specimens may be difficult to separate from *D. acuminatum* var. *lindheimeri*, which has larger, fewer-fruited inflorescences and a more northerly distribution. There may be some justification for the separation of the glabrous (traditionally *Panicum longiligulatum*) and pubescent (*P. leucothrix*) specimens at the varietal level; most previous authors have indeed split this taxon into at least two taxa based on forms of pubescence. The pubescence, however, intergrades completely from the extremes, while otherwise the taxon is quite homogeneous. Therefore, we have chosen not to recognize the segregates.

This species is common throughout Florida, mostly in pine flatwoods.

Dichanthelium oligosanthes (Schultes) Gould, Brittonia 26: 60. 1974. *Panicum pauciflorum* Elliott, Sketch Bot. S. Carolina 1: 120. 1816, non R. Brown 1810. *Panicum oligosanthes* Schultes, Mant. 2: 256. 1824. *Panicum scoparium* Lamarck var. *pauciflorum* Lamson-Scribner, Tennessee Agric. Exp. Sta. Bull. 7: 48. 1894. TYPE: United States. Georgia: *Elliott Herb. s.n.* (lectotype, CHARL: isotype, US, fragm.). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 285. 1910).

Panicum macrocarpon Torrey, Fl. N. Middle United States 143. 1823, non LeConte 1819. TYPE: United States. Massachusetts: Franklin Co., banks of the Connecticut River, near Deerfield, *Cooley s.n.* (holotype, NY).

Panicum scoparium Lamarck var. *angustifolium* Vasey, U.S.D.A. Div. Agrost. Bull. 8: 32. 1889. TYPE: United States. South Carolina: *Ravenel s.n.* (lectotype, US). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 286. 1910).

Panicum scribnerianum Nash, Bull. Torrey Bot. Club 22: 421. 1895. *Panicum oligosanthes* Schultes var. *scribnerianum* (Nash) Fernald, Rhodora 36: 80. 1934. *Dichanthelium oligosanthes* (Schultes) Gould var. *scribnerianum* (Nash) Gould, Brittonia 26: 60. 1974. TYPE: United States. Pennsylvania: Bradford Co., Wysox, July 1836, *Carey s.n.* (lectotype, GH). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 283. 1910). Gould & Clark (1978) erroneously stated that this name is based on *Panicum macrocarpon* Torrey.

Panicum helleri Nash, Bull. Torrey Bot. Club 26: 572. 1899. *Panicum oligosanthes* Schultes var. *helleri* (Nash) Fernald, Rhodora 36: 80. 1934. TYPE: United States. Texas: Kerr Co., Kerrville, 14–21 May 1894, *Heller 1759* (holotype, NY).

Panicum pernervosum Nash, Bull. Torrey Bot. Club 26: 576. 1899. TYPE: United States. Texas: Harris Co., Houston, 16 Apr. 1872, *Hall 830* (holotype, NY).

Most recent authors have followed Fernald in recognizing *P. scribnerianum* at least at the varietal level. The characteristics of pubescence used to separate the taxa, however, are very unreliable and seem not to be correlated with any other concrete evidence that differentiation has occurred in this species. There seems to us little to be gained by the formal recognition of these pubescence phases.

This species is rather uncommon in the northern tier of counties, occurring in dry pine–oak–hickory woods.

Dichanthelium ovale (Elliott) Gould & Clark, Ann. Missouri Bot. Gard. 65: 1115. 1978. *Panicum ovale* Elliott, Sketch Bot. S. Carolina 1: 123. 1816. TYPE: United States. Georgia: Camden Co., St. Marys, *Baldwin s.n.* (holotype, CHARL).

Panicum villosum Elliott, Sketch Bot. S. Carolina 1: 124. 1816, non Lamarck 1791. *Panicum consanguineum* Kunth, Révis. Gramin. 1: 36. 1829. *Panicum commutatum* Schultes var. *consanguineum* (Kunth) Beal, Grasses N. Amer. 2: 141. 1896. *Dichanthelium consanguineum* (Kunth) Gould & Clark, Ann. Missouri Bot. Gard. 65: 1115. 1978. TYPE: United States: *Elliott Herb. s.n.* (holotype, CHARL; isotype, US, fragm.).

Panicum ciliiferum Nash, Bull. Torrey Bot. Club 24: 195. 1897. TYPE: United States. Florida: Lake Co., Eustis, 12–31 Mar. 1894, *Nash 147* (holotype, NY; isotypes, MO, US).

Panicum malacon Nash, Bull. Torrey Bot. Club 24: 197. 1897. TYPE: United States. Florida: Lake Co., Eustis, 1–15 May 1894, *Nash 628* (holotype, NY; isotypes, MO, NY, US).

Panicum georgianum Ashe, J. Elisha Mitchell Sci. Soc. 15: 36. 1898. *Panicum cahoonianum* Ashe, J. Elisha Mitchell Sci. Soc. 15: 113. 1899, nom. illegit. TYPE: United States. Georgia: McIntosh Co., Darien Junction, 27 June 1895, *Small s.n.* (lectotype, US). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 169. 1910).

Panicum strictifolium Nash, Bull. Torrey Bot. Club 26: 579. 1899. TYPE: United States. Florida: Lake Co., Eustis, 3 May 1894, *Nash 603* (holotype, NY; isotypes, NY, US).

Panicum erythrocarpon Ashe, J. Elisha Mitchell Sci. Soc. 16: 90. 1900. TYPE: United States. North Carolina: New Hanover Co., 1 mi. N of Wilmington, 19 May 1899, *Ashe s.n.* (holotype, NCU; isotype, US).

Panicum euchlamydeum Shinners, Amer. Midl. Naturalist 32: 170. 1944. *Panicum commonsianum* Ashe var. *euchlamydeum* (Shinners) R. Pohl, Amer. Midl. Naturalist 38: 507. 1947. *Dichanthelium commonsianum* (Ashe) Freckmann var. *euchlamydeum* (Shinners) Freckmann, Phytologia 39: 271. 1978. TYPE: United States. Wisconsin: Adams Co., 12 mi. SE of Adams, *Shinners & Shaw 4415* (holotype, WIS; isotypes, GH, MIL, MIN, US).

As defined here, *Dichanthelium ovale* consists of the large-fruited specimens of the *D. acuminatum* complex. If smaller-fruited plants are included in this taxon, as in past treatments, problems in naming the many overlapping specimens become insurmountable. By delimiting the species as we have, a more homogeneous and practical system results, one where almost every specimen can be classified.

Gould & Clark (1978) recognized *Dichanthelium consanguineum* as a separate species characterized by pilose upper leaf surfaces. Again, the pubescence character seems insufficient for the separation of species.

Dichanthelium ovale is common in sandhills, pinelands, and disturbed habitats throughout Florida.

Dichanthelium portoricense (Desvaux ex Hamilton) B. F. Hansen & Wunderlin, comb. nov. BASIONYM: *Panicum portoricense* Desvaux ex Hamilton, Prodr. 11. 1825. TYPE: Puerto Rico: *Desvaux Herb. s.n.* (holotype, P).

Panicum lancearium Trinius, Gram. Panic. 223. 1826. TYPE: United States: "Am. bor.," *Enslin s.n.* (holotype, LE; isotype, US, fragm.).

Panicum heterophyllum Bosc. ex C. Nees von Esenbeck in Martius, Fl. Bras. Enum. Pl. 2(1): 227. 1829, non Sprengel 1822. TYPE: United States: *Bosc s.n.* (holotype, B-W).

Panicum webberianum Nash, Bull. Torrey Bot. Club 23: 149. 1896. TYPE: United States. Florida: Lake Co., Eustis, 16–31 May 1894, *Nash 781* (holotype, NY; isotypes, MO, NY, US).

Panicum columbianum Lamson-Scribner, U.S.D.A. Div. Agrost. Bull. 7: 78, f. 60. 1897. *Dichanthelium columbianum* (Lamson-Scribner) Freckmann, Phytologia 39: 270. 1978. *Panicum acuminatum* Swartz var. *columbianum* (Lamson-Scribner) Lelong, Brittonia 36: 270. 1984. TYPE: United States. District of Columbia: Brookland, 14 July 1894, *Lamson-Scribner s.n.* (lectotype, US). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 247. 1910).

Panicum nashianum Lamson-Scribner, U.S.D.A. Div. Agrost. Bull. 7: 79, f. 61. 1897. *Panicum portoricense* Desvaux ex Hamilton var. *nashianum* (Lamson-Scribner) Lelong, Brittonia 36: 267. 1984. TYPE: United States. Florida: Lake Co., vicinity of Eustis, 15–30 Apr. 1894, *Nash 466* (lectotype, US; isotype, MO). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 273. 1910).

Panicum tsugetorum Nash, Bull. Torrey Bot. Club 25: 86. 1898. TYPE: United States. New York: Bronx, New York Botanical Garden, 22 June 1896, *Nash 287* (holotype, NY; isotype, US, fragm.).

Panicum patentifolium Nash, Bull. Torrey Bot. Club 26: 574. 1899. TYPE: United States. Florida: Lake Co., Eustis, 12–31 Mar. 1894, *Nash 72* (holotype, NY; isotypes, MO, NY, US).

Panicum psammophilum Nash, Bull. Torrey Bot. Club 26: 576. Nov. 1899, non Welwitsch July 1899. TYPE: United States. New Jersey: Ocean Co., Tom's River, 25–31 July 1898, *Clute 175* (holotype, NY; isotype, US).

Panicum onslowense Ashe, J. Elisha Mitchell Sci. Soc.

16: 88. Feb. 1900. TYPE: United States. North Carolina: Onslow Co., near Ward's Mill, 11 mi. E of Jacksonville, 19–21 May 1899, *Ashe s.n.* (lectotype, NCU: isotypes, NCU, US). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 276. 1910). Lelong (1984) cited the lectotype as residing at UNC, but Hitchcock & Chase clearly stated that the type is in Ashe's herbarium, now at NCU.

Panicum pauciciliatum Ashe, J. Elisha Mitchell Sci. Soc. 16: 87. Feb. 1900. TYPE: United States. North Carolina: New Hanover Co., near Wilmington, 20 May 1899, *Ashe s.n.* (lectotype, NCU; isotype, US). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 272. 1910). Specimen at NCU not located.

Panicum nashianum Lamson-Scribner var. *patulum* Lamson-Scribner & Merrill, U.S.D.A. Div. Agrost. Circ. 27: 9. Dec. 1900. *Panicum patulum* (Lamson-Scribner & Merrill) A. Hitchcock, Rhodora 8: 209. 1906. *Panicum lancearium* Trinius var. *patulum* (Lamson-Scribner & Merrill) Fernald, Rhodora 36: 80. 1934. *Dichanthelium sabulorum* (Lamarck) Gould & Clark var. *patulum* (Lamson-Scribner & Merrill) Gould & Clark, Ann. Missouri Bot. Gard. 65: 1113. 1978. TYPE: United States. Florida: Manatee Co., Braidentown [Bradenton], 3 Sep. 1898, *Combs 1296* (holotype, US).

As pointed out by Lelong (1984), *Panicum sabulorum* Lamarck, whose type is from Uruguay, is not conspecific with our material, contrary to the treatment by Gould & Clark (1978). This leaves as the earliest name in the taxon *Panicum portoricense* Desvaux ex Hamilton, which unfortunately necessitates a new combination in *Dichanthelium*.

Gould & Clark (1978) and Lelong (1984, 1986) recognized two varieties in this species, based on spikelet length, inflorescence size, and leaf length. In the Florida material, however, spikelet size is but poorly correlated with inflorescence size, both of which seem unrelated to leaf size. Infraspecific taxa have therefore not been applied to this species.

Panicum columbianum was classified by Lelong (1984) as a variety of *P. acuminatum*. According to the description of Hitchcock & Chase (1910), *P. columbianum* and its synonym (fide Lelong) *P. tsugetorum* have ligules up to 1.5 mm long. The short ligules take *P. columbianum* out of the *P. acuminatum* complex.

Dichanthelium portoricense is probably the most commonly collected member of the genus in Florida. It occurs in a variety of habitats throughout the state.

Dichanthelium ravenelii (Lamson-Scribner & Merrill) Gould, Brittonia 26: 60. 1974. *Panicum ravenelii* Lamson-Scribner & Merrill, U.S.D.A. Div. Agrost. Bull. 24: 36. 1901. TYPE: United States. South Carolina: *Elliott s.n.* (lectotype, CHARL). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 287. 1910).

Panicum scoparium Lamarck var. *major* Vasey, U.S.D.A. Div. Agrost. Bull. 8: 32. 1889, as "majus." TYPE: United States. South Carolina: *Ravenel s.n.* (holotype, US).

This large grass, related to *D. scoparium*, is known in Florida only from the panhandle region, occurring in dry hammocks.

Dichanthelium scabriusculum (Elliott) Gould & Clark, Ann. Missouri Bot. Gard. 65: 1110. 1978. *Panicum scabriusculum* Elliott, Sketch Bot. S. Carolina 1: 121. 1816. *Panicum viscidum* Elliott var. *scabriusculum* (Elliott) Beal, Grasses N. Amer. 2: 143. 1896. TYPE: United States. Georgia: Chatham Co., Savannah, *Baldwin s.n.* (holotype, CHARL).

Panicum lanuginosum Bosc ex Sprengel, Syst. Veg. 1: 319. 1825, non Elliott 1816. *Panicum eriophorum* Schultes ex Kunth, Enum. Pl. 1: 128. 1833. TYPE: United States. Georgia: *Bosc s.n.* (holotype, B-W).

Panicum nealleyi Vasey, Bull. Torrey Bot. Club 13: 25. 1886. TYPE: United States. Texas: May 1885, *Nealley s.n.* (holotype, US).

Panicum dichotomum Linnaeus var. *elatum* Vasey, U.S.D.A. Div. Agrost. Bull. 8: 31. 1889. TYPE: United States. Alabama: Mobile Co., 18 June 1888, *Mohr s.n.* (lectotype, US). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 298. 1910).

Panicum cryptanthum Ashe, N. Carolina Agric. Exp. Sta. Bull. 175: 115. 1900. TYPE: United States. North Carolina: Johnston Co., Wilsons Mill, 15 July 1897, *Ashe s.n.* (lectotype, NCU; isotypes, NCU). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 299. 1910).

Panicum aculeatum A. Hitchcock & Chase, Rhodora 8: 209. 1906. TYPE: United States. District of Columbia: Takoma Park, 27 July 1904, *Chase 2520* (holotype, US).

Panicum recognitum Fernald, Rhodora 40: 331, pl. 497–498. 1938. TYPE: United States. New Jersey: Camden Co., headwaters of branch of Timber Creek, Albion, 27 June 1912, *Long 7671* (holotype, GH; isotype, PH). Gould & Clark (1978) erroneously cited the location of the holotype as US.

This species is quite common in northern Florida, ranging southward to Orange County. It is primarily found in bogs, cypress swamps, and wet woods.

Dichanthelium scoparium (Lamarck) Gould, Brittonia 26: 60. 1974. *Panicum scoparium* Lamarck, Encycl. 4: 744. 1798. *Panicum scoparium* Lamarck var. *genuinum* Lamson-

Scribner, Tennessee Agric. Exp. Sta. Bull. 7: 48. 1894, nom. inadmiss. TYPE: United States: "Caroline," *Michaux s.n.* (holotype, P-M). Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 287. 1910) mistypified var. *genuinum* with Elliott's material of *P. ravenelii*. Lamson-Scribner's citation of *P. scoparium* Lamarck necessitates the obvious disposal of this inadmissible varietal epithet here.

Panicum pubescens Lamarck, Encycl. 4: 748. 1798. *Panicum laxiflorum* Lamarck var. *pubescens* (Lamarck) Chapman, Fl. South. U.S., ed. 3. 586. 1897. *Chasea pubescens* (Lamarck) Nieuwland, Amer. Midl. Naturalist 2: 64. 1911. TYPE: United States. South Carolina: *Michaux s.n.* (lectotype, P-M). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 294. 1910).

Panicum viscidum Elliott, Sketch Bot. S. Carolina 1: 123, pl. 7(3). 1816. TYPE: United States: *Elliott Herb. s.n.* (lectotype, CHARL). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 294. 1910).

Panicum nitidum Lamarck var. *velutinum* Döll in Martius, Fl. Bras. 2(2): 247. 1877. TYPE: United States. Texas.

Although this species is usually locally abundant, it is confined in Florida to the northern tier of counties. It occurs in marshes, moist woods, and roadsides.

Dichanthelium sphaerocarpon (Elliott) Gould, Brittonia 26: 60. 1974. *Panicum sphaerocarpon* Elliott, Sketch Bot. S. Carolina 1: 125. 1816. *Panicum dichotomum* Linnaeus var. *sphaerocarpon* (Elliot) Alph. Wood, Class-Book Bot., ed. 1861. 786. 1861. *Panicum microcarpon* Muhlenberg var. *sphaerocarpon* (Elliott) Vasey, Grass. U.S. 12. 1883. TYPE: United States. Georgia: *Baldwin s.n.* (holotype, CHARL).

Panicum kalmii Swartz, Adnot. Bot. 6. 1829. TYPE: United States. Pennsylvania?: *Kalm s.n.* (holotype, S).

Panicum nitidum Lamarck var. *crassifolium* A. Gray ex Döll in Martius, Fl. Bras. 2(2): 247. 1877. TYPE: United States. New Jersey: *Gray? 30* (holotype, KR?; isotype, GH).

Panicum vicarium Fournier, Mexic. Pl. 2: 20. 1886. TYPE: Mexico. Veracruz: Córdoba, s.d., *Schaffner 285* (holotype, P).

Panicum inflatum Lamson-Scribner & J. G. Smith, U.S.D.A. Div. Agrost. Circ. 16: 5. 1899. *Panicum sphaerocarpon* Elliott var. *inflatum* (Lamson-Scribner & J. G. Smith) A. Hitchcock in Hitchcock & Chase, Contr. U.S. Natl. Herb. 15: 253. 1910. TYPE: United States. Mississippi: Harrison Co., Biloxi, Oct. 1898, *Tracy 4622* (holotype, US).

Panicum mississippiense Ashe, J. Elisha Mitchell Sci. Soc. 16: 91. 1900. TYPE: United States. Louisiana: Orleans Par., "Banks of the Mississippi River below New Orleans in October," *Ashe s.n.* (holotype, not located).

This species occurs in bogs and seeps in the panhandle area of Florida.

Dichanthelium strigosum (Muhlenberg ex Elliott) Freckman, Brittonia 33: 457. 1981. *Panicum strigosum* Muhlenberg ex Elliott, Sketch Bot. S. Carolina 1: 126. 1816. TYPE: United States. "Hab. in humidis. Car: & Georg:," *Elliott Herb. s.n.* (lectotype, CHARL; isotype, US, fragm.). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 164. 1910).

Freckmann (1981b) recognized that *strigosum* was the earliest specific epithet for this species and made the necessary combinations for the three rather well marked (for this genus) varieties.

KEY TO THE VARIETIES OF *DICHANTHELIUM STRIGOSUM*

1a. Spikelets puberulent or pubescent, 1.5–2.1 mm long .... var. *leucoblepharis*
1b. Spikelets glabrous, 1.1–1.8 mm long.
    2a. Leaf blade surfaces glabrous; spikelets 1.2–1.8 mm long .... var. *glabrescens*
    2b. Leaf blade surfaces pilose; spikelets 1.1–1.5 mm long .... var. *strigosum*

Dichanthelium strigosum (Muhlenberg ex Elliott) Freckmann var. **strigosum**

Panicum laxiflorum Lamarck var. *pubescens* Vasey, Contr. U.S. Natl. Herb. 3: 30. 1892. *Dichanthelium leucoblepharis* (Trinius) Gould & Clark var. *pubescens* (Vasey) Gould & Clark, Ann. Missouri Bot. Gard. 65: 1101. 1978. *Panicum ciliatum* Elliott var. *pubescens* (Vasey) Freckmann ex R. Pohl, Fieldiana, Bot., n.s. 4: 356. 1980. *Panicum leucoblepharis* Trinius var. *pubescens* (Vasey) Beetle, Phytologia 48: 192. 1981. TYPE: United States. Florida: Duval Co., *Curtiss H* (lectotype, US). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 164. 1910).

Panicum longipedunculatum Lamson-Scribner, Tennessee Agric. Exp. Sta. Bull. 7: 53, pl. 16(61). 1894. TYPE: United States. Tennessee: White Cliff Springs, July 1890, *Lamson-Scribner s.n.* (lectotype, US). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 164. 1910).

Uncommon in Florida, this variety ranges from northern Florida south to the central peninsula.

Dichanthelium strigosum (Muhlenberg ex Elliott) Freckmann var. **glabrescens** (Grisebach) Freckmann, Brittonia 33: 457. 1981. *Panicum dichotomum* Linnaeus var. *glabrescens* Grisebach, Fl. Brit. W. I. 553. 1864.

Dichanthelium leucoblepharis (Trinius) Gould & Clark var. *glabrescens* (Grisebach) Gould & Clark, Ann. Missouri Bot. Gard. 65: 1100. 1978. TYPE: Jamaica: *Purdie s.n.* (holotype, K).

Panicum polycaulon Nash, Bull. Torrey Bot. Club 24: 200. 1897. TYPE: United States. Florida: Hillsborough Co., Tampa, 20 Aug. 1895, *Nash 2420a* (holotype, NY; isotype, US, fragm.).

This variety is common throughout Florida in moist pinelands, bogs, and coastal swales.

Dichanthelium strigosum (Muhlenberg ex Elliott) Freckmann var. **leucoblepharis** (Trinius) Freckmann, Brittonia 33: 457. 1981. *Panicum leucoblepharis* Trinius, Clav. Agrostogr. Antiq. 234. 1822. *Dichanthelium leucoblepharis* (Trinius) Gould & Clark, Ann. Missouri Bot. Gard. 65: 1099. 1978. TYPE: United States. "Am. bor.," *Enslin s.n.* (lectotype, LE). Lectotypified by Hitchcock & Chase (Contr. U.S. Natl. Herb. 15: 162. 1910).

Panicum ciliatum Elliott, Sketch Bot. S. Carolina 1: 126. 1816, non Märcklin 1792. *Panicum ciliatifolium* Kunth, Révis. Gramin. 1: 36. 1829. TYPE: United States. *Elliott Herb. s.n.* (holotype, CHARL).

Panicum ciliatifolium Desvaux, Opusc. Sci. Phys. Nat. 88. 1831, non Kunth 1829. TYPE: "America boreali" (specimen unknown).

When making the new combination *Panicum ciliatum* Elliott var. *pubescens* (Vasey) Freckmann ex R. Pohl (1980), based on *P. laxiflorum* var. *pubescens* Vasey (1892), Pohl created the autonym *Panicum ciliatum* Elliott var. *ciliatum*. At first glance, this autonym would seem to be the earliest varietal name for this taxon. However, *Panicum ciliatum* Elliott, 1816, is illegitimate because it is a later homonym of *Panicum ciliatum* Märcklin, 1792, as pointed out by Veldkamp (1976). Since an autonym can only be established on a legitimate name (ICBN Art. 26), as verified by Dan Nicolson (pers. comm.), the next epithet in line, *leucoblepharis*, must be chosen.

This variety is rare in Florida, found only in the northern counties, occurring in pinelands.

EXCLUDED SPECIES

Dichanthelium linearifolium (Lamson-Scribner) Gould

This northern species was reported from the Florida panhandle by Clewell (1985), but no supporting specimens have been found.

INDEX

NOTES

PASSIFLORA EGLANDULOSA, A NEW SPECIES IN SECTION *CIECA* (MEDIKUS) DC. FORMERLY INCLUDED WITH *P. TRINIFOLIA* MASTERS

Passiflora trinifolia Masters "is very common in the forests of the Occidente" of Guatemala according to Standley & Williams (1961). Indeed, this name has been applied to a locally abundant apetalous passionflower of the wet montane forests of northern Central America. However, while preparing a revision of *Passiflora* L. section *Cieca* (Medikus) DC., extreme and bimodal variation of vegetative characters was noted among the specimens circulated as *P. trinifolia*. Consequently, closer analysis revealed the existence of two distinct species: the actually very rare *P. trinifolia*, and the more common but previously unnamed species described below.

Passiflora eglandulosa MacDougal, sp. nov. TYPE. Guatemala. San Marcos: wet mountain forest at Aldea Fraternidad, W-facing slope of Sierra Madre between San Rafael Pie de La Cuesta and Palo Gordo [ca. 14°56′N, 91°52′W], 1,800–2,400 m, 10–18 Dec. 1963, *Williams, Molina & Williams 25997* (holotype, F; isotypes, ENCB, G, NY, S, US, W—2 sheets). Figures 1, 2B, 3.

Passiflora ad sectio *Cieca* pertinens, scandens; stipulae ovatae 2.5–9 mm latae; petioli eglandulosi; folia eglandulosa trilobata haud peltata, lobis acuminatis vel caudatis, lobo centrali quam lateralibus longiori, marginibus integris; pedunculi ebracteati; petala nulla; coronae filamenta biseriata, filamentis exterioribus 3–4 mm longis, usque ad 0.2–0.3 mm diametro, filamentis interioribus ad 1.5 mm longis; operculum plicatum; ovarium glabrum; semina reticulato-foveata.

Slender, climbing, perennial herb 2–4 m long, minutely puberulent and sparsely to lightly pubescent with trichomes of 2 size classes: smaller (microscopic) trichomes 0.05–0.10 mm, unicellular, clavate and antrorsely bent or appressed, present throughout; larger trichomes (0.2–)0.4–0.6(–0.8) mm, unicellular, cylindrical and pointed, slightly bent antrorsely. Stem perennial with little secondary growth, terete or subterete but drying strongly obtusely sulcate, glabrescent below, sparsely to lightly pubescent above with trichomes 0.25–0.6 (–0.7) mm, pubescence often restricted to one side of stem; posture of shoot apex straight, negatively geotropic. Stipules (3.5–)5–14(–20) × (2.5–)3–8(–9) mm, ovate, with ca. 5–7 veins departing from stem, the midvein only slightly off center (stipule only slightly oblique), apex acute, often apiculate, margins ciliolate-setose. Petioles (0.6–) 1–3.5(–4.6) cm, eglandular, slightly canaliculate and adaxially pubescent (at least distally) with trichomes (0.2–)0.3–0.5(–0.6) mm, abaxially glabrescent with only microscopic trichomes. Laminas 2.8–10(–12) × 4.0–15(–17) cm at fertile nodes, with 5 primary veins, 3-lobed ca. ¼–½ the distance to the shallowly cordate base, the lobes triangular to deltate or ovate, long-acuminate to caudate, the angle between the lateral lobes (120–)125–160 (–170)°, the central lobe longest, with the ratio of lateral to central lobe lengths (0.68–)0.75–0.90 (–0.95), the ratio of laminar width to length 1.30–1.65(–1.75), adaxially nearly glabrous or glabrescent with a few (0.2–)0.3–0.6(–0.8) mm trichomes restricted to the primary veins, abaxially sparsely to lightly puberulent with microscopic trichomes 0.05–0.06 mm; laminas not variegated (except trace of pericostal whiteness seen on very few leaves at distal flowering nodes of *MacDougal 316*); laminar nectaries absent; seedling and juvenile laminas depressed obovate or narrowly transversely rhombic/elliptic, more shallowly 2–3-lobed, the angle between the long-acuminate lateral lobes 105–120° in seedlings and 160–170° in juveniles, central lobe shortest (or reduced to a cusp), with ratio of lateral to central lobe lengths 1.25–2.8, ratio of laminar width to length 2.0–5.7. Tendrils straight

ANN. MISSOURI BOT. GARD. 75: 1658–1662. 1988.

during development at shoot apex, often suppressed on fertile determinate axillary branches. Prophyll of vegetative ramifying bud 1, narrowly ovate, acute. Peduncles (5–)8–19(–23) mm, geminate or occasionally solitary, uniflorous, ebracteate. Flowers ca. 1.5–2 cm diam.; hypanthium 4–5.5 mm diam. with 5 retrorse spurs 0.4–0.8 mm long between bases of sepals, or sometimes spurs obsolete; stipe (2.0–)3.0–5.0(–8.0) mm; flowers borne between horizontally and erect, pale to light yellow-green except as noted, nearly inodorous; sepals (6.5–)7.5–9.0 × 2.3–3.9 mm, broadly lanceolate, rounded at apex, the 2–3 outermost cucullate and with a (0.5–)0.8–1.2 mm blunt subapical cornus, often abaxially flushed with very deep red to purplish red; petals absent; filamentous corona in 2 series, the outer filaments ca. 29–31, 3.0–4.0 mm long, 0.2–0.3 mm diam., filiform, widest at base, slightly attenuate distally, reflexed above the middle and the tips often slightly incurved, yellowish green at base, light yellow distally; inner series (0.7–)1.0–1.5 mm, capillary to subclavate, suberect; operculum 1.5–2.0 mm, membranous, plicate, sometimes with an inconspicuous narrow purplish band near middle, apex white-papillose; nectary trough without raised annulus; limen (disk) not colored or spotted; staminal filaments connate (2.5–)3.0–3.6(–4.0) mm along androgynophore, the free portions ca. 3 mm, spreading but not perpendicular to androgynophore; anthers 2.2–2.7 mm, oriented perpendicular or nearly so to their filaments at anthesis; ovary 1.5–1.9 × 1.0–1.4 mm, ellipsoid to widely ellipsoid, glabrous; styles ca. 4–5 mm, filiform, typically geniculate above middle; stigma capitellate, 0.7–0.9 mm diam. Fruit 10–13(–16) × 9–13(–14) mm, widely ellipsoid to subglobose or slightly obovoid, pericarp bluish black, glaucous, insipid; arils only half the length of the seed, firm, whitish or grayish, insipid; seeds 4.6–5.0 mm long, (2.9–)3.1–3.5 mm wide, (2.0 –)2.2–2.5 mm thick, reticulate-foveate with (15–)18–21(–24) foveae per side, obovate to widely obovate or subpyriform, the chalazal beak obtuse or obsolete, the micropylar beak obtuse or often somewhat oblong and blunt.

Additional specimens examined. EL SALVADOR. AHUACHAPAN: nebelwald region, Cerro Grande de Apaneca, ca. 1,700 m, 26 Aug. 1958 (fl), *Weberling 2610* (M—2 sheets). SANTA ANA: disturbed cloud forest near top of Cerro Verde, 30 July 1977, *Croat 42222* (MO); cloud forest, Mountain Cerro Verde, 1,800 m, 20 Feb. 1968 (fr), *Molina & Montalvo 21514* (F, NY). HONDURAS. SANTA BÁRBARA: bosque nublado, Cerro Santa Bárbara, cuestas de piedra caliza, 10 km E of Lago Yojoa, 14°55′N, 88°05′W, 1,500–2,000 m, 28–30 Apr. 1973 (fl, fr), *Clewell & Hazlett 3858* (MO, TEFH). GUATEMALA. EL PROGRESO: Montaña Canahuí between Finca San Miguel and summit of mountain, near upper limits of Finca Caieta [ca. 14°59′N, 89°54′W], 1,600–2,300 m, 10 Feb. 1942, *Steyermark 43787* (BR, F). GUATEMALA: Finca Nacional "La Aurora," 1938–1939, *Aguilar 89* (F); cerca encino y *Pinus maximinoi*, Choacorrán, km 20 a San Juan Sacatepéquez, 2,000 m, 17 Sep. 1982 (fl), *J. Castillo et al. 82.347* (F); moist thickets in deep ravines, vicinity of San Andrecillo, 1,700 m, 26 Sep. 1972 (fl, fr), *Molina & Molina 27543* (ENCB, F, US); ravine near Canales, 1,900 m, 25 Jan. 1947 (fr), *Williams & Molina 11822* (F). JALAPA: Volcán Jumay, N of Jalapa, 1,300–2,200 m, 1 Dec. 1939, *Steyermark 32352* (F). QUEZALTENANGO: cultivated at Duke University 1978–1982 from roots collected 2.5 mi. below tunnel at Santa María de Jesús, between Km posts 202–203 on Hwy. 9S, July 1978, *MacDougal 316* (AAU, BM, DUKE, F, HUA, MEXU, MO, USCG); moist forest at and above Aguas Amargas, slopes of Volcán de Zunil, 2,430–2,850 m, 17 Feb. 1939, *Standley 65404* (F); wet hillside forest, Aguas Amargas, western slope of Volcán de Zunil, 2,450 m, 14 Jan. 1941 (fl), *Standley 83336* (F); damp thicket along road above Santa María de Jesús, ca. 1,680 m, 25 Jan. 1941 (fr), *Standley 84846* (F, US); densely forested white sand quebrada, El Pocito, S of San Martín Chile Verde on road to Colomba, 2,200 m, 27 Jan. 1941, *Standley 84997* (F, G—2 sheets); damp dense mixed forest on white sand slopes above Mujuliá, between San Martín Chile Verde and Colomba, 1,800 m, 1 Feb. 1941, *Standley 85571* (F); thickets on slopes and ridges between Quebrada Chicharro and Montaña Chicharro, on SE-facing slopes of Volcán María, 1,300–1,400 m, 18 Jan. 1940 (fl, fr), *Steyermark 34360* (F); western slopes of Volcán Zunil, opposite Santa María de Jesús, 1,500 m, 21 Jan. 1940 (fr), *Steyermark 35094* (F). SAN MARCOS: wet forested quebrada, Barranco Eminencia, road between San Marcos and San Rafael Pie de la Cuesta, in upper part of the barranca between Finca La Lucha and Buena Vista, 2,500–2,700 m, 6 Feb. 1941, *Standley 86368, 86379* (F); thickets in pine woods in flat below cliffs along Río Malacaté, barrancos 6 mi. S & W of town of Tajumulco, NW slopes of Volcán Tajumulco, 2,300–2,380 m, 26 Feb. 1940, *Steyermark 36663* (F, US); montane cloud forest on outer slopes of Tajumulco Volcano, ca. 8–10 km W of San Marcos, ca. 2,300 m, 31 Dec.–1 Jan. 1964 (fl), *Williams et al. 26864* (F, GH, NY). SUCHITEPEQUEZ: Volcán Santa Clara, between Finca El Naranjo and upper slopes, 1,250–2,650 m, 23 May 1942, *Steyermark 46628, 46692* (F, US). ZACAPA: cloud forest in ravine bordering Quebrada Alejandria, summit of Sierra de las Minas, vicinity of Finca Alejandria, 2,500 m, 13 Oct. 1939 (seedling), *Steyermark 29859* (F).

The following common names are recorded from herbarium specimens: "granadilla de culebra" (Guatemala, Guatemala); "Hoja de murciélago," "flor de murciélago," "granadilla" (Quezaltenango, Guatemala).

Specimens of *P. eglandulosa* were not collected until after Killip's 1938 monograph, so the description there of *P. trinifolia* applies strictly to Masters's species. The description of *P. trinifolia* in Standley & Williams (1961), however, is a composite drawn from Killip and their observations of *P. eglandulosa*. *Passiflora eglandulosa* is superficially similar to the poorly known *P. trinifolia* by

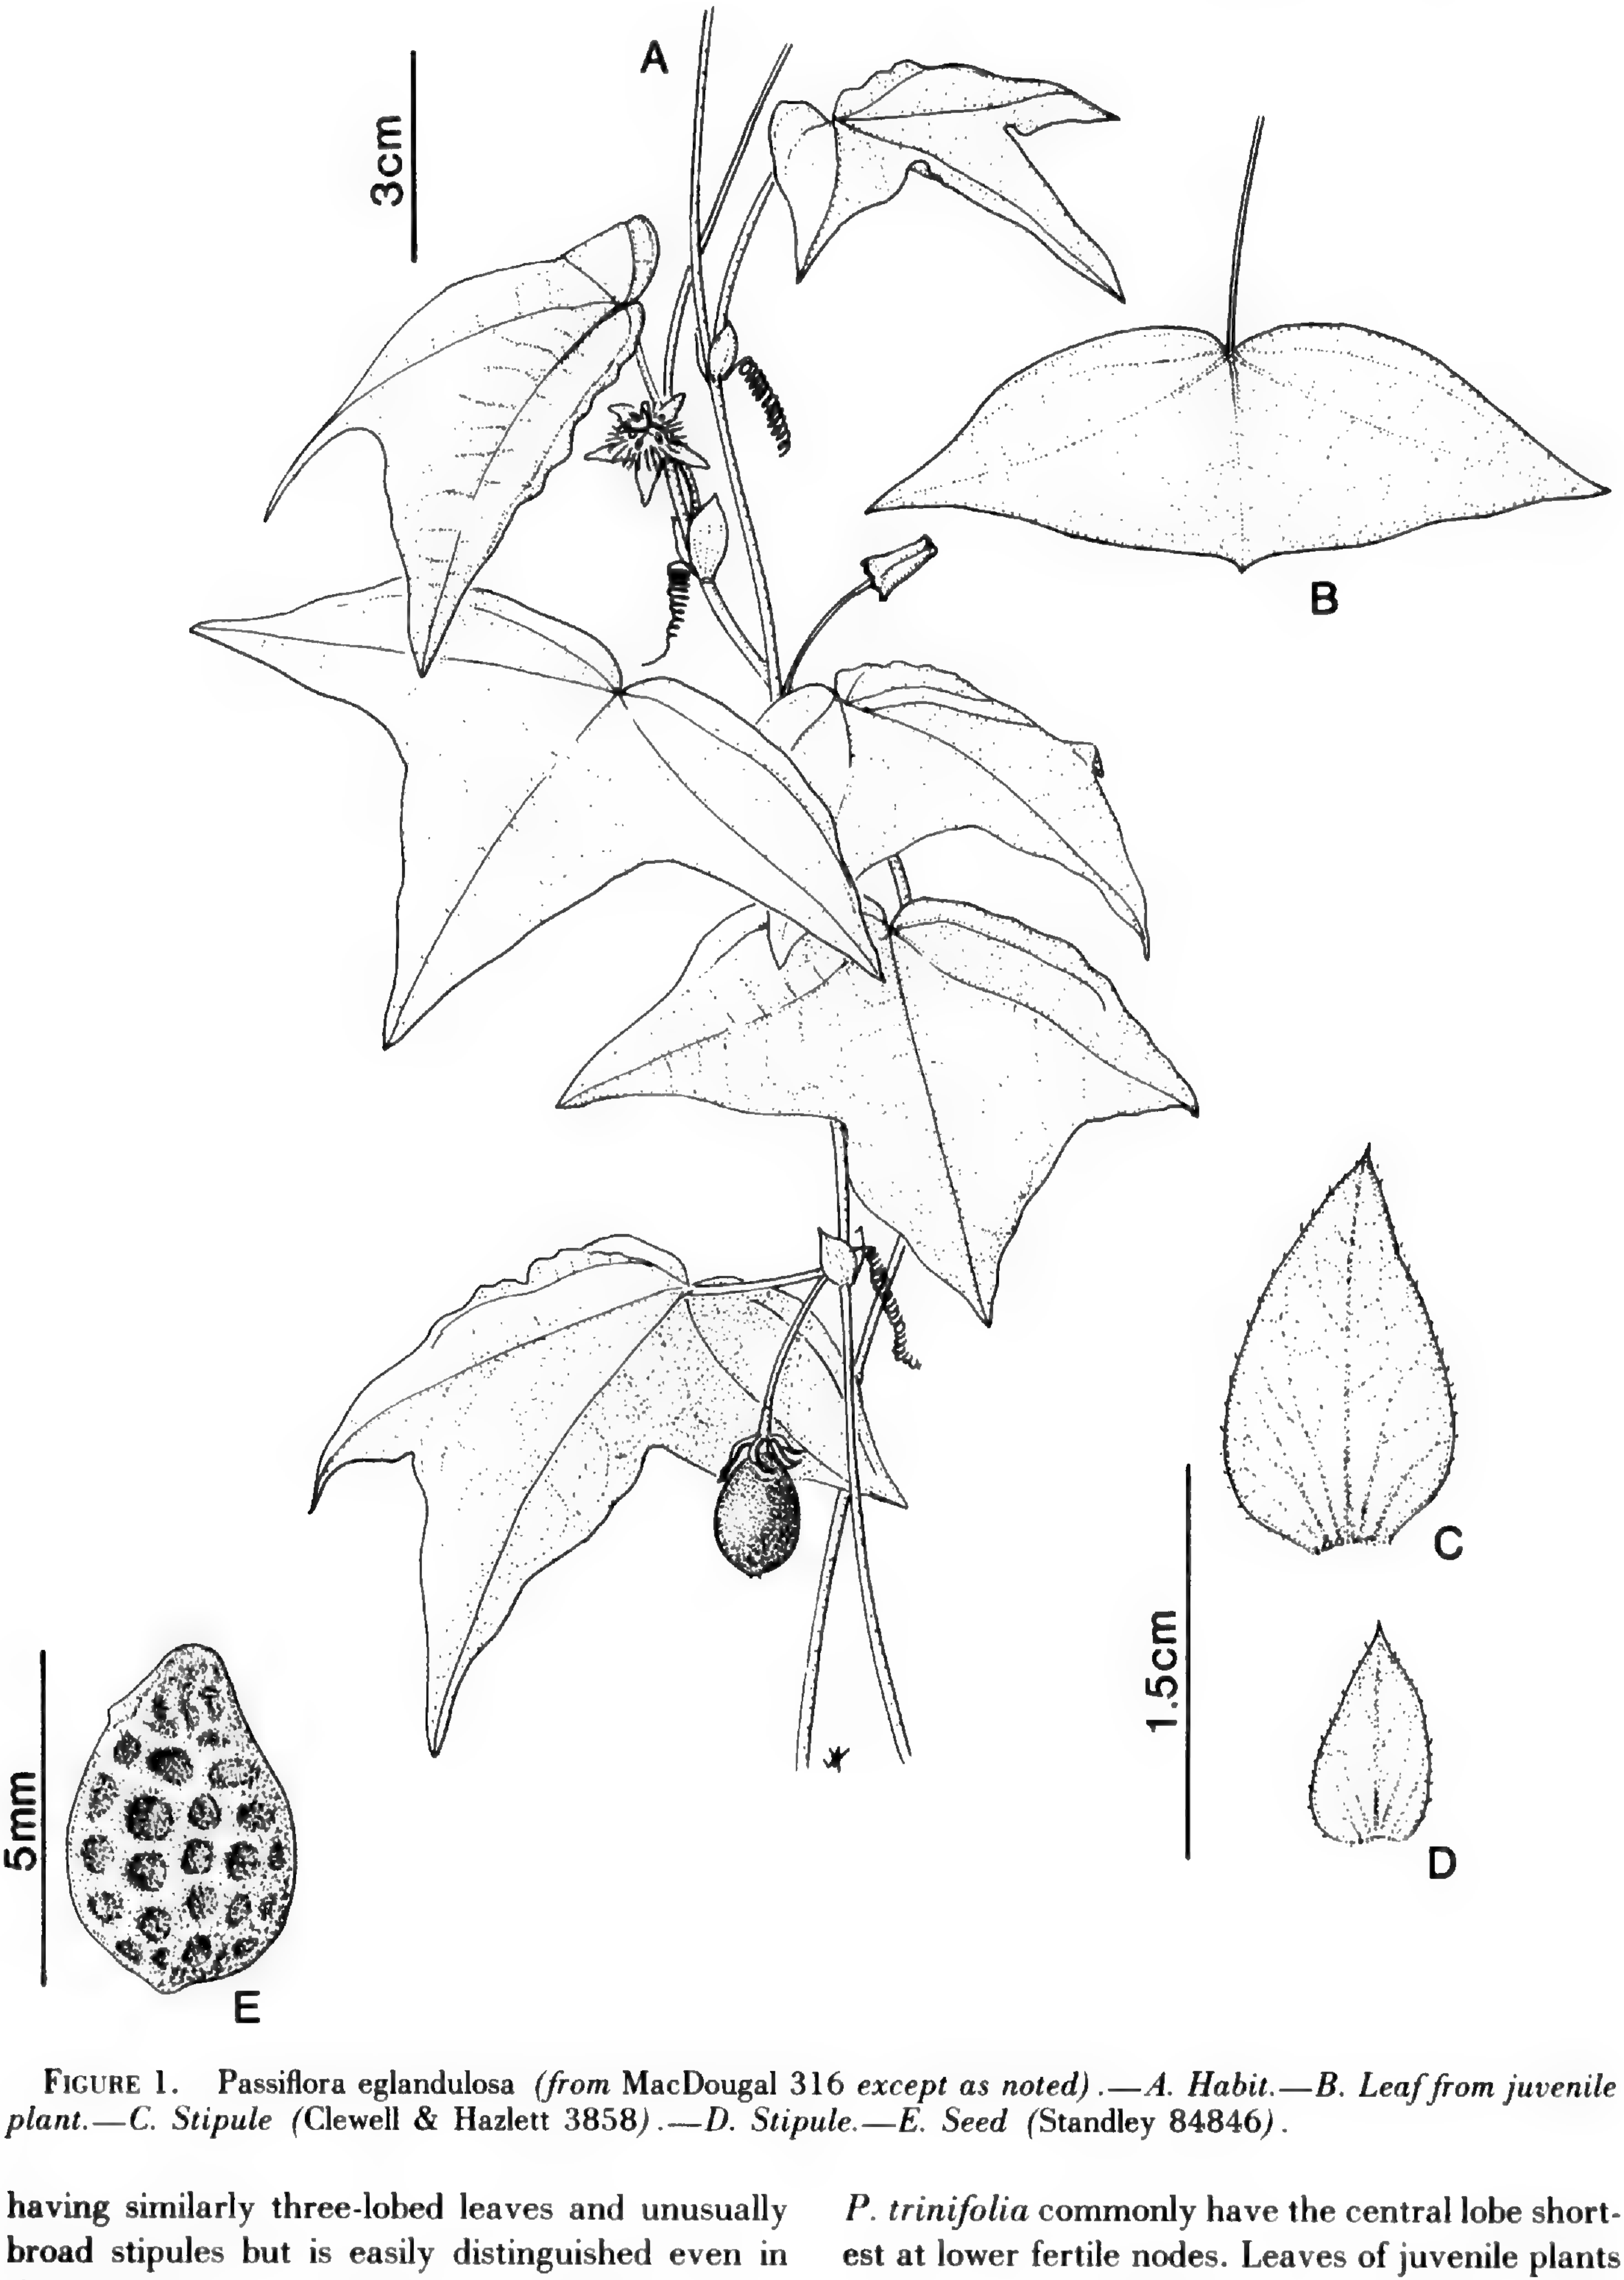

FIGURE 1. Passiflora eglandulosa *(from* MacDougal 316 *except as noted).—A. Habit.—B. Leaf from juvenile plant.—C. Stipule (*Clewell & Hazlett 3858*).—D. Stipule.—E. Seed (*Standley 84846*).*

having similarly three-lobed leaves and unusually broad stipules but is easily distinguished even in the herbarium by the absence of petiolar and laminar nectaries. Additionally, at fertile nodes the leaves of *P. eglandulosa* always have the central lobe longest; the laminas resemble those of the sympatric *Oreopanax sanderianus.* The leaves of *P. trinifolia* commonly have the central lobe shortest at lower fertile nodes. Leaves of juvenile plants are transversely bilobed in both species but are occasionally peltate in *P. trinifolia,* resembling miniature leaves of *P. coriacea* A. L. Juss. The leaves of juveniles are never at all peltate in *P. eglandulosa.*

FIGURE 2. *A. Flower of* Passiflora trinifolia *from type locality* (MacDougal 637GR).—*B. Flower of* Passiflora eglandulosa (MacDougal 316).

Living material of both species was collected in the field by the author and grown at Duke University, allowing detailed comparison of the flowers (Fig. 2). *Passiflora eglandulosa* differs notably in having flowers oriented above rather than near or below the horizontal plane; buds slightly horned at the apex; sepals proportionally narrower; outer coronal filaments much finer and broadest at the base; inner coronal filaments not broadly capitate; limen smaller and unspotted; more gracile androecium and gynoecium; and anthers that present pollen distally to laterally instead of subproximally. This anther orientation is unusual in the section and genus as a whole, and may be associated with a mode of pollination different than that of the other species in the section.

The habits and habitats of the two species are remarkably different, and they are not sympatric (Fig. 3). *Passiflora eglandulosa* climbs to around four meters in shady ravines and at the edges of wet premontane to montane broad-leaved forest on the volcanic cones of southern Guatemala to central Honduras. The chartaceous leaves are bright green adaxially and usually exhibit drip tips. In contrast, *P. trinifolia* is known only from Baja Verapáz, Guatemala, from three stations within 12 km of each other. The habitat is open, strongly seasonally dry pine with oak forest, associated with grasses and agave. Although perennial, the species has annual shoots that are only up to 1 m long, and some fertile shoots may be but 0.25 m long. The leaves are dark green, without drip tips, and are very stiff and rigid.

Passiflora trinifolia is apparently self-incompatible, since 33 attempts to self-pollinate it in the greenhouse failed to yield fruit. Fully mature fruits are unknown in this species. *Passiflora eglandulosa,* on the other hand, proved to be significantly self-compatible but not autogamous in cultivation. No unpollinated flowers set fruit over several years of cultivation, but 10 of 18 self-pollinated flowers produced (1–)3–9 seeds per fruit. The fruits turned purple 40–44 days after pollination. Nine or 10

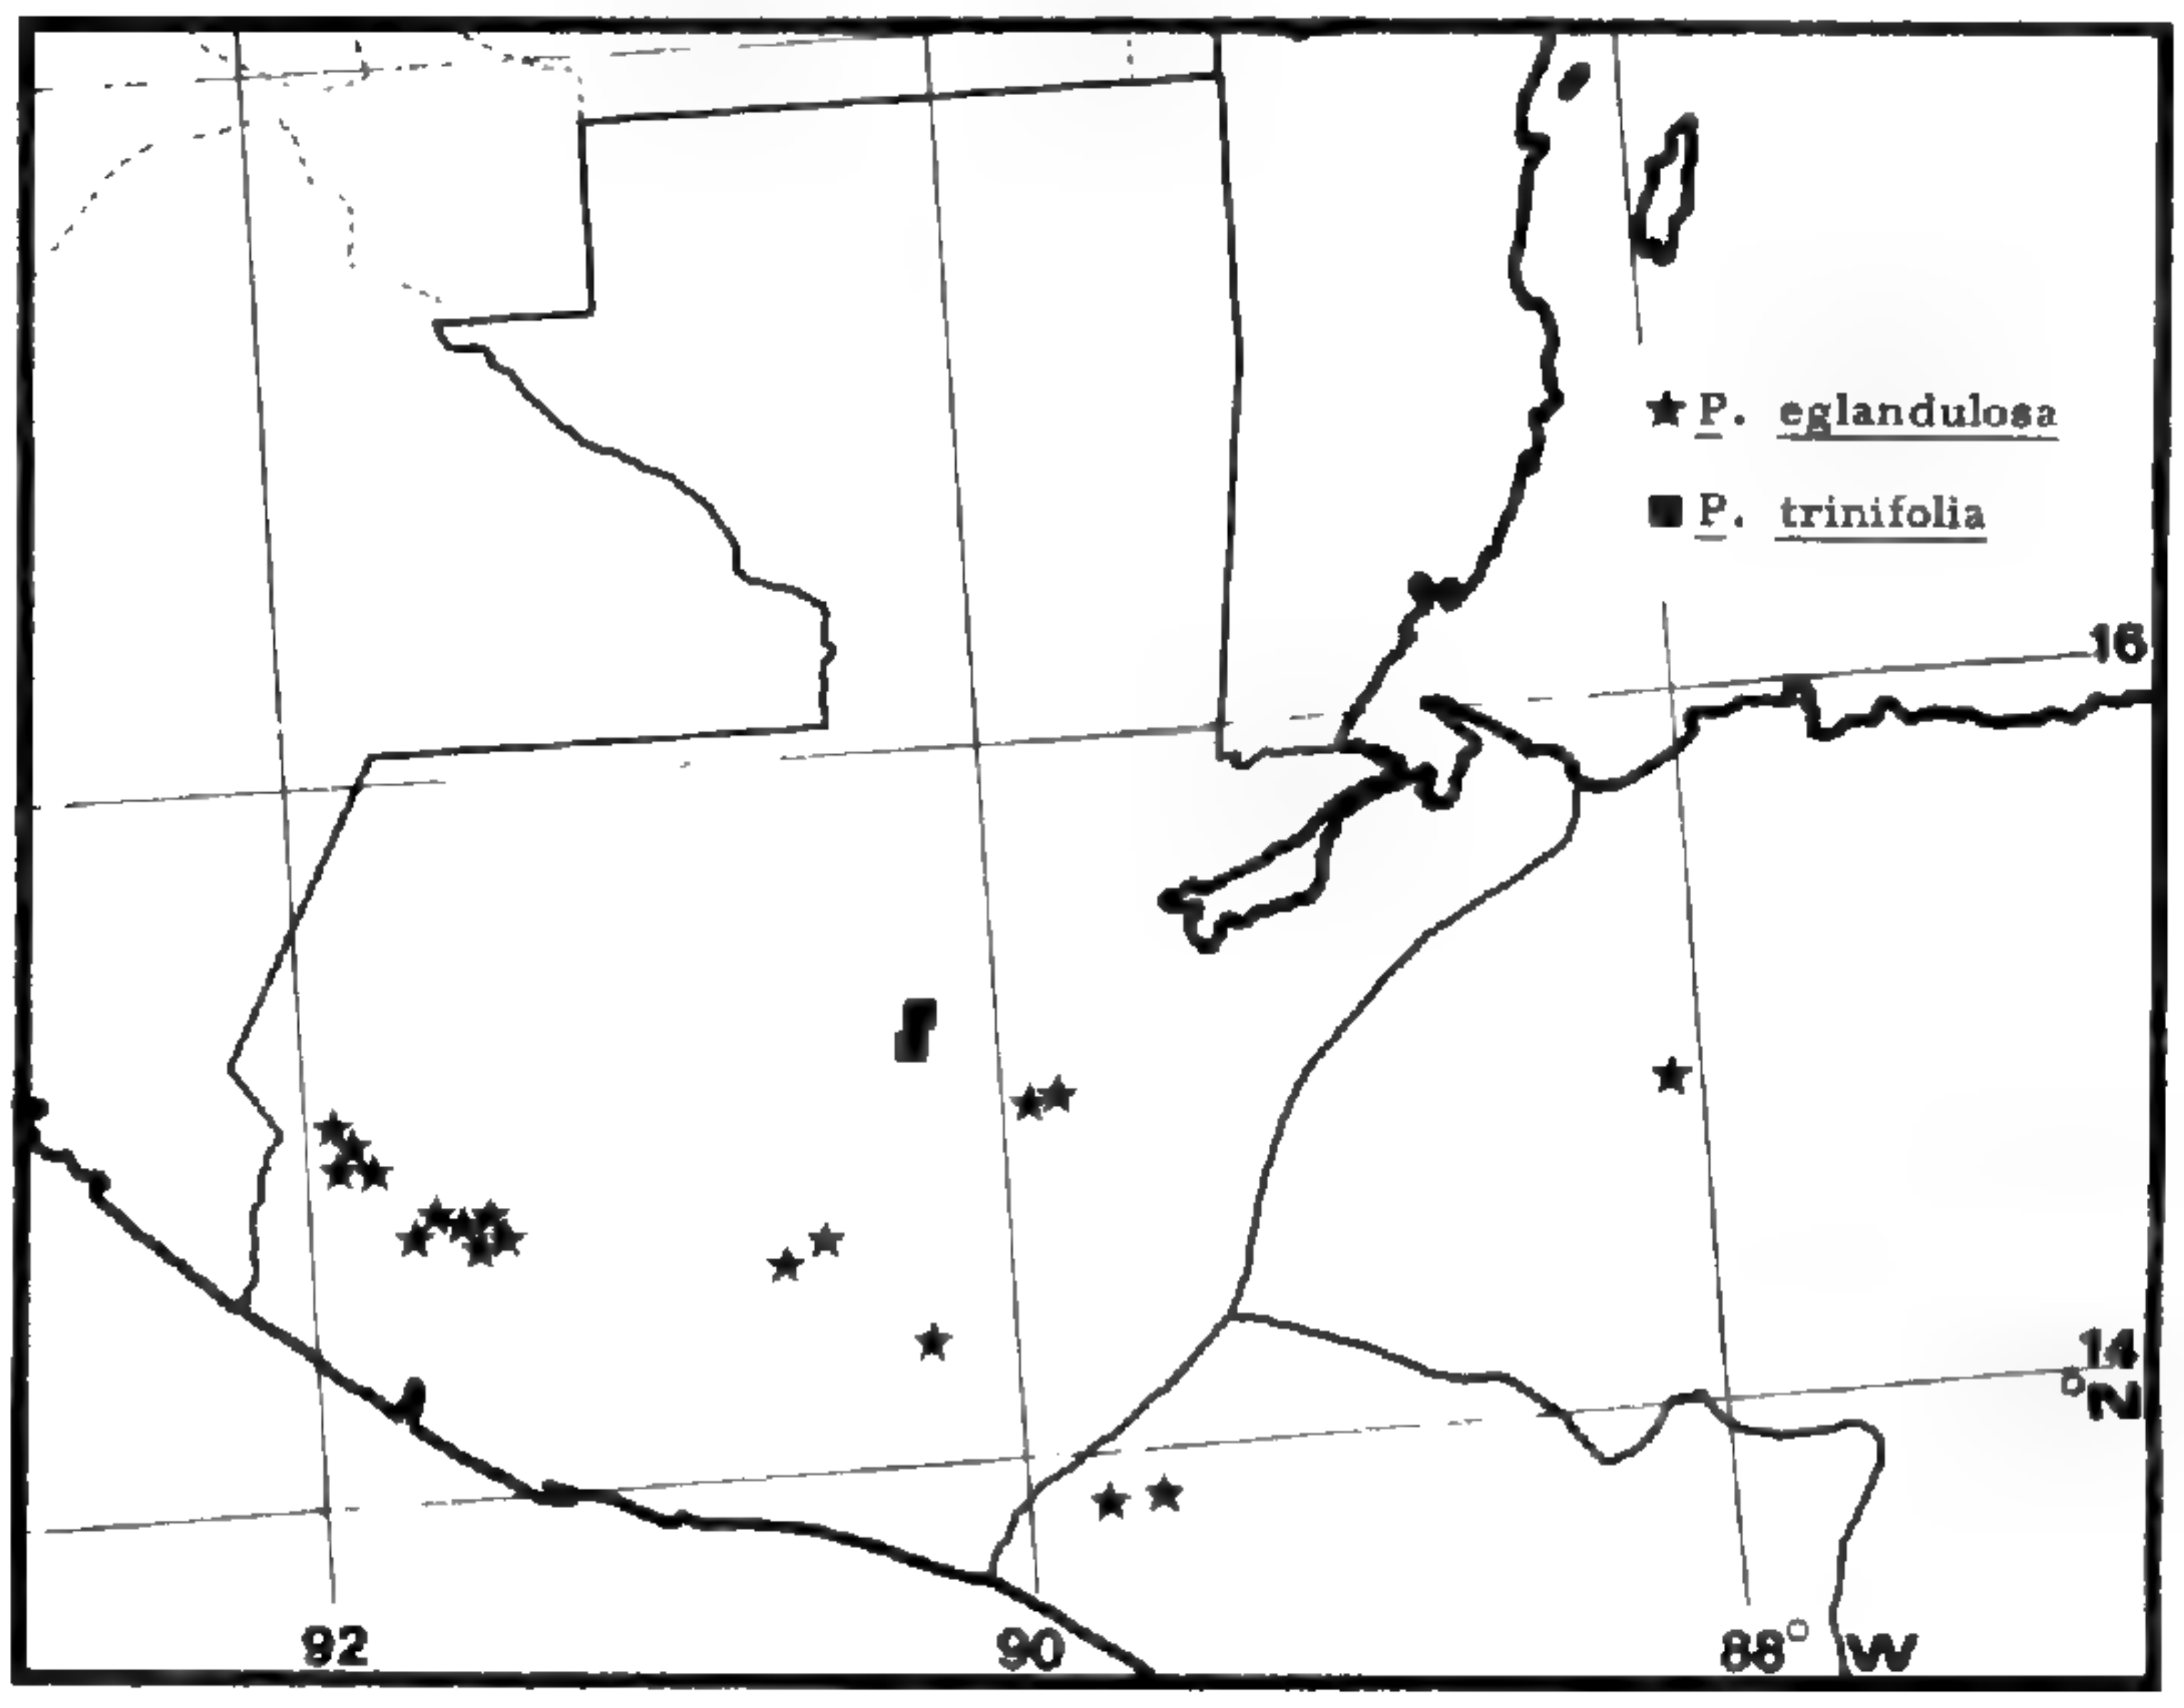

FIGURE 3. *Map of Guatemala and neighboring countries showing distributions of* Passiflora eglandulosa *and* P. trinifolia.

seeds per fruit appears to be the normal maximum for this species, judging from the several fruiting collections examined.

Passiflora eglandulosa (misidentified as *P. trinifolia*) has been included in three other studies of passionflowers. The development and physiology of the floral nectary of a clone of *MacDougal 316* was examined by Durkee et al. (1981), who found it to be similar to the others in their study. Dried leaf samples of *MacDougal 316* were chromatographically screened by McCormick (1982) for flavonoids. Concentrations were so low that no compounds could be verified, but according to McCormick (pers. comm.), traces of 3-*O*-glycosylflavonols but not *C*-glycosylflavones were detected. This is similar to several other species in section *Cieca*. Benson et al. (1975) reported the passionflower butterfly *Heliconius hortense* to be an herbivore of this species, a report that I confirm from field observations (insect voucher identified by J. Mallet).

I am grateful to D. E. Stone of Duke University, who directed the fieldwork and establishment of the living collections. The initial research was accomplished during graduate studies at Duke University under a National Science Foundation Fellowship, further supported by NSF grant DEB-7912607. Postdoctoral support has been generously provided by the Jessie Smith Noyes Foundation. John Myers prepared the drawing.

MOLLINEDIA (MONIMIACEAE), A NEW GENUS FOR PARAGUAY

Two genera of Monimiaceae have been reported previously for Paraguay—the monotypic *Hennecartia* (*H. omphalandra* Poisson, endemic to Southern Brazil, eastern Paraguay, and northeastern Argentina) and *Siparuna* (*S. guyanensis* Aubl., cited by Hassler, 1917: 19). A third genus, *Mollinedia* (*M. clavigera* Tulasne), has recently been collected in eastern Paraguay. This is a predictable occurrence, since the species grows in the nearby states of São Paulo, Paraná, and Santa Catarina in southern Brazil (Peixoto, 1979).

Paraguayan material of Mollinedia clavigera *examined.* PARAGUAY. CANENDIYU: 15 km SE of Katueté, isolated pond in middle of cultivated field dominated by grasses with zone of agricultural weeds next to soybean field, 24°15'S, 65°40'W, *Hahn 2087*, 15 Feb. 84 (PY).

The three genera of Monimiaceae found in Paraguay can be distinguished as follows:

1a. Drupes free on a flat receptacle. Ovule pendulous. Anthers sessile, longitudinally dehiscent .... *Mollinedia*

1b. Drupes surrounded by a concave receptacle.
  2a. Drupes 1–2. Receptacle opening in segments. Anthers sessile, transversely dehiscent. Ovule pendulous .... *Hennecartia*
  2b. Drupes many. Receptacle not opening. Anthers stipitate, valvately dehiscent. Ovule erect .... *Siparuna*

A NEW SPECIES OF *RUELLIA* (ACANTHACEAE) FROM WESTERN MEXICO

Ruellia L., of tribe *Ruellieae* Nees emend. Bremekamp (1944), is a tropical and subtropical genus of 200 species (Long, 1964). Its variation is impressive and its taxonomy complex. Lindau's (1895) circumscription is adopted here, and its unifying characters are contorted aestivation of the corolla lobes; didynamous stamens with muticous, equal or nearly equal two-celled anther lobes; and spheroid or ellipsoid, three- or more-porate, reticulate, and spinulose or banded pollen grains.

The primary centers of diversity of the genus are Indo-Malaya, Brazil, Africa, Mexico, and Central America (Long, 1970). In Mexico there are about 40 species of *Ruellia*, many of which occur locally, which suggests evolution by fragmentation (Ramamoorthy & Lorence, 1987). The variation in shape, size, and color of the corolla is very pronounced, indicating strong adaptive radiation to pollen vectors, which has led to definable natural constellations of infrageneric species groups. These deserve sectional ranks, but their recognition awaits revisionary studies (Ramamoorthy, in prep.). Among these is the chiropterophilous group: *Ruellia bourgaei*, *R. coulteri*, *R. palmeri*, *R. pulcherrima*, *R. jaliscana*, and the new species described below. The bats pollinating some of these are *Leptonycteris nivalis* and *Anoura geoffreyi*, both of the subfamily *Glossophaginae*.

Ruellia sarukhaniana Ramamoorthy, sp. nov. TYPE: Mexico. Michoacán: Coalcomán, S of Naranjillo, 1,200 m, in woods, 24 Nov. 1938, *G. Hinton et al. 12659* (holotype, GH). Figure 1.

Ruellia jaliscanae Standley affinis a qua foliis oblanceolatis differt.

Suffrutescent herbs to 1 m high. Stem distinctly 4-angled, with numerous cystoliths; angles reddish brown. The leaves 15–22 cm long, 2–3.8 cm wide, oblanceolate, acuminate at tip, narrowed and decurrent onto the 1-cm-long petiole, sinuately dentate along margin, chartaceous, venation (12–14 pairs) actinodromus, pilose above with short, multicelled, white hairs, pubescent along nerves below, cystoliths numerous. Inflorescence terminal and axillary, cymose-panicles, the peduncle and its branches densely tomentose with white hairs, interspersed with glandular hairs. Leaves subtending inflorescences reduced, bractlike, to 8 cm long, to 0.05 cm wide, oblanceolate. Bracts to 4.2 cm long, narrowly oblanceolate, tomentose with white hairs; bracteoles linear to subulate, glandular hairy. Pedicel to 2 cm long, tomentose glandular hairy. Calyx 3.2 cm long, deeply subequally 5-lobed with 2 lobes longer than the rest, the lobes to 2.2 cm long, 0.3 cm wide, linear, villous with glandular hairs. Corolla to 7 cm long (the tube 3.5 cm long, 4 mm wide), yellowish, the throat 2.5 cm long, 1 cm wide, the lobes 1 cm long, 1 cm wide. Stamens 4 in pairs, the filaments 1.5 cm long; anthers 0.7 cm long. Ovary 6 mm high, glabrous, the nectariferous disc surrounding ovary 2 mm high, fleshy, the style 5.7 cm long, the stigma of 2 flat lobes. Seeds not known.

The species is named after Dr. José Sarukhán Kermez, formerly Director of the Instituto de Biología and currently coordinator of scientific research in the National University of Mexico.

Ruellia sarukhaniana is similar to *R. jaliscana* with which it shares the glandular hairy, linear-lanceolate calyx lobes and its corolla form and branched inflorescence. The new species differs from the broadly ovate leaved *R. jaliscana* by having oblanceolate leaves.

The two are allopatric: *Ruellia jaliscana* is restricted to northwestern parts of the transmexican volcanic chain in the state of Jalisco, and *R. sarukhaniana* is found in the Coalcomán area, the northernmost parts of the Sierra Madre del Sur. Their similarities and affinities suggest a possible common origin for the two species, with allopatry contributing to their differentiation.

I thank Drs. D. Wasshausen (US) and T. Daniel (CAS) for comments on an earlier version of the typescript, and Fernando Chiang (MEXU) for the Latin diagnosis.

A NEW SPECIES OF *STILLINGIA* (EUPHORBIACEAE) FROM NORTHERN PERU

The predominantly neotropical genus *Stillingia* Garden ex L. was last revised by Rogers (1951), who recognized 23 American species. He did not treat the three or four paleotropical species that are distributed from Madagascar to Fiji. One additional species has since been described from Minas Gerais, Brazil (*S. argutedentata* Jabl., *Phytologia* 14: 451. 1967). A recently discovered species in northern Peru brings the total of American species to 25.

Stillingia parvifolia Sánchez Vega, Sagást. & Huft, sp. nov. TYPE: Peru. Dept. Cajamarca: Prov. Cajamarca, Distr. Namora, en la quebrada del Río Llallumayo, 2,775 m, 18 June 1984, *I. Sánchez Vega & W. Ruiz Vigo 3618* (holotype, CPUN, F neg. 62127; isotype, HUT). Figure 1.

Frutex glaber plus minusve ramosissimus, ramulis teretibus; folia brevipetiolata, alterna vel in brachyblastis 2–4 mm longis portata, laminae coriaceae, ovato-ellipticae, 6–11(–13) mm longae, margine callosae aequaliter serratae, dentibus glanduliformibus. Inflorescentiae terminales, bisexuales; cymulae masculinae uniflorae, bracteis navicularibus; cymulae femineae 1–3 basi inflorescentiae, sepala 3, orbicularia, navicularia, persistentia; capsulae globosae, profunde trilobae; semina (immatura) laevia, carunculata.

Shrub, glabrous, ± highly branched, the branchlets terete, ± maroon, the bark irregularly sulcate; short shoots 2–4 mm long. *Leaves* alternate or borne on short shoots, short-petiolate; petioles canaliculate, 1–1.5 mm long; blades coriaceous, ovate-elliptic, 6–11(–13) mm long, 5–6 mm wide, 1.25–2.2 times as long as wide, broadly obtuse to rounded at base, obtuse to rounded at apex; margin callose, minutely and remotely serrulate, the teeth glanduliform, 4–19 per side, the base eglandular; midrib conspicuous, prominent below, the secondary veins obscure. *Inflorescences* terminal, 1–2 cm long, bisexual. *Staminate cymules* single-flowered, the bracts obovate, acute, navicular, ca. 1.2 mm long, persistent, biglandular at base, the glands oblong or suborbicular, 0.8–1 mm long, patelliform; calyx 2-lobed, ca. 1 mm long; stamens 2, the filaments 1–1.2 mm long, the anthers 2, ca. 0.8 mm long, longitudinally dehiscent. *Pistillate cymules* 1–3 at base of inflorescence, single-flowered, the bracts as in the staminate cymules; sepals 3, orbicular, navicular, ca. 12 mm long, the apex truncate or obtuse, slightly erose; ovary sessile, 3-carpellate; styles 3, free, 1.5–1.7 mm long, recurved at tip. *Capsule* globose, glabrous, deeply 3-lobed, ca. 5 mm long; lobes of the persistent gynobase 3–4 mm long; seeds (only immature seen) ca. 4 mm long, ca. 1.5 mm wide, smooth, prominently carunculate.

Rogers (1951) distinguished two subgenera in *Stillingia*. Subgenus *Stillingia* is characterized by staminate cymules with 3–13 flowers, pistillate flowers with two or three well-developed sepals, and carunculate seeds, whereas subgenus *Gymnostillingia* (Muell. Arg.) D. Rogers is characterized by staminate cymules with a single flower, pistillate flowers with obsolete or minute and fugacious sepals, and usually ecarunculate seeds. The single-flowered staminate cymules of *S. parvifolia* would seem at first sight to place that species in subg. *Gymnostillingia*, but the ample and persistent sepals of the pistillate flowers and the carunculate seeds argue against an easy accceptance of that disposition. Furthermore, the restriction of subg. *Gymnostillingia* to Mexico and adjacent areas of Guatemala and the United States makes such a conclusion even more unlikely. In addition, *S. parvifolia* is not particularly close morphologically to any of the species that comprise subg. *Gymnostillingia*.

Stillingia parvifolia shares several specialized characters with two South American species of subg. *Stillingia*, *S. peruviana* D. Rogers (the only other species of the genus in Peru), and *S. bodenbenderi* (Kuntze) D. Rogers of Brazil and Argentina. All three species are shrubs, have small short-petiolate leaves that are often borne on small peg-like short-shoots, and leaf margins that are evenly serrate, often callose, and with peculiar glanduliform serrations.

The most reasonable interpretation of *S. par-*

ANN. MISSOURI BOT. GARD. 75: 1666–1668. 1988.

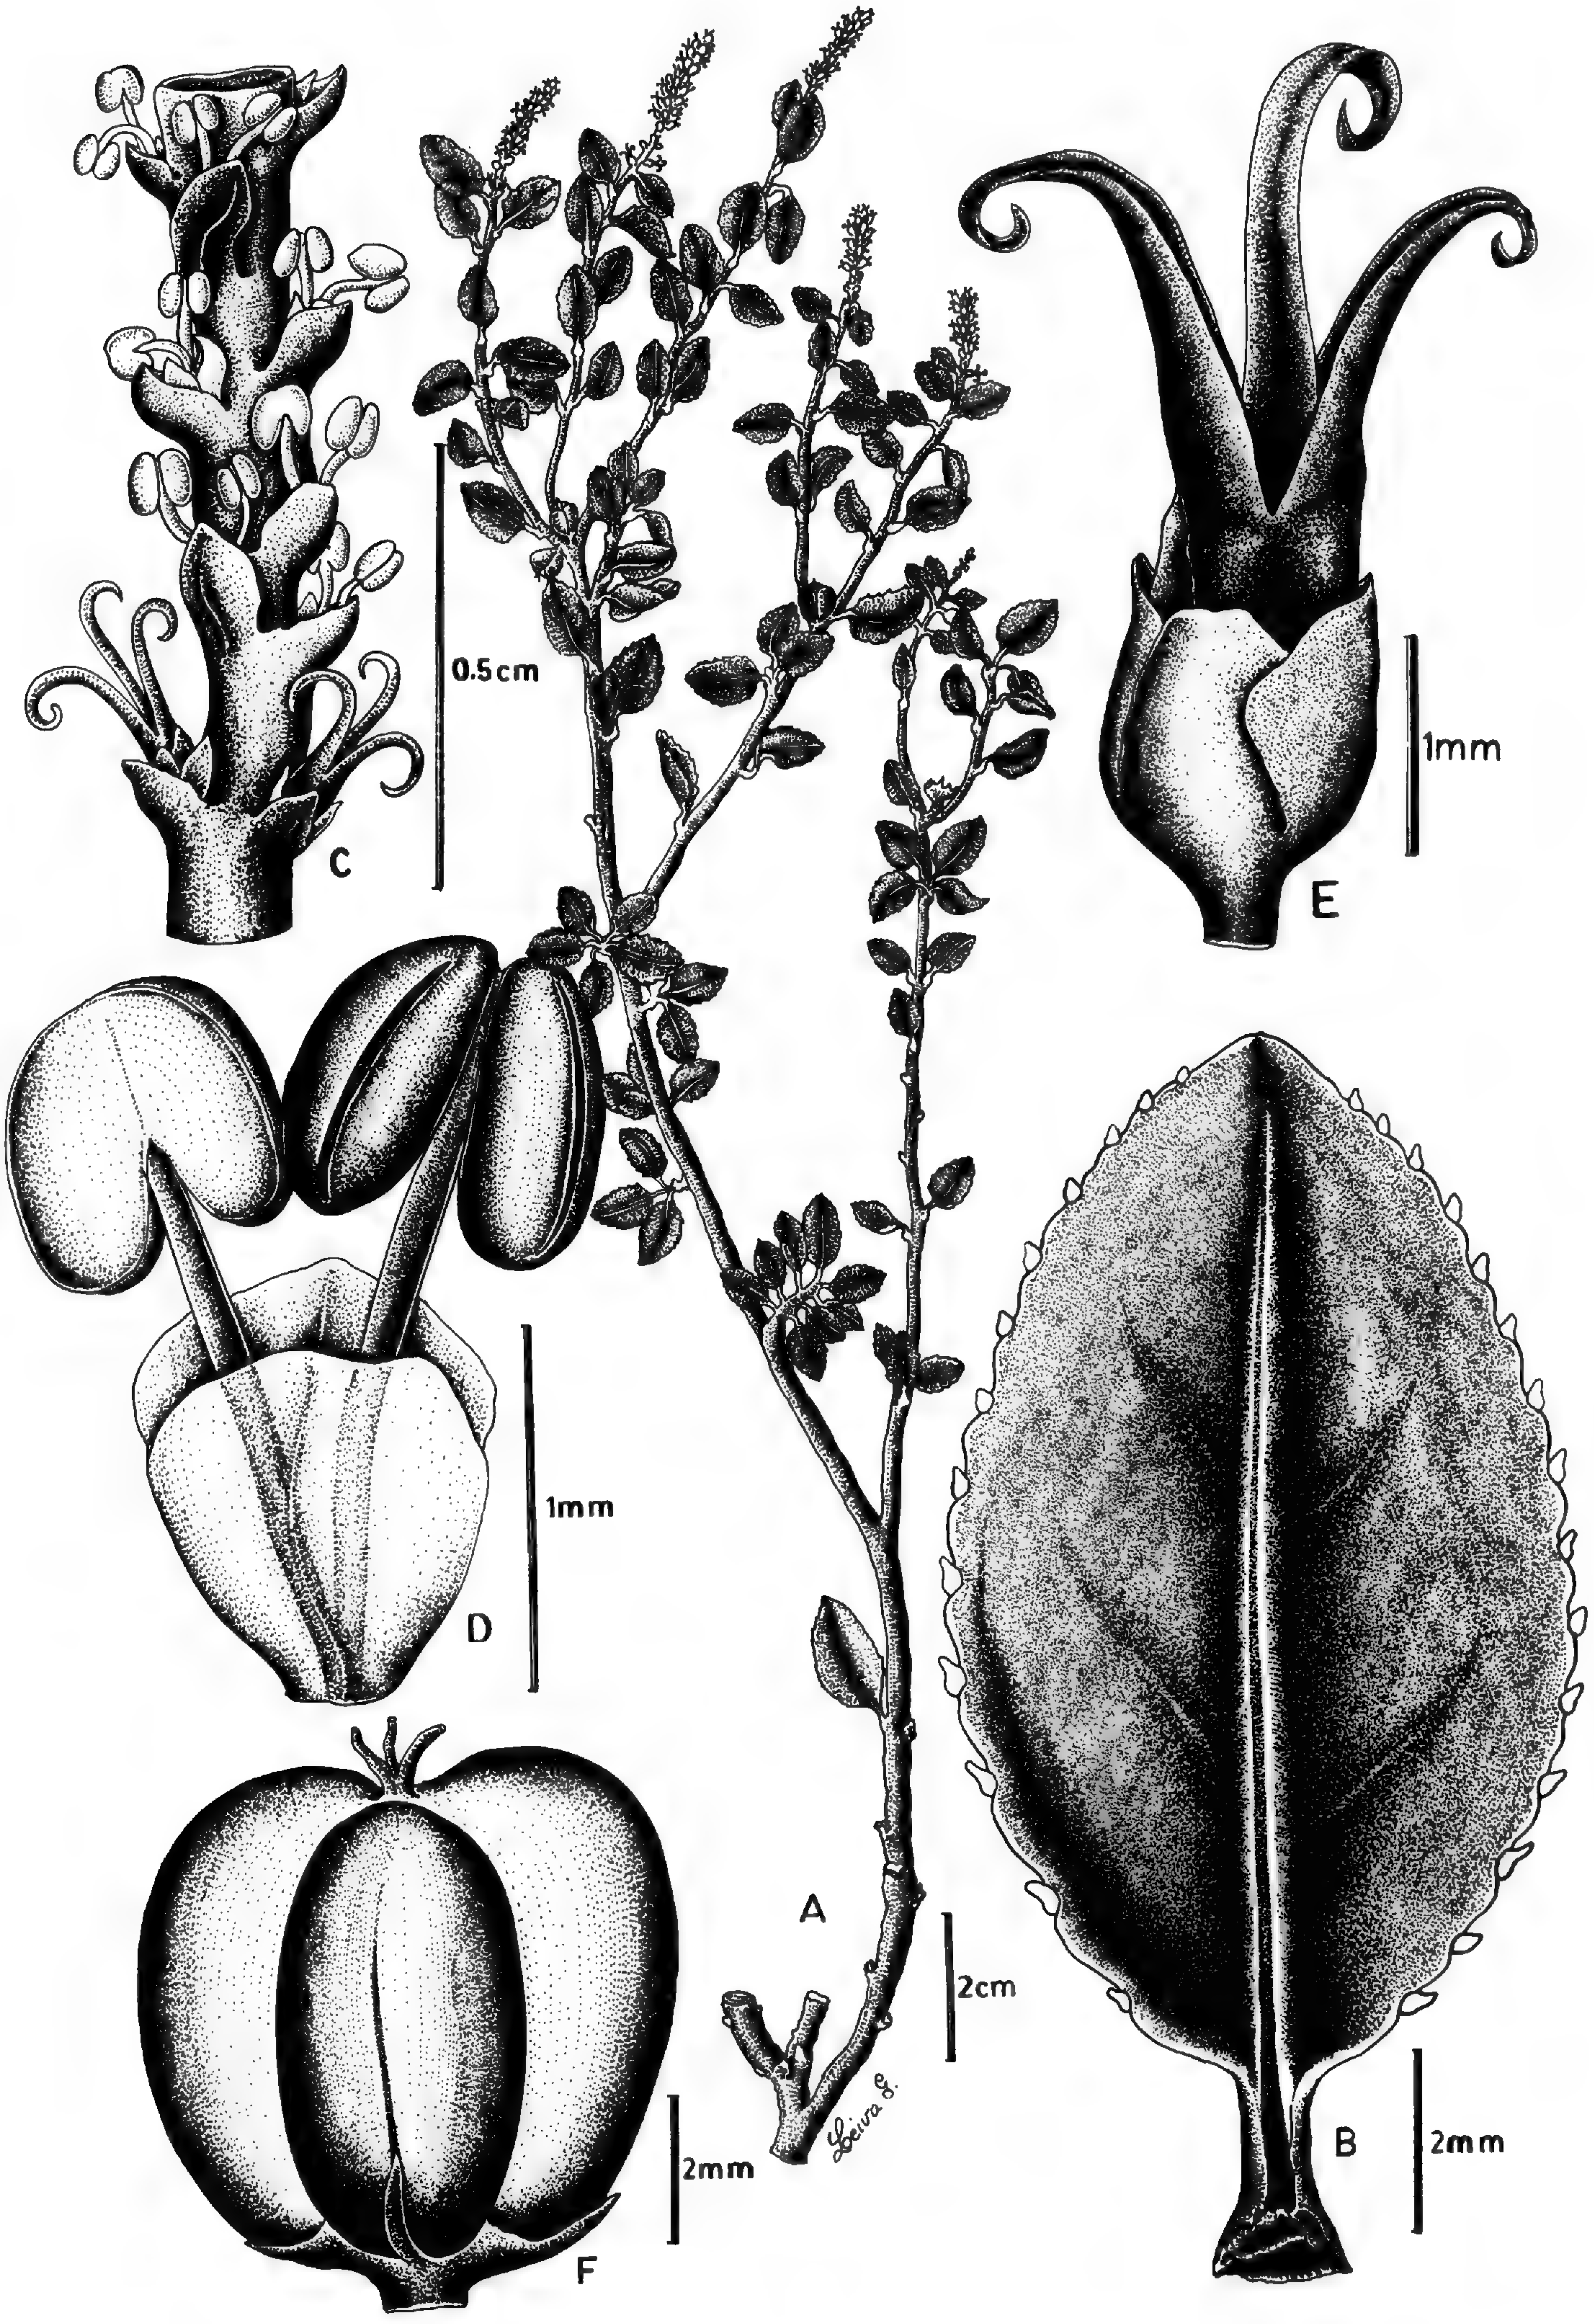

FIGURE 1. Stillingia parvifolia (Sánchez Vega & Ruiz Vigo 3618, *CPUN*).—*A. Flowering branch.—B. Leaf.—C. Lower portion of inflorescence.—D. Staminate flower.—E. Pistillate flower.—F. Capsule.*

vifolia would seem to be that it belongs to subg. *Stillingia*, where it is particularly closely related to *S. bodenbenderi* and *S. peruviana*, and that it has developed a reduced staminate cymule independently from the species in subg. *Gymnostillingia*.

Stillingia parvifolia may be distinguished from its closest relatives by means of the following key:

KEY TO *STILLINGIA PARVIFOLIA* AND RELATIVES

1a. Staminate cymules 5–7(–9)-flowered; branchlets slender, wandlike, 1–1.5 mm thick; petioles 2–3(–7) mm long; blades (0.8–)2–4 cm long, tapering to an acute (rarely rounded) apex; staminate bracts plane.
    2a. Petioles 0–3 mm long; leaf margins prominently callose, the serrations obscurely glanduliform; staminate bracts rounded, not mucronate .... *S. bodenbenderi*
    2b. Petioles 2–7 mm long; leaf margins obscurely callose, the serrations prominently glanduliform; staminate bracts deltate, mucronate .... *S. peruviana*
1b. Staminate cymules 1-flowered; branchlets not wandlike, 2–3 mm thick; petioles 1–1.5 mm long; blades 6–11(–13) mm long, not tapering to apex, this rounded or obtuse; staminate bracts navicular .... *S. parvifolia*

All three species in this group have highly restricted distributions and are poorly known. *Stillingia peruviana* is known from three collections in Huancavelica Province, Peru, while *S. bodenbenderi* is known from only two collections in Córdoba Province, Argentina, and a third from the state of São Paulo, Brazil. The distinctions between *S. bodenbenderi* and *S. peruviana* are not entirely convincing; the relative status of these two species will depend on the future availability of more ample collections.

Stillingia parvifolia is known only from the type collection from dry forest in a rocky ravine with clayey soil, where its associates include the shrubs *Myrica* sp., *Prunus* sp., *Piper* sp., and *Gynoxys* sp.; the herbaceous perennials *Calceolaria phaceliifolia* Edwin and *Dalea* sp.; as well as several annuals.

We are grateful to Segundo Leiva González for preparing the drawing and to Dr. Michael O. Dillon of the Field Museum for facilitating communications between the authors.

KUBITZKIA VAN DER WERFF, A SUPERFLUOUS NAME OR NOT?

Kostermans (1988) discussed the need for a new generic name to replace *Systemonodaphne* Mez and came to the conclusion that the new name *Kubitzkia* van der Werff (Taxon 35: 164. 1986) is superfluous. Kostermans's argument is that Meissner (1864) cited *Laurus geminiflora* Desv. as the basionym of his *Goeppertia geminiflora* with a question mark; his opinion is that citation of a doubtful synonym in the description of a new taxon rules out this doubtful synonym as the basionym of the new taxon and that, in the case of *Kubitzkia, Laurus geminiflora* Ham. is not the basionym of *Goeppertia geminiflora,* and therefore also not the type species of *Systemonodaphne* Mez. The difficulty is that here one is led to speculate whether Meissner, when he cited *Laurus geminiflora* Ham. as a basionym of his *Goeppertia geminiflora* with a question mark, accepted what he published or published what he did not accept (see Articles 34.1 and 34.2 of the Code). In his particular case, the choice is an easy one for the following reasons: A) Meissner (1864, p. 175), under his description of *Goeppertia* (?) *geminiflora,* cited the earlier references as follows: "*Laurus geminiflora* Desv. in Hamilt. Prodr. Fl. Ind. occ. p. 37. Walp. Ann. 1 p. 578? (non Reinw.)." In Walpers (1848), this species is cited as follows, "*L.* ? *geminiflora* Dsvx. in Hamilt. Prodr. 37 (nec Reinw. mss.)." It seems very likely that Meissner, in citing the Walpers reference, cited him correctly and included Walpers's question mark. This question mark reflected the doubt Walpers expressed about the correct generic placement of *Laurus geminiflora* Ham. and not any doubt from Meissner as to *L. geminiflora* being the basionym of *Goeppertia geminiflora.* B) Meissner (1864) also included lists of excluded species at the end of each genus and gave the generic placement he accepted. On p. 236 he lists "*L. geminiflora* Desv. = *Goeppertia* (?) *geminiflora.*" When Meissner had doubt about the placement of certain species, he clearly expressed this; see p. 239: "*L. surinamensis* Sw. = Species obscura, cfr. *Oreodaphne guianensis* N.," or p. 236: "*L. dubia* Wall. = *Cinnamomum iners* Rw. δ ?" In my opinion, Meissner's treatment of *Goeppertia geminiflora* shows that Meissner accepted without doubt *Laurus geminiflora* Ham. as the basionym for his *Goeppertia geminiflora* and that for reasons explained earlier (van der Werff, 1986), *Kubitzkia* is the valid name for *Systemonodaphne* sensu Mez non sensu typi.

EDITOR'S NOTE

THANKS

The editors wish to close the year with an expression of gratitude to Dr. John Dwyer and Dr. Henk van der Werff for a year of willing, cheerful, and able help in reviewing and polishing Latin descriptions.

Instructions for Authors, *Annals of the Missouri Botanical Garden*

The *Annals* publishes original articles in systematic botany and related fields. Text may be in English or Spanish. When in Spanish, an English abstract in addition to a Spanish abstract is required. Short papers, especially nomenclatural matters and new taxa, are treated as "Notes," which have their own format as described below. Authors are urged to contact the editor prior to submitting manuscripts. Manuscripts sent already reviewed and revised are generally subject to the full normal review process initiated here. Manuscripts not properly prepared may be returned for revision prior to review. This includes manuscripts with improper abbreviations or with diacritical marks not indicated.

Page costs are $70 per page, although charges may be reduced under certain circumstances. Corrections in proof will be billed nonnegotiably to the author at $2.50 per line.

Manuscripts must be typed (output from dot matrix printers must be entirely clear) on one side of nonglossy 8½ × 11 inch paper. Leave at least one inch as margin all around, except on the first page. There three inches should be left blank at the top. **The text should be double-spaced or triple-spaced throughout,** including abstract, notes, legends, tables, specimen lists, Literature Cited, and footnotes. **Do not justify the right-hand margin, and do not break words there.** Italics, boldface, or other special typefaces should not be used—they will appear later as communicated to the printer by the editor. Words to be set in italics should be underlined. **Accents, umlauts, and other diacritical marks are the responsibility of the author.**

Footnotes should be typed double-spaced as paragraphs on a page apart from the other text. The first footnote contains acknowledgments, including information on granting agencies, and herbaria that loaned specimens. The second footnote is the author's address. Addresses for additional authors are each separate additional footnotes. No other footnotes are permitted, except footnotes in tables, and these are best avoided. In papers formatted as "Notes," there are no footnotes: the acknowledgments make up the paragraph preceding the Literature Cited section, and the author's name and address make up the last paragraph of the article. In Notes, the names and addresses of multiple authors are all placed in the same paragraph.

Long, complex tables are discouraged. Tables not neat and easily understood will be returned for improvement. Leave out vertical lines, and avoid horizontal lines. Lines are added as needed by the editor and/or printer. Type table captions double-spaced as paragraphs at the tops of the tables.

A concise abstract should accompany each paper other than "Notes."

Periods are used after all abbreviations (which should be minimized) except metric measures, compass directions, and herbarium designations. States are not abbreviated, and cities are usually spelled out, although "St." is acceptable. **Abbreviate periodicals according to *BPH* (*Botanico-Periodicum-Huntianum*), authors according to *The Draft Index of Author Abbreviations Compiled at the Herbarium, Royal Botanic Gardens, Kew*, and books according to *Taxonomic Literature*.** Note, however, that book abbreviations are to be capitalized, and that books listed in the Literature Cited section should have their titles spelled out when feasible. Note further that names of taxonomic authorities may be spelled out in major taxonomic citations such as the formal citation at the head of a taxonomic treatment. Except by prior arrangement with authors not having access to crucial references, the editor does not provide the service of looking up abbreviations.

In the Literature Cited, periodicals should be listed as follows: author's last name, initial(s). Year. Full title of article. Journal abbreviated as in BPH. Volume: pages. Do not give parenthetical part numbers after volume numbers unless each part is paginated separately, which is unusual. For more than one author, follow this style: author's last name, initial(s), second author's initial(s), last name & third author's initial(s), last name. Citations of books should appear as follows: author's last name, initial(s). Year. Full Title (edited by Editor), 3rd edition, Volume 2. Publisher, Place. Citations of work "in prep." and similar references to inaccessible sources are strongly discouraged. Except by prior arrangement when necessary, the editor does not perform library research to fill in missing bibliographic information.

A brief Latin diagnosis for each new taxon is preferred to a complete Latin description.

Use one paragraph per basionym as follows: *Taxon* author, literature citation, type citation, e.g., *Bauhinia dipetala* Hemsl., Diag. Pl. Nov. 1880. *Casparia dipetala* (Hemsl.) Britt. & Rose, N. Amer. Fl. 23: 216. 1930. TYPE: Mexico. Veracruz: Valle de Cordóba, *Bourgeau 1713* (holotype, K; isotypes, F, GH, P, US). Exclamation points are not used for specimens examined. Indicate unseen types as "n.v."

Keys should be dichotomous, indented, and consistent with descriptions. Couplets should be numbered as 1a, 1b, 2a, and so forth.

Cite specimens as follows:

Additional specimens examined (or *Selected specimens examined* or *Paratypes*). MEXICO. OAXACA: Sierra San Pedro Nolesco, Talea, 3 Feb. 1987 (fl), *Jergensen 865* (BM, G, K, US). Dates and reproductive status are optional.

Send copies of illustrations; originals will be requested if the manuscript is accepted and will be returned after publication. All illustrative materials should be mounted on stiff cardboard. The maximum size for printed illustrations is 5½ × 8¼ inches. Presize illustrations to fit either column width (2⅝ inches or ca. 68 mm) or full page width (5½ inches or ca. 140 mm). Figures are numbered in Arabic numerals in the order of their citation in the text. Parts of figures are labeled with capital letters. Photographs should be black-and-white prints. Transparencies and negatives are not accepted. Group figures into composite plates when possible, and abut edges of photographs. Do not use stripping between plate or figure segments. Make sure edges are squared. Maps should include reference to latitude and longitude. Scale bars should appear on illustrations, on photographs, and on maps. Magnifications/reductions indicated in captions are unwelcome to the point of usually not being accepted. Scanning electron micrographs should be free of conspicuous charging. Axes on graphs are all labeled. No explanatory text is to appear in figures. Rather, provide clear captions in sequential paragraphs apart from the other text, one paragraph for each group of figures, and following the style in current issues of the *Annals*.

For other aspects of style, consult a recent issue of the *Annals*; the latest edition of *The Chicago Manual of Style*; or write the editor. Communication with the editor at all points of the publication process is encouraged.

Manuscripts and correspondence should be addressed to the Editor, *Annals of the Missouri Botanical Garden*, P.O. Box 299, St. Louis, Missouri 63166, U.S.A.

VOLUME 75
1988

The ANNALS, published quarterly, contains papers, primarily in systematic botany, contributed from the Missouri Botanical Garden, St. Louis. Papers originating outside the Garden will also be accepted. Authors should write the Editor for information concerning arrangements for publishing in the ANNALS.

Colophon

This volume of the ANNALS of the Missouri Botanical Garden has been set in APS Times Roman. The text is set in 9 point type while the figure legends and literature cited sections are set in 8 point type.

The volume has been printed on 70# Centura Gloss, an acid-free paper designed to have a shelf-life of over 100 years. Centura Gloss is manufactured by the Consolidated Paper Company.

Photographs used in the ANNALS are reproduced using 300 line screen halftones. The binding used in the production of the ANNALS is a proprietary method known as Permanent Binding.

The ANNALS is printed and distributed by Allen Press, Inc. of Lawrence, Kansas 66044, U.S.A.
